
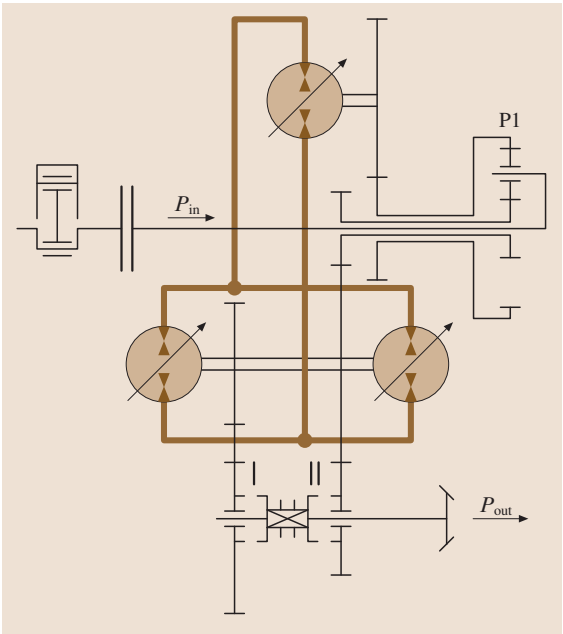

Fig. 14.30 Structure of the continuously variable transmission (after [14.30])

Operation Elements

It is only in combination with work devices that a tractor becomes a working machine. These devices may be attached, hitched, or mounted to the tractor. For rear device attachment, a three-bar linkage combined with a power lift has proved to be useful for the following reasons:

- Statically defined rigid connection between tractor and device
- Adjustable device due to the power lift
- The three-bar linkage can be adjusted to different devices by control devices
- The possibility of lateral mobility restriction or height and lateral mobility restriction

The three-bar linkage consists of two lower links and one upper link. The three-bar linkage's individual part dimensions are standardized into four categories (I–IV) for different power classes [14.31].

For a long time, rear hitches have been equipped with a control device that automatically lifts and lowers the power lift depending on a control value. By means of this power lift control, the driver is relieved of a task and working efficiency is increased by reducing the slip between the tyre and the soil as well as by raising the drive force. Possible control values are the device position relative to the tractor (position control), the traction force acting between the tractor and the device (traction force control), the device position related to the soil (depth control), and a mixture of traction force and position control (mixed control).

When using slip control, the actual driving speed is measured by a radar sensor. The theoretical speed is defined by a wheel-speed sensor. The electronics determines the speed difference and the slip. If the speed difference is smaller than a fixed limit, the electronic lifting control only works with traction force control. If the speed difference exceeds this limit, the traction force is changed by working depth modification so as to reduce the working depth and the slip. Another function of the electronic lifting control is active vibration removal, which involves balancing of the device's vibrations when passing on roads by means of automatic hydraulic steering in the opposite direction. This helps to improve driving comfort and steering conditions when driving with heavy devices attached to the tractor. The force-measuring bolts of the lower links serve to measure the force signal of the lifted device. The dynamic part emerged by vibrations is used as an actual value for lifting device control. In a restricted control area, for damping the lifting device is lifted or lowered slightly together with the attached device.

Control System and Electronics

The task of electronics is to control a tractor's components [14.32]:

- Motor
- Engine
- Hydraulics
- Gears
- Devices
- Data collection and storage
- Diagnosis

Modern tractors mainly use microcontrollers [14.26] (Fig. 14.31), equipped with CAN interfaces for communication. This yields new possibilities of diagnosis and overall optimization of the tractor's system. Due to the fact that tractors are applied with very different devices attached, which also using electronic control systems, it is important to make them communicate by a uniform interface, e.g., according to the ISO 11783 standard [14.33].

14.3 Machinery for Concrete Works

14.3.1 Concrete Mixing Plants

Since they must be well suited to their intended use and to construction needs, concrete mixing plants form a class of machinery with highly diverse designs. The diversity of concrete mixing plants' design features is connected with their capacity (10–250 m^3/h), their compatibility with the means of receiving the produced concrete mix, the production process control automation, the need for printing certificates for the sold concrete mix, the required assembly area, and the climatic conditions in which they are operated.

Concrete mixing plants can be classified as follows [14.34]:

- Concrete mixing plants (equipped with a mixer) producing ready-made concrete mix and concrete mix batching plants for proportioning and feeding

concrete mix constituents into truck mixers. Both kinds of plants can be built in vertical (tower concrete mixing plants) or horizontal configuration. Concrete mix batching plants may feed, depending on the time needed for transporting concrete mix to the destination, only dry constituents (aggregate and cement) or aggregate, cement, and water into truck concrete mixers.

- Stationary, transferable, and mobile concrete mixing plants. The kind of concrete mixing plant is determined by the operating costs, dependent on the length of time of operation at a given location.
- Continuous and batch production concrete mixing plants. Batch production concrete mixing plants are used on sites where the produced concrete

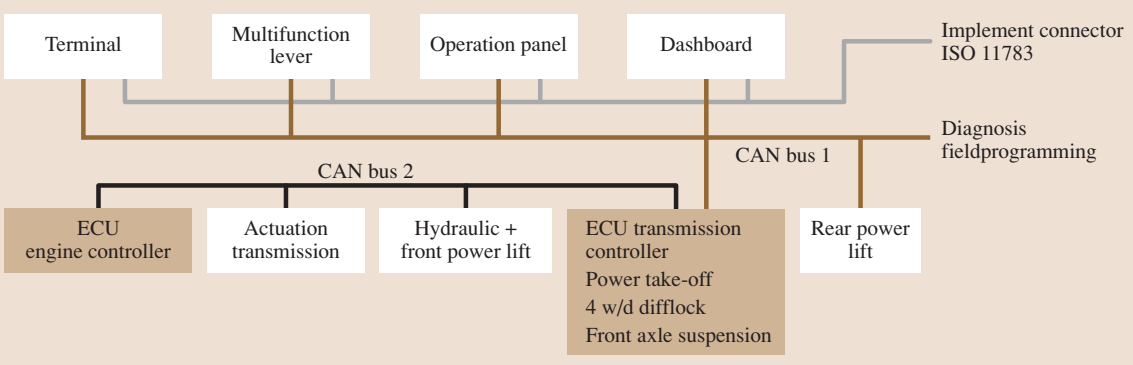

Fig. 14.31 Structure of a tractor control system

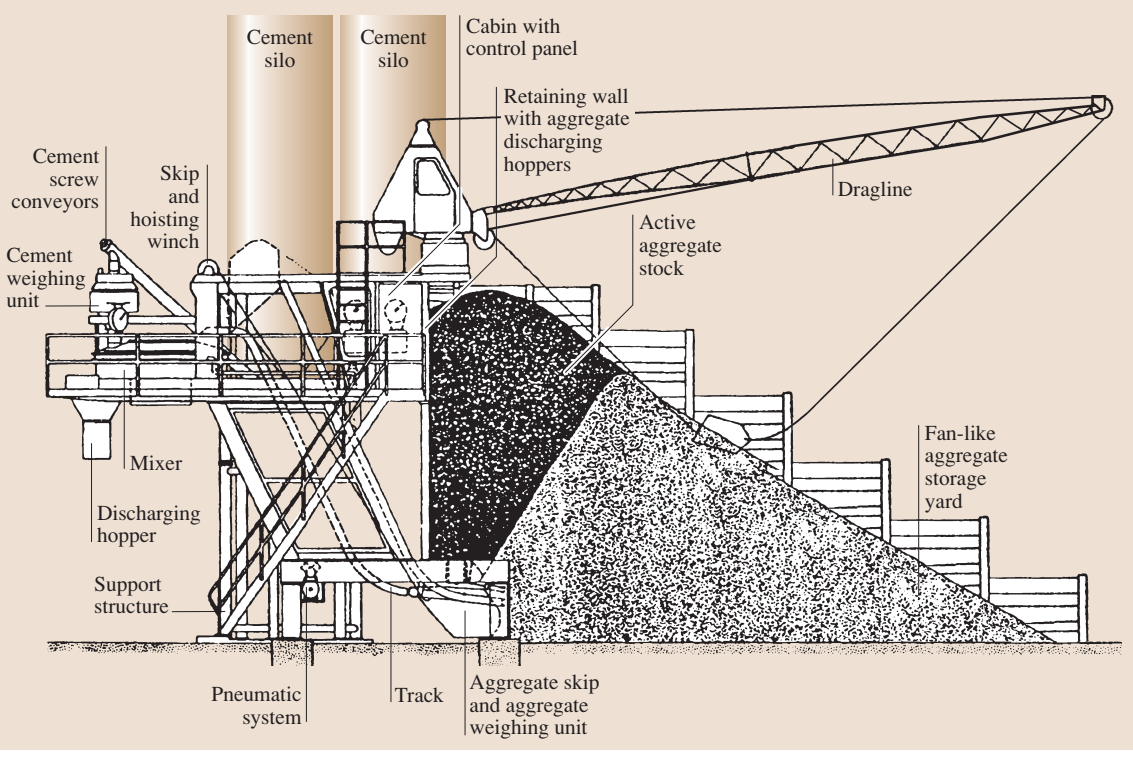

Fig. 14.32 Horizontal concrete mixing plant

mix's composition often needs to be changed, while continuous production mixing plants are used on construction sites which require large quantities of homogenous concrete, such as dams or airfields. Schematics of two basic types of batch production concrete mixing plants – horizontal and vertical (tower) – are shown in Figs. 14.32 and 14.33.

The concrete mixing plant's working cycle begins with the filling of the proportioners with aggregate, cement, water (if the latter is dosed by a weighing unit), and admixtures, which are then fed in the appropriate order into the mixer.

If flow-type water dosage units are used, water is fed into the mixer after the dry constituents have been charged into it. When the mixing process ends, the contents of the mixer is discharged into the recipient. Modern concrete mixing plants perform 50–60 working cycles per hour.

In order to achieve the desired technological capacities, the pressure of the water with which the concrete mix plant is supplied should be 0.4–0.6 MPa. The active aggregate stock (Fig. 14.32) represents the free-falling amount of aggregate which can be fed into the skip without using the dragline. The concrete mixing plant's personnel usually consists of two operators (operating the concrete mixing plant and the dragline). Nowadays automatically controlled charging skip hoists are increasingly being employed, allowing the operating personnel to be reduced to one person.

Because of their technological and economic advantages, horizontal concrete mixing plants are most commonly used in the construction industry.

The other type, vertical concrete mixing plants (Fig. 14.33), is characterized by the location of aggregate storage bins above the mixer. In vertical concrete mixing plants aggregate is usually transported to the storage bins by belt or bucket conveyors.

Because of the considerable height of vertical concrete mixing plants and the weight of their supporting structures they are constructed as stationary facilities within prefabricated concrete plants and as readymix concrete mixing plants for permanent locations. Their advantages include the ease of fitting them into concrete products manufacturing plants and adapting for concrete mix loading into overhead trolleys as well as easier adaptation to operation at low ambient temperatures. As a rule they are built for year-round operation.

Mainly electric motors are used in the power transmission systems of concrete mixing plants.

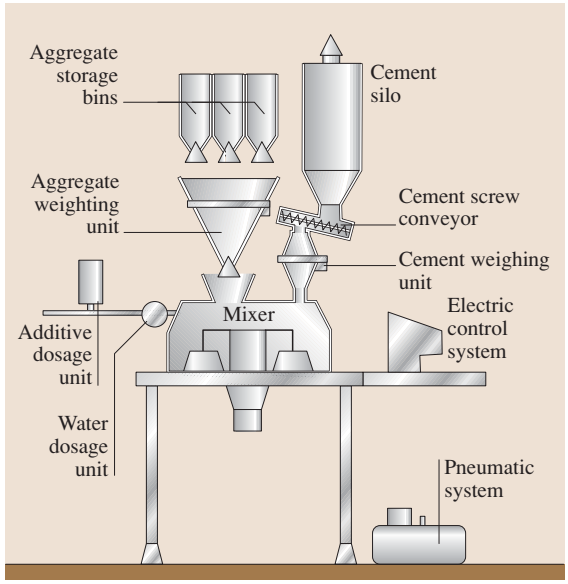

Fig. 14.33 Schematic of vertical concrete mixing plant

Only the closing of the devices batching concrete mix components is effected by pneumatic actuators because of the high speed of motion required.

Since it is capable of generating great forces, a hydraulic drive is usually used to open and close the mixer's discharging gate.

The most popular type of concrete mixing plant appears to be the transferable horizontal concrete mixing plant, which is characterized by a simple design and that lends itself to quick assembly on the construction site. The components of horizontal concrete mixing plants are transported to the site on generally available means of road transport. Concrete mixing plants specially designed for quick relocation are referred to as mobile. They are usually mounted on specially designed trailers.

Concrete mixing plants are usually built according to the needs of the individual user, who can choose the kind of mix, the height at which the concrete mix is discharged, the kind of aggregate storage facility (Fig. 14.34), the number of aggregate fractions and grades of cement, the batchers' weighing systems, the use of admixture and additive proportioners, the automatic make-up water dosage unit, the type of control system, the operator's cabin, adaptation to operation at low temperatures, and environmental compatibility.

Depending on the size of the concrete mixing plant, users can choose from simple concrete mix batcher weighing units with a spring head with an accuracy of ±0.5% or electronic ones based on strain gauges whose

accuracy, according to some manufacturer's specifications, is as high as ±0.1%.

An additional advantage of weighing units based on strain gauges is that the signals can be processed directly, whereas in older systems the weighing head indicator rotation had to be converted into an electric signal by means of coupled voltmeters or reed relays mounted on the head's dial.

The use of make-up water dosage devices which take aggregate moisture into account is essential when high concrete homogeneity is required.

Automatic make-up water dosing devices which take aggregate moisture into account can be divided into two groups:

- Devices determining the water content in aggregate (chiefly sand) and adjusting on this basis the amount of water fed into the mixer. The water content is determined by gauges, built in at the outlet from the sand storage bins, measuring electric conductivity, microwave flow, permittivity or the moderation of fast neutrons.
- Devices dosing water to the concrete mix on the basis of concrete mix consistency determinations. The consistency is determined by measuring the electrical resistance of the concrete mix. Gauges built into the mixer's bottom or electrodes mounted similarly as mixing blades are used for this purpose.

State-of-the-art systems for controlling the production process in the concrete mixing plant are available to order.

The application of personal computers (PCs) and programmable logic controllers (PLCs) represents a revolution in concrete mixing plant control systems, making it possible to use any number of recipes, produce batches constituting any percentage of the nominal batch of concrete, choose the number of batches, transfer data remotely to program recipes, print certificates for the manufactured concrete mixes, and accurately control concrete mix inventories and sales.

Contemporary concrete mixing plants must meet environmental requirements, firstly air protection requirements. This is ensured by sealing off (with closing flaps and dust filters) the mixers as they are filled with dry components and using efficient air–cement mixture filters in the cement silos. Also the concrete mix residues from washing the mixer must be utilized.

14.3.2 Concrete Mixers

According to the definition given in [14.34], the concrete mixer is a machine designed for the production of concrete mix by mixing measured (by mass or volume) proportions of water, cement, aggregate, and chemical additives (if used) within a certain time limit. Depending on its design, the concrete mixer consists of a basic unit, called a mixer, and ancillary units such as: a wheeled supporting frame or a support structure, a charging skip (possibly with a weighing device) for transporting concrete mix components, a water dosage unit, a mechanical shovel, and a control box.

Concrete mixers form the largest group of construction machines. One can find them on nearly each construction site. They are highly diverse as regards size, which is defined in terms of dry component capacity or the volume of ready concrete obtained from one batch [14.35], and design.

There are concrete mixers with a dry components capacity of 50–12 000 l. Small concrete mixers with a capacity of 50–250 l usually work as single machines with manual transport of concrete mix components to the mixer. In order to use their potential rationally, concrete mixers with a capacity above 375 l should work in conjunction with mechanized concrete mix components transport, i. e., they should be incorporated into a concrete mixing plant.

Depending on the way they operate, concrete mixers can be classified as follows:

- Freefall (gravity) concrete mixers versus compulsory concrete mixers
- Batch- versus continuous-type concrete mixers.

Freefall mixers find application in monolithic construction for production concrete mixes with consistency ranging from liquid to plastic. They are usually used for the construction of residential buildings and livestock and public utility structures. Depending on their discharging method, three types of freefall mixers can be identified: tipping-drum concrete mixers, reversing-drum concrete mixers, and discharging chute concrete mixers. Tipping-drum concrete mixers with a dry components capacity of 50–250 dm^3, used for the production of concretes and mortars in family housing, form the most numerous group among gravity mixers (Fig. 14.35). Similarly as for electrical appliances, they are distributed by chain stores. The main hazard associated with their use is the possibility of electric shock. This hazard can be eliminated through the use of an integrated double-insulated motor switch unit.

To facilitate their transport on public roads concrete mixers can be fitted with towbars with a hook coupling, pneumatic tyres, a brake, and lights.

For more thorough washing after work the mixing drum is closed with a special cover so it can be rotated horizontally.

Tipping-drum freefall concrete mixers have a capacity of 350–1000 dm^3, whereas reversing-drum concrete mixers typically have a capacity of 350–1000 dm^3. Discharging chute concrete mixers are being phased out and replaced by mixers of the above two types. Their design used to be advantageous when combustion engines with one sense of rotation were employed to drive them whereby reversing gears did not have to be used. As electric drives have been widely introduced and the production of concrete mix could be automated, their design became obsolete.

Current development of freefall concrete mixers is directed towards improving their operational safety conditions, reducing noise emission, and facilitating their transport on public roads and maintenance.

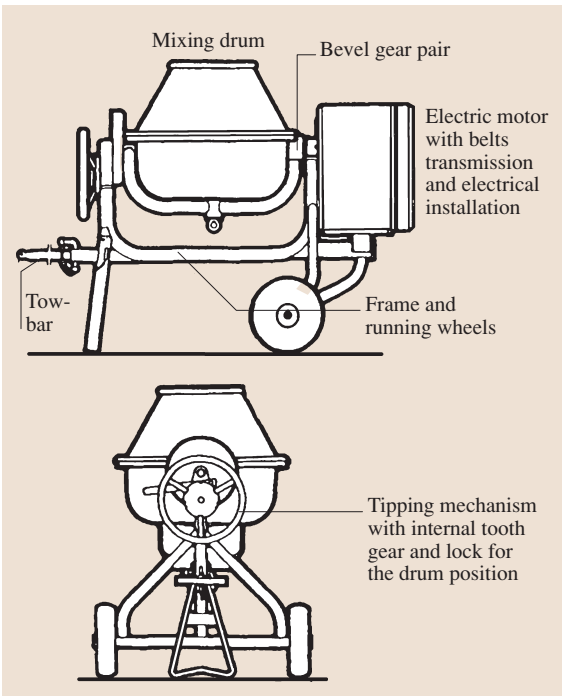

Fig. 14.35 Small-sized tipping-drum gravity concrete mixer equipped with traveling wheels

Compulsory concrete mixers are used for the production of all types of concrete mixes and, from the concrete preparation technology point of view, their application is unlimited.

Compulsory concrete mixers are divided into two classes: pan-type and paddle-type (trough-type) concrete mixers.

In pan-type concrete mixers, mixing is effected by the rotation of a set of agitators inside a pan with a vertical axle, whereas in paddle concrete mixers the set of agitators revolves in a trough with a horizontal axle.

Within the class of pan-type concrete mixers six types of machines can be identified: turbo concrete mixers, planetary concrete mixers, turbo planetary concrete mixers, countercurrent operation concrete mixers, concurrent operation concrete mixers, and concrete mixers with a high-speed stirrer. In the present-day construction industry and the concrete prefabrication industry the first three types of concrete mixers, i. e., turbo concrete mixers, planetary concrete mixers, and turbo planetary concrete mixers, are the most commonly used. The operation of these machines' agitators is illustrated in Fig. 14.36.

A planetary concrete mixer with a capacity of 1000 dm^3 is shown in Fig. 14.37.

As already mentioned, turbo concrete mixers, planetary concrete mixers, turbo planetary concrete mixers, and one- and two-agitator paddle mixers are the most popular types amongst the numerous group of compulsory concrete mixers. No clear advantage in terms of the quality of the produced concrete mixes of a single concrete mixer type over the other types is observed for ordinary concretes [14.35]. As regards special concretes (e.g., with a very low water/cement (W/C) ratio, extreme consistencies or made using non-mineral aggregates) the application of a particular type of concrete mixer should be agreed on between the purchaser and the manufacturer. When purchasing a concrete mixer one should also take into consideration the particular features of each concrete mixer type, such as:

- The possibility of using large-size coarse aggregates: concrete mixers with elastically suspended mixing blade arms are better suited for this purpose than those with rigid suspension of the mixing blade arms.
- The power demands of the mixing process: one can assume that the power demands for the mixing process in a planetary concrete mixer will be lower (by about 25%) than that of a turbo concrete mixer.
- Environmental compatibility: the design of the upper cover of the mixer should protect the environment against cement dust emission and concrete mix splashing, and the seal of the discharge gate should prevent concrete mix leakage.

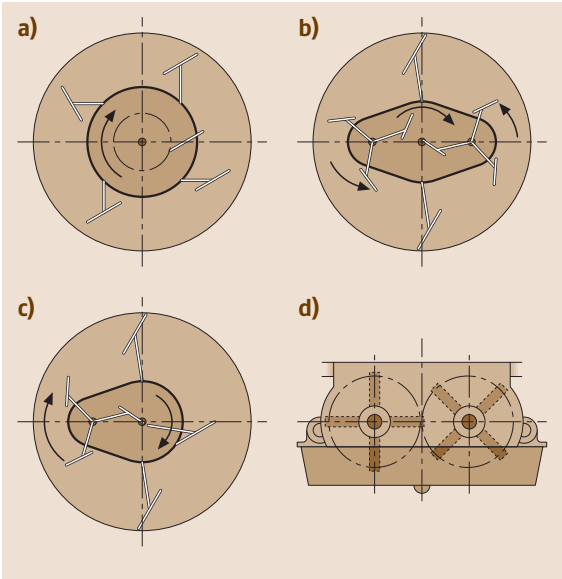

Fig. 14.36a–d Schematics illustrating operation of selected types of pan-type concrete mixers and two-agitator paddle concrete mixer

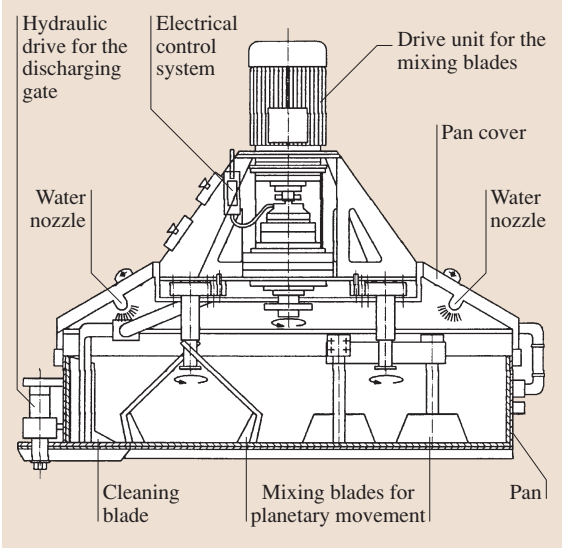

Fig. 14.37 Planetary mixer with a capacity of 1000 dm^3

- Protection against agitator drive system overload: the use of hydraulic torque converters prevents drive system overloads and ensures a smooth start of the rotation of the agitators as the mixer is filled; also elastic suspension of the mixing blade arms protects the drive against overloading and deformation of the mixing blade arms.
- Quick distribution of make-up water in the mass of dry components to reduce mixing time: several suitably arranged water nozzles ensure that the concrete mix quickly becomes homogenous.
- The concrete mixer's dimensions should be suitable for transport on public roads.
- The use of abrasion-resistant materials for the blades and the linings.

14.3.3 Truck Concrete Mixers

The truck mixer (Fig. 14.38) is designed for producing homogenous concrete mix and transporting it over long distances. It consists of a pear-shaped drum (usually a freefall, reversing one) inclined at an angle of 15° and a self-propelled chassis or a trailer. Its accessories include: a water tank, a water dosage unit, a charging hopper, and discharging chutes. The drum is supported by a cylindrical pin on the drive side and by two rollers mating with a rigid ring fastened on the drum. As concrete mix components are loaded into the drum and mixed, the drum revolves in one direction. During discharging the drum revolves in the opposite direction.

It is required that the mixing drum can rotate at several rotational speeds: at the highest speed while being filled or emptied (e.g., into a concrete pump), at a lower speed during mixing, and at the lowest speed during travel. For this reason a hydraulic drive is most commonly used for rotating the drum. This drive enables stepless change of the drum's revolutions in a range of 0–14 rpm in both directions. This ensures the most suitable mixing drum revolution rate for concrete mix loading, transport, and unloading, adjusted to concrete mix placement on the construction site. The truck mixer's hydraulic drive powered by the vehicle's engine is shown schematically in Fig. 14.39. It consists of a combustion engine, a hydraulic pump with an adjustable rate of delivery, a hydraulic engine, and a planetary gear to drive the mixing drum. The prime mover of the mixing drum in truck mixers can be an independent combustion engine or the engine that propels the chassis.

The factor limiting the distance over which concrete mix can be transported by truck concrete mixers is the setting time, determined mainly by the ambient temperature and the temperature of the concrete mix. If the expected transporting time is longer than the setting

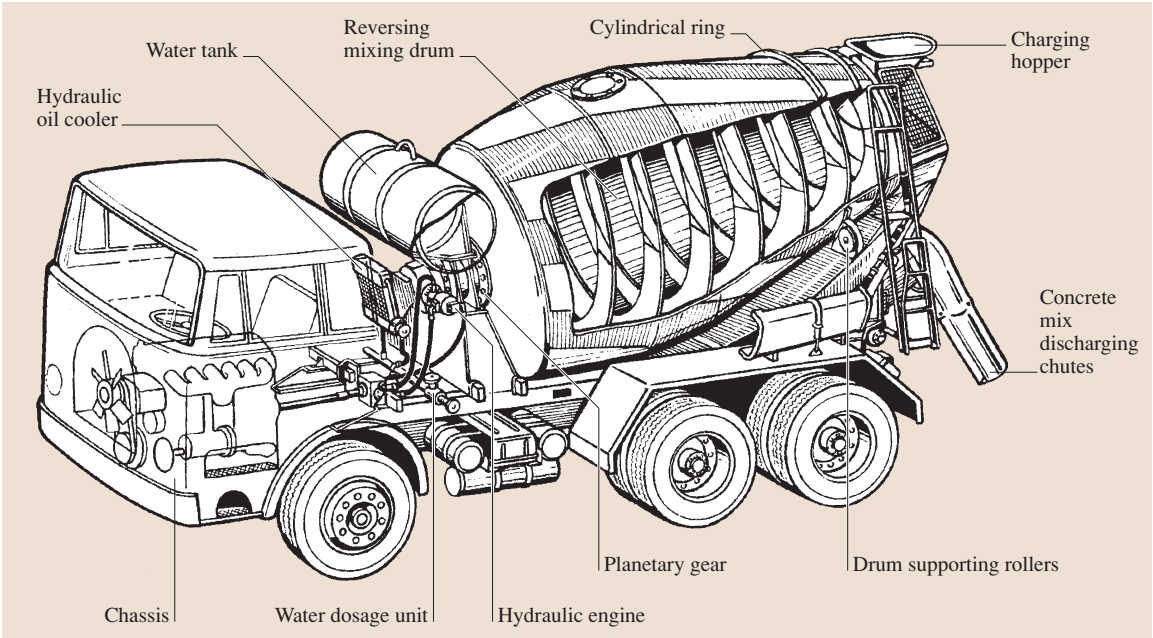

Fig. 14.38 Truck mixer with drum driven by the truck's engine

time, dry components are fed into the concrete mixer and, 35 min before discharge, water is added and mixing is started.

While the truck concrete mixer filled with both concrete mix and dry components is traveling the contents is mixed at a low rate (about 3 rpm) in order to prevent concrete mix segregation or cement setting in contact with moist aggregate.

The following trends in the development of truck concrete mixers can be observed:

- The use of mixing drums with an ever greater capacity – 9, 10, and 12 m^3 – aimed at reducing transport costs and making it easier to maintain continuity of concreting when erecting large concrete structures. In order to increase the load capacity of concrete mixers they are fitted out with an additional rotary axle at the back of the truck, which is raised during discharging and while driving without a load.
- The combination of a truck concrete mixer and a concrete pump with a distributing boom or a belt conveyor for direct placement of the concrete mix on small construction sites;
- The adaptation of the truck concrete mixer for concrete mix transport at low temperatures (as low as −60 °C). In this case, the mixing drum is made of two shells (an outer shell and an inner shell) and hot exhaust gas is fed into the space between the shells.

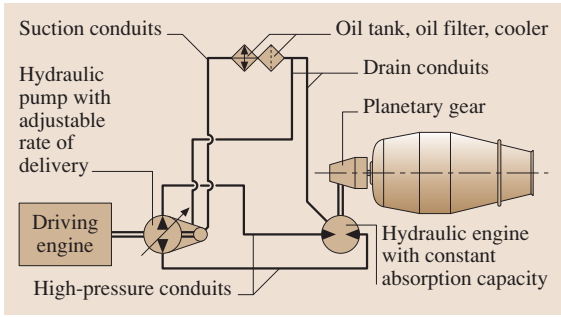

Fig. 14.39 Schematic of a truck mixer drum's hydraulic drive powered by the truck's engine

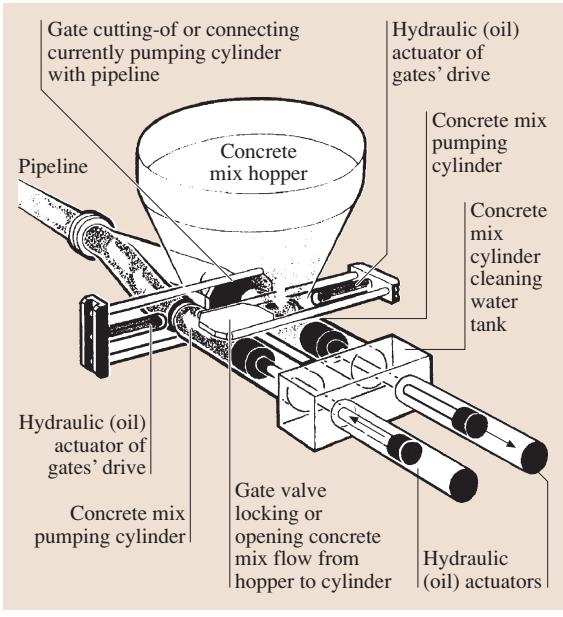

Fig. 14.40 Principle of operation of a concrete pump with control valves in the form of flat gates with connecting ports

14.3.4 Concrete Pumps

Concrete pumps have become the dominant means of concrete mix conveyance on the construction site. They have entirely supplanted pneumatic feeders, which deliver concrete mix in batches. The rapid development of concrete pumps started once hydraulic drives were incorporated into their design, supplanting crank power drives.

Another breakthrough in the development of concrete pumps was the use of distributing booms, which greatly facilitated the placement of of concrete in the work area by delivering concrete mix directly to the placement area and distributing it there.

Currently the most common pump design is a pump with two parallel, alternately operating concrete mix cylinders whose pistons are driven by hydraulic (oil) actuators connected to them in series (Fig. 14.40).

The reciprocating motion of the concrete mix pistons is controlled by means of two noncontact limit switches located in the cleaning water tank. Switches of the same type are also used to control the motion of the cutoff valves.

An important distinguishing feature of particular piston-type concrete pump designs is the system of valves that controls the flow of concrete mix from the hopper to the cylinders and from the cylinders to the conveying pipe.

Besides valves in the form of flat gates, other valve systems, such as the conveying pipe's swing segment (C- and S-valves), plug valves, etc., are employed. Attempting to bypass patented designs individual manufacturers of concrete pumps have developed new valve system designs for piston-type concrete pumps [14.36].

A further major advance in the development of systems for controlling the flow of concrete mix in concrete pumps was the use of C- and S-valves. Their operation consists in the alternate connection of the conveying pipe's swing segment fully (S-valves) or partially (C-valves – the elephant-type system) submerged in the concrete mix hopper while the cylinders are in the pumping phase.

In order to minimize wear, concrete mix pumping cylinders are characterized by large diameters, long length, and low rate of displacement. These parameters, in conjunction with reduced speed of the piston as it approaches the dead center and fast switching of the control valves, reduce pumping fluctuations so that the flow of concrete mix is almost continuous.

Pumps are selected depending on the type of structure to be erected. The extreme examples are high-capacity pumps with a short delivery distance versus low-capacity pumps and a long conveying distance. Depending on the application needs, pumps with concrete mix cylinders with a diameter of 100–280 mm and a forcing pressure of 8–26 MPa are used. Pumping capacities range from 20 to 200 m^3/h.

For some construction projects special pumps are built. In the technical literature one can find information about concrete mix pumped to an elevation of 530 m and over a distance of 4000 m (the construction of the Schaeftlarn tunnel). Such pumping distances are achieved when specially designed pumpable concrete mixes are pumped. The design features of these mixes include: the consistency, the cement content, the additives content, and the shape and grading of the aggregates. Another crucial factor is the ambient temperature. A high ambient temperature accelerates concrete mix setting and limits the pumping distance.

Concrete pumps (Fig. 14.41) are usually manufactured as self-propelled machines on chassis or trailers to be towed by a tractor. Concrete pumps mounted on self-propelled chassis are usually powered by the vehicle's engines while those mounted on trailers are driven by a separate engine.

Stationary pumps are fitted with skids or driving axles, which are dismantled on the construction site. They are driven by diesel engines or electric motors.

The choice of a concrete pump (self-propelled, mounted on a trailer or stationary) is determined by economic factors and the character of the construction project. One should take into account that the ratio of the concrete mix placing time to the formwork and to the reinforcement time is relatively low, roughly 1:5.5.

Self-propelled concrete pumps with a distributing boom (Fig. 14.42) ensure very efficient concrete mix transport and distribution.

The distributing boom consists of two, three, four or five segments with a delivery pipe with a rubber hose attached to it. The reach of pumps with a distributing boom is 17–65 m in the horizontal plane. An exemplary nomogram of a 19 m long pump boom's horizontal and vertical reach is shown in Fig. 14.43.

Booms require appropriate chassis and supports. The angle of rotation of the boom around the vertical axis is limited to 270° because the hydraulic conduits feeding the boom folding cylinders are located next to the concrete mix delivery pipe's articulated joint. In order to adapt them better to the characteristics of construction sites, the distributing masts are built as foldable from top or bottom. The folding and slewing of the mast is effected by push-button control. In the case of five-segment masts, folding is effected by a control system following a program.

The approximate commercial specifications of mass-produced self-propelled concrete pumps with a distributing boom are as follows:

Reach in horizontal plane:	12–58 m
Reach in vertical plane:	16–62 m

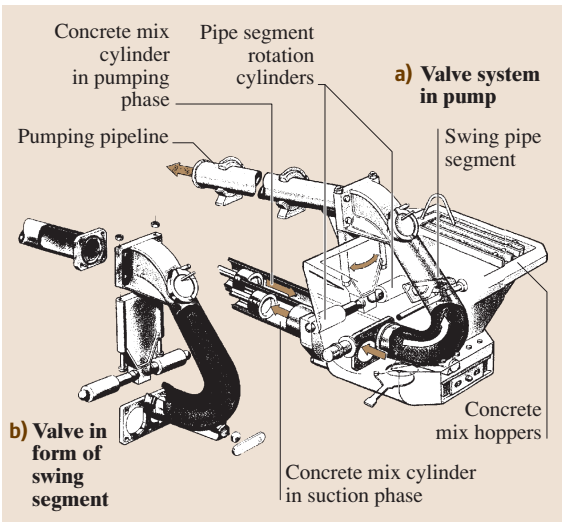

Fig. 14.41a,b Principle of operation of a concrete pump with a valve system in the form of the conveying pipe's swing segment connecting conveying pipe with cylinders during the pumping phase (C-valves – elephant-type system). **(a)** valve system in pump; **(b)** valve in the form of a swing segment

Slewing angle:	360°
Conveying pipe diameter:	100–125 m
Length of rubber hose for	
Distributing concrete mix:	3.5–5 m
Charging hopper capacity:	350–500 dm^3
Rated pumping capacity:	36–150 m^3/h
Concrete pumping pressure:	45–130 bar
Concrete mix pumping	
Cylinder diameter:	160–230 mm
Piston stroke:	1000–2100 mm
Number of boom segments:	2–5

Self-propelled concrete pumps are also made in versions adapted for attaching a pipeline made from steel pipes for conveying concrete mix over considerable distances.

Besides piston-type concrete pumps also rotary-type pumps, based on the principle of the peristaltic pump, are manufactured (Fig. 14.44).

In the rotary-type concrete pump concrete mix is pumped as a result of squeezing it out of a reinforced rubber hose by two rollers attached to the rotor. The hose recovers its circular cross-section owing to elastic restoration or negative pressure inside the casing (vacuum restore). The pumping pressure in rotary-type pumps amounts to about 3 MPa, allowing concrete mix to be delivered over a distance of about 200 m in the horizontal plane and to an elevation of about 80 m.

The design of the rotary-type concrete pump is simple but the conveying hose needs to be replaced quite often.

Concrete pumps' conveying pipelines are made from 0.5, 2, and 3 m long steel pipes usually 125 mm in diameter, but pipes 100, 150, and 180 mm in diameter are also used.

The pipeline attachments include pipe fittings with 90°, 120°, 135°, 150°, and 165° angles of flare. Individual pipes and pipe fittings are connected by clamping rings and rubber gaskets. The pipeline is tipped with a flexible conduit which facilitates the distribution of concrete mix in a work area.

After work, concrete mix residues are removed by a porous rubber ball forced through by a water jet or compressed air.

Besides the above self-propelled, trailer mounted, and stationary concrete pumps, there are also pumps mounted on tower cranes. These are used on construction sites with a large amount of reinforcement or difficult access for concrete mix placement by other methods, when large-diameter cylindrical tanks are to be built, and so on.

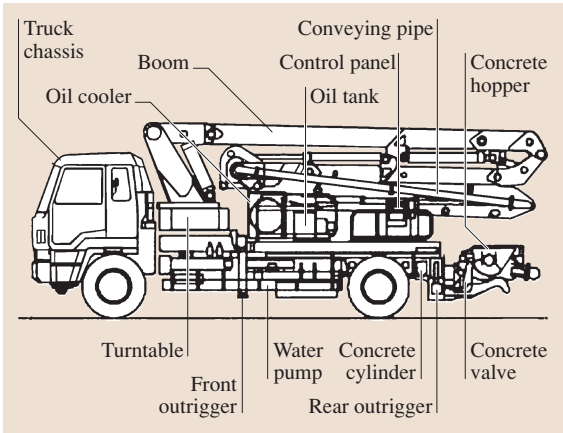

Fig. 14.42 Truck-mounted pump with distributing boom

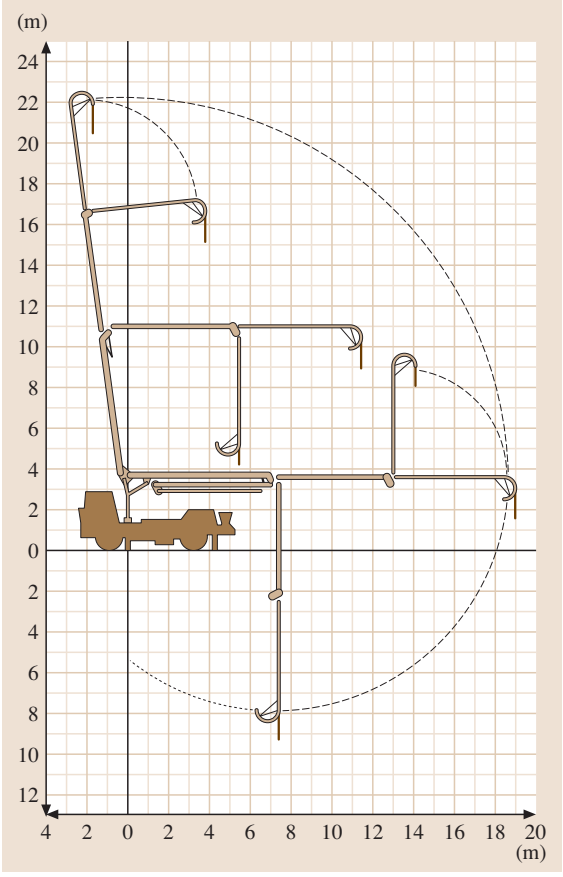

Fig. 14.43 Horizontal and vertical reach of pump with 19 m-long boom

14.3.5 Concrete Spraying Machines

Concrete spraying machines are used for spraying concretes and mortars onto structures. They are mainly used to coat the outer surface of the reinforcement in reinforced concrete structures, steel structures, tensioning cables, slope reinforcements, etc., to protect them against corrosion. Concrete mix can be sprayed onto concrete, rock, and steel bases, brick walls, and wooden formwork. Various kinds of cement concrete, including polymeric concretes and epoxy concretes, can be used for spraying. Sprayed concrete is characterized by good adhesion to the base and chemical resistance.

Besides being used for spraying concrete, concrete mixture sprayers can also be used for sand blasting and conveying concrete mix. In the literature on the subject one can find a third use for concrete sprayers, i. e., semi-wet spraying, which is particularly recommended when concrete mix is to be transported over long distances. Two main modes of operation of concrete sprayers are distinguished [14.37]:

- Dry spraying
- Wet spraying

The operation of a dry mixture sprayer consists of feeding dry components (cement and aggregate) into a charging hopper and pneumatically conveying them to a spraying nozzle, where water is added under a pressure of 0.4–0.6 MPa.

The advantage of the dry method is the possibility of spraying a layer of high-strength concrete owing to the low W/C ratio. A dry mixture sprayer designed for small-sized spraying works is shown in Fig. 14.45.

The machine's main assembly is a rotor mixing the material contained in the space where atmospheric pressure prevails with compressed air at an overpressure of 0.5–0.6 MPa. The principle of operation of the rotor is

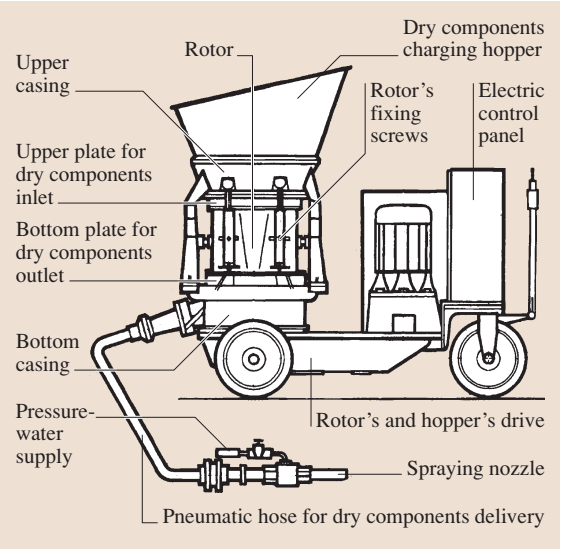

Fig. 14.45 Dry mixture sprayer for small-sized spraying works

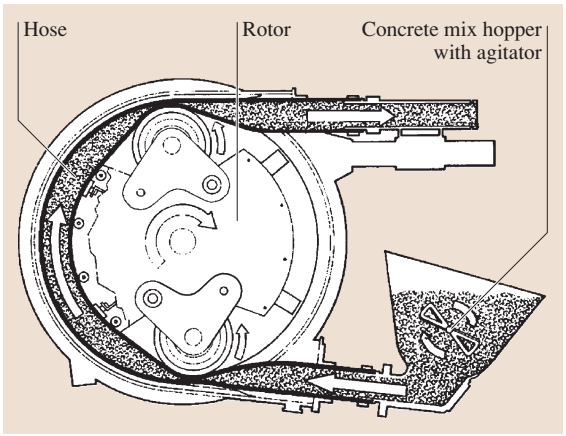

Fig. 14.44 Principle of operation of rotary type concrete pump

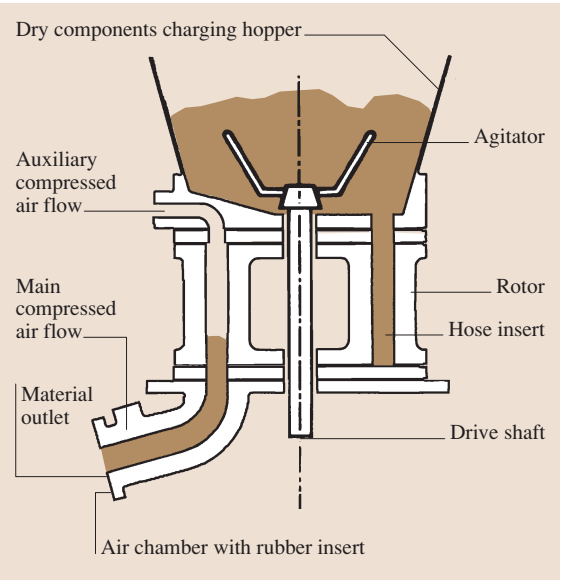

Fig. 14.46 Principle of rotor operation (example of rotor for dry spraying)

illustrated in Fig. 14.46. The aggregate and cement fed into the charging hopper under gravity fall into ports in the rotor and are forced by compressed air into the hose.

Dry sprayers' spraying capacity ranges from 0.2 to 11 m^3/h. Hoses 32, 38, 50, 60, and 65 mm in diameter are most commonly used.

It should be noted that concrete sprayers can also be used to transfer dry concrete mix components over considerable distances – up to 300 m in the horizontal plane and 40 m in the vertical plane – and to sandblast structures.

In wet sprayers ready-made (prepared in separate devices) concrete mix or mortar is conveyed to a spraying tip. In the group of dry sprayers two types of machines can be identified:

- Sprayers equipped with a rotor, in which concrete mix is delivered by compressed air (Fig. 14.47)
- Sprayers in which concrete mix is fed into a spraying tip by means of a concrete pump (Fig. 14.48)

In concrete-pump-type sprayers the concrete mix is conveyed by means of a pump and in the final stage also by compressed air, and is sprayed by a nozzle. Apart from nozzles with compressed air supply, impeller-type spraying units may be used as well.

In smaller devices the spraying nozzle is usually manually guided, whereas in large machines, mainly used in tunnel construction and mining operations, distributing booms wire-guided from portable control consoles are employed. Distributing booms can be mounted as self-contained machines mounted on wheeled or crawler carriers or form an integrated unit with a sprayer as shown in Fig. 14.48. A recent invention, besides nozzles spraying concrete mix by means of compressed air, is impeller-type spraying tips, where concrete mix is sprayed by a rotating impeller, using the centrifugal force directed by the latter assembly. According to the manufacturers, the impeller-type tip causes less dust and the concrete mix losses due to its bouncing off the wall are smaller.

Besides dry or wet mixture sprayers, there are also rotor-type sprayers in which dry and wet mixture spraying processes can be performed alternately after quick reconfiguration.

14.3.6 Internal Vibrators for Concrete

Internal vibrators for concrete are immersed in the concrete mix to transmit vibrations directly to it and thereby cause its compaction. As a result of this vibration the viscosity of the concrete mix decreases and its particles shift quickly relative to one another. The particular grains slide against one another and, due to settling under gravity, expel some of the air and water contained in the concrete mix, resulting in compaction and greater strength of the concrete after curing. When erecting concrete structures, in order to compact concrete mix effectively by means of immersion vibrators appropriate (in terms of frequency and amplitude) vibrators must be used.

The radius of action of an immersion vibrator depends on the exciting force and the frequency and ranges from 20 to 100 cm. Depending on the drive system, flexible drive immersion vibrators, built-in motor type electric immersion vibrators, pneumatic immersion vibrators, and hydraulic immersion vibrators are distinguished [14.38].

Flexible drive immersion vibrators are designed for driving a pendulum (Fig. 14.49) or eccentric vibration generator (Fig. 14.50). Pendulum-type immersion vibrators are driven by an electric motor or a combustion engine and a flexible shaft to which a vibration generator rolling on a raceway is attached.

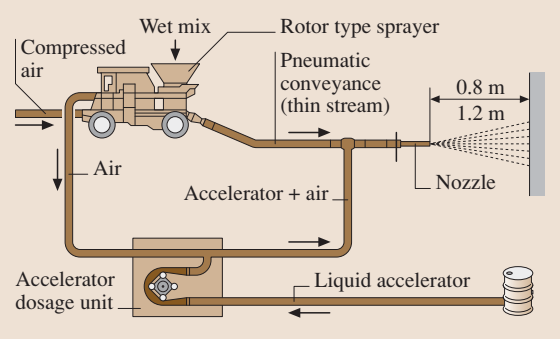

Fig. 14.47 Wet process with use of rotor-type sprayer

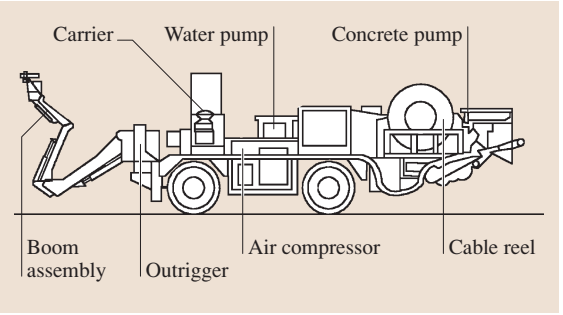

Fig. 14.48 Concrete-pump-type spraying machine (wheeled type)

The diameters of the vibration heads of the vibrators usually range from 25 to 70 mm and the frequencies generated are 300–200 Hz, respectively.

Modern pendulum-type immersion vibrators with a flexible shaft are driven by single-phase commutator motors; under load they can generate frequencies as high as 200 Hz (Fig. 14.50).

The diameters of vibration heads driven by commutator motors are usually 25–65 mm.

Built-in motor type electric immersion vibrators (Fig. 14.51) usually operate in conjunction with a voltage and frequency converter supplying a voltage of 42 V at 200 Hz. They can also be supplied from generating sets with an appropriate rated frequency. Because of the considerable permissible length of the power lead from the generator to the vibration head (about 15 m) these vibrators are suitable for compacting high elements. The vibrator's vibration heads are usually 35–85 mm in diameter and the vibration frequency is 200 Hz.

Pneumatic immersion vibrators are made with vibration heads that are 25–140 mm in diameter. They are characterized by simple design and high durability. These vibrators are used in places where, for safety reasons, it is inadvisable to use electric immersion vibrators or combustion engine immersion vibrators and in places with access to compressed air supply. Depending on their design, their frequency ranges from 160 to 300 Hz.

Hydraulic immersion vibrators are made with an eccentric vibration generator coupled with a hydraulic engine. They are used for compacting concrete mix when building large structures such as dams, bridges, and large foundations. The vibrators are supplied from special hydraulic feeders or from the hydraulic systems of earthmoving machines.

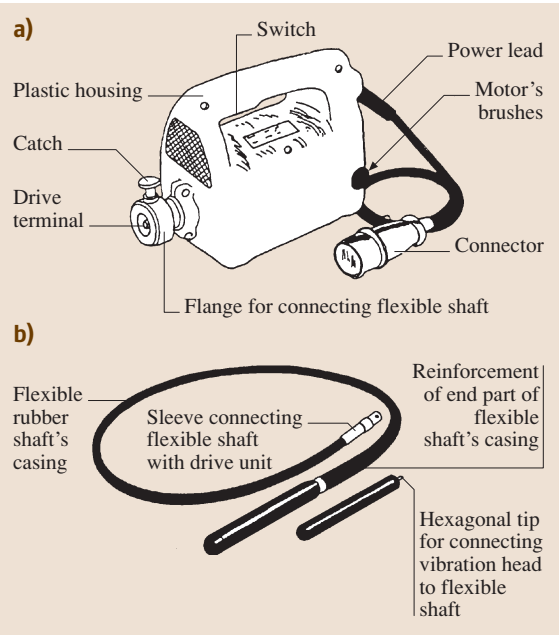

Fig. 14.50a,b Eccentric-type immersion vibrator driven by single-phase commutator motor and flexible shaft: **(a)** drive unit; **(b)** flexible shaft and vibration head

14.3.7 Vibrating Beams

Vibrating beams are used for leveling, compacting, and preliminary smoothing of the top surface of fresh concrete while building horizontally formed structures such as concrete road surfaces, airfields, storage yards, concrete floors in dwellings, and factory floors.

A vibrating beam consists of a rigid beam with a vibration generator mounted on it and flexible connectors for moving the beam. A vibrating beam with a vibration generator in the form of an attachable electric vibrator supplied with a voltage of 42 V is shown in Fig. 14.52.

In order to maintain the rectilinearity of the leveled surfaces and because of the considerable vertical gravity loading and exciting force loading, vibrating beams must have high vertical bending rigidity and relatively low deadweight so that they can be easily carried from one place to another on the construction site. These

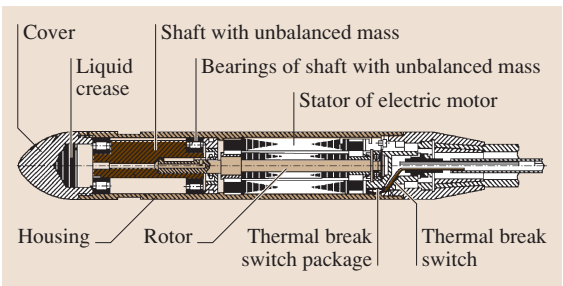

Fig. 14.51 Built-in motor-type electric immersion vibrator

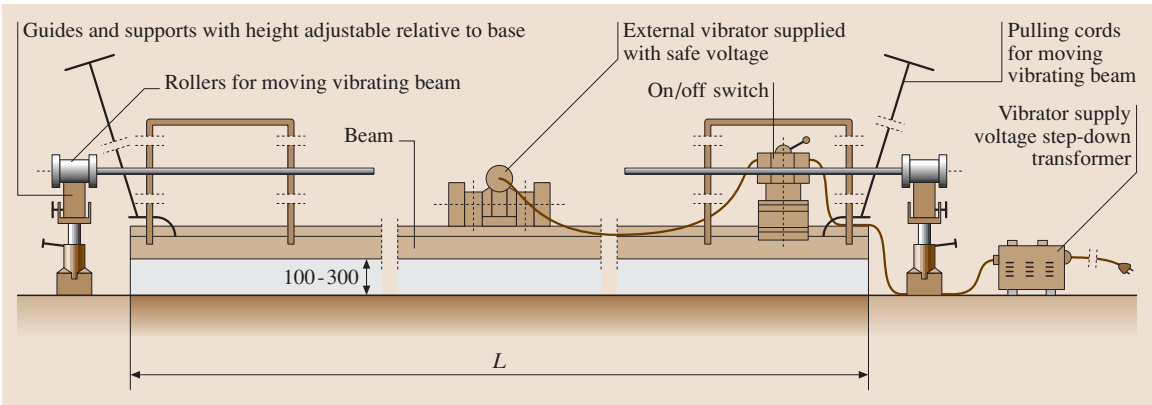

Fig. 14.52 Vibrating beam with vibration generator in the form of an external electric vibrator

requirements are met through the use of beams made from special multihole aluminum sections and by imparting negative deflection to the beams through built-in struts. The beams are used as single elements or double elements connected by lacings.

In order to reduce the harmful effect of vibration on the operators' hands, pulling cords or specially protected handles are used. Attachable vibrators with adjustable exciting force, driven by electric motors, combustion engines or compressed-air engines, are used as the vibration generators. Vibrating beams equipped with attachable electric vibrators are often adapted to a safe voltage supply to eliminate the electric shock hazard.

Vibrating beams of the type shown in Fig. 14.52 are manufactured 2.7–5.7 m long and can compact 10–30 cm thick bases.

The development of vibrating beams is directed towards increasing their length, obtaining uniform compaction of concrete mix along the whole length of the vibrating beam, and improving operational safety and transportability on the construction site. To a large extent the above requirements are met by the multipoint pneumatic vibrating beam shown in Fig. 14.53. The vibrating beam is 6.1 m long and consists of two end segments and one middle segment, joined together by bolts. The individual segments have a lattice structure triangular in cross section. Two stringers, one in the form of an angle and the other a T-bar, form the vibrating beam's base. The upper stringer is made from a pipe, which also serves as the compressed air conduit that supplies the vibrators. The vibrating beam is equipped with 16 pneumatic vibrators spaced at different intervals on both the lower stringers. The vibrators generate vertical vibrations that are transmitted to the concrete mix. The intensity of vibration is linked to the exciting force, the amplitude, and the frequency, and can be adjusted by controlling the supply air pressure. The upper stringer is joined together by turnbuckles which are also used to set the vibrating beam's deflection. The end segments are equipped with manually operated hoisting winches. The above vibrating beams are made up to 18 m long.

Vibrating beams can be equipped with different number of vibrators, depending on the length of the vibrating beam, the thickness of the compacted layer, and the desired surface smoothness. In practice, however, up to two vibrators driven by an electric motor or a combustion engine are used. In the case of reciprocating-motion pneumatic vibrators, this number is about 2–3 vibrators per running meter.

In recent years 1–3 m long smoothing vibrating beams have been introduced. These vibrating beams have low mass and are designed for smoothing elements made of semiliquid concrete mixes. The beam

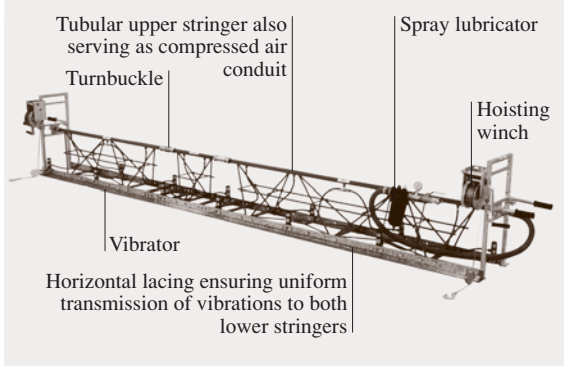

Fig. 14.53 Multipoint pneumatic vibrating beam

is equipped with an attachable electric or combustion engine vibrator and connected in an articulated way to a drawbar guided by one operator. In order to obtain high rigidity the vibrating beam's beam is made from properly formed (by bending) steel or aluminum sheet. Such beams are equipped with one vibrator, driven usually by a combustion engine or an electric motor.

14.3.8 Floating Machines for Concrete

The aim of floating is to obtain a high-quality concrete surface. Floating results in a level surface, a better compacted top surface, greater resistance to abrasion, corrosion, and the destructive effect of moisture, and a reduction in dusting. The floated surfaces can be painted or different kinds of flooring can be glued to them. Floating is performed after the base has gained some mechanical strength.

Rough and finishing floating are distinguished. In the case of older types of floating machines, rough floating was effected using a slowly rotating solid disk, while finishing floating was effected using blades set at an appropriate angle to the base. Now this practice has changed and the entire process is carried out using blades and changing the angle of their inclination, though solid disks are also used.

Single-disk floating machines (Fig. 14.54) are used for smaller concrete works. The working tools are blades or solid disks that are 600–1200 mm in diameter. They are driven by combustion engines or electric motors with a power of up to 8 kW. Combustion engine floating machines feature stepless control of the floating tools' rotational speed. Electric floating machines are equipped with two-speed electric motors whereby one can select the appropriate speed of rotation for the rough and finishing floating tools. Modern single-disk floating machines have the following features:

- A long handle, enabling access to floated surfaces with no need to walk on them (during transport of the floating machine the shaft is folded).
- The angle of inclination of the blades can be adjusted from the handle.
- The machine is equipped with a safety cutout switch (the so-called dead-man's grip), which automatically stops it once the operator's grip on the handle is released.
- Electric protection against switching the opposite direction of rotation.
- Road wheels for short-distance transport.
- The blades and the floating disks are made of high-quality materials to ensure long lifetime.

Two-disk floating machines (Fig. 14.55) are used for floating large surfaces.

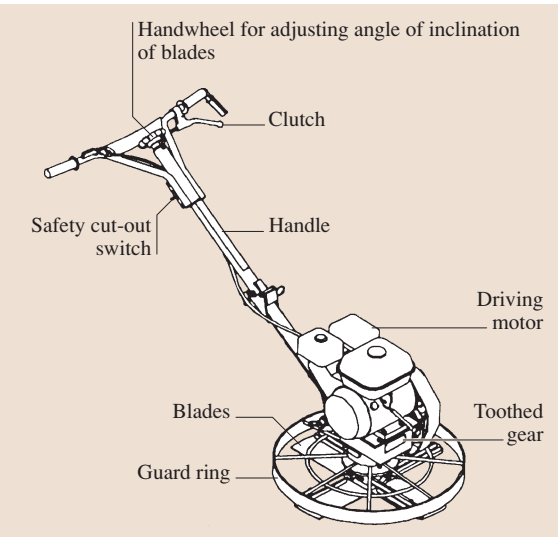

Fig. 14.54 Single-disk floating machine for concrete

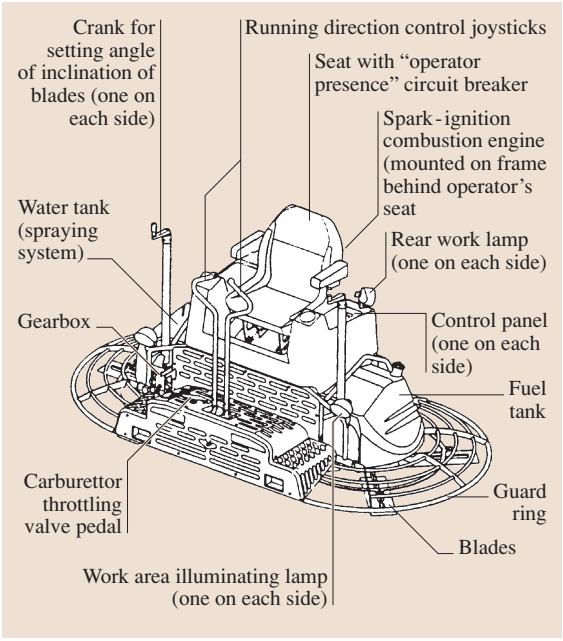

Fig. 14.55 Two-disk floating machine equipped with blades

For these machines the width of the floated strip in one pass ranges from 1700 to 2400 mm. The floating machine's control system consists of push-buttons, two joysticks for controlling the running direction, and two knobs for setting the angles of inclination of the blades.

The operator controls the floating machine while sitting in a centrally situated seat whose symmetry axis coincides with the machine's lateral axis. There are also tandem systems in which the symmetry axis of the operator's seat coincides with the machine's longitudinal axis.

In two-disk floating machines two floating system designs are used. In one of them the floating blades' outline circles may overlap while in the other there is a gap between the outline circles. The former design makes it possible to cover the whole floating width but no solid floating disks can be used. In the latter design floating disks can be used but the pass path needs to be corrected.

Depending on the floating width, machines of this type usually weigh 300–450 kg and the engine's maximum power rating is 24 kW. In the latest designs the mechanical systems are replaced by hydraulic systems, which ensure the smooth operation of the machine.

In two-disk floating machines the angle of inclination of the blades is adjusted by flexible-connector-type control systems. The control of the floating machine's running direction is based on the principle of differentiation of the friction forces acting in the particular quadrants of the outline circles, by changing the inclination of the blade ring. This principle applies to both one- and two-disk floating machines. Control is effected by means of the cranks, for each blade ring independently.

In order to ensure operational safety, safety cutout switches, usually in the form of a pedal pressed during operation by the operator's foot, are used in two-disk floating machines. If the operator falls out of the seat, the floating machine is automatically stopped.

14.3.9 Equipment for Vacuum Treatment of Concrete

Vacuum treatment is used to make high-quality concrete bases and floors. Its advantages include:

- Rapid increase in concrete strength in the initial period after placing concrete mix and applying the vacuum process
- A 15% increase in the final strength and the resulting cement savings
- Improved concrete features such as frost resistance, compression strength, imperviousness to water, and reduction in shrinkage deformation and floor dusting
- Reduction in the harmful effect of low temperatures on the curing of fresh concrete
- Quick execution of works

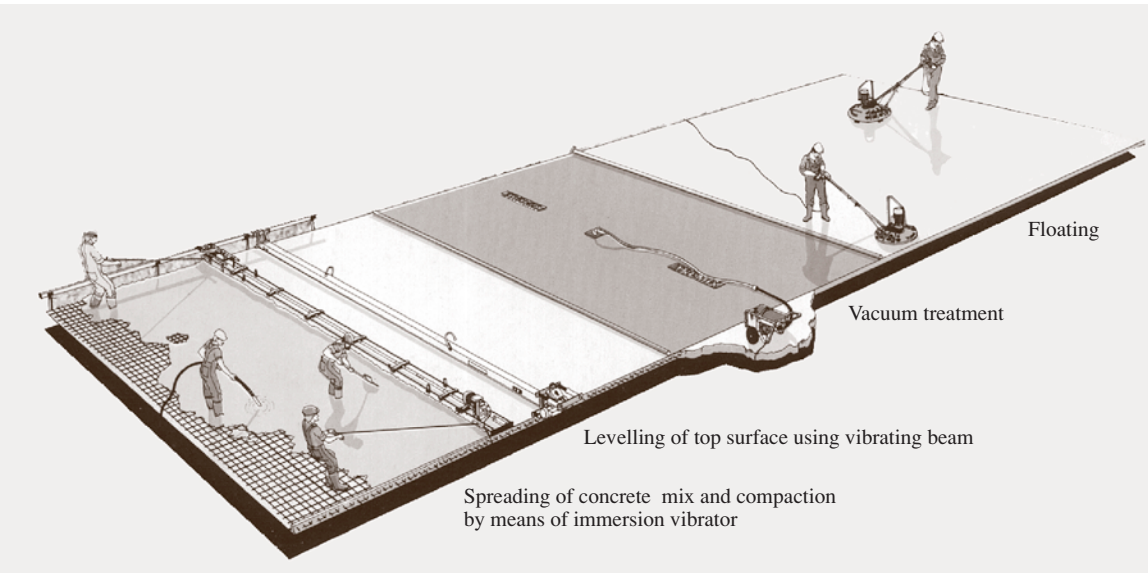

Fig. 14.56 Execution of concrete base with vacuum treatment use

- Ease of spreading of the concrete mix because of its semiliquid consistency

The use of vacuum processing of concrete is especially advantageous at low ambient temperatures (down to −5 °C) since the removal of excessive water and air bubbles to a large extent eliminates destructive processes.

The execution of concrete bases by the vacuum process can be divided into four operations (Fig. 14.56):

- Spreading of concrete and compaction by an immersion vibrator
- Compaction and leveling of the concrete mix's top surface by means of a vibrating beam pulled on guideways
- Covering with a suction mat and vacuum treatment
- Floating of the surfaces by means of rough and finishing floating machines

Roughly, the rate of vacuum treatment is 2 min/cm of base thickness. This means that a 10 cm thick base is treated for about 20 min. Floating is started when a boot impression in the concrete is about 3 mm deep.

The floating equipment includes immersion vibrators, vibrating beams, guideways with supports, expansion-joint inserts, vacuum unit with a suction mat, and floating machines.

The vacuum unit's main assembly (Fig. 14.57) is a vacuum pump with a driving motor. The pump usually has a sealing water-ring. The vacuum unit also includes: a vacuum tank, functioning as a settling tank for the sucked in impurities, connected to an atmospheric tank from which the air and water that has been sucked in is carried off, a wheeled frame, and an electric system.

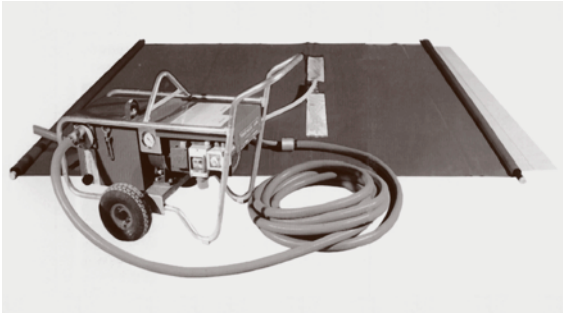

Fig. 14.57 Concrete vacuum treatment unit and suction mat

The development of vacuum units is directed towards reducing the mass and size of the vacuum unit and improving the mat. The currently used vacuum units made by leading manufacturers enable one-time sucking off of a concrete base 60 m^2 in area with a 4 kW driving motor and a machine mass of about 90 kg. The releaent pressure range for vacuum treatment of concrete is 75–95% vacuum (0.75–0.95 kg/cm^2 negative pressure).

Great advances have been made in the design of the suction mat. Older mat designs consisted of three layers, in the form of a filter cloth, a plastic flow mesh, and a tight cover, laid in turn on the vacuumed concrete mix. Current mats are manufactured as one integrated cover performing all three functions, i. e., ensuring the filtration and flow of the sucked off water and air and providing tight covering.

14.4 Site Lifts

14.4.1 Material and Equipment Lifts

Construction material lifts are intended for the vertical transport of building materials during the erection of new buildings and repairs. They may also be employed for the assembly of scaffolds and other construction site protection structures.

A classification of material and equipment lifts according to different criteria is shown in Table 14.1.

The most common type on construction sites are mast lifts with a cable or rack-and-pinion hoisting gear. Depending on the lifting height the lifts can be operated free-standing or anchored. The maximum lifting height of free-standing lifts depends on the stability of the supporting structure. The maximum lifting height of an unanchored lift does not usually exceed 12 m.

Mast Material and Equipment Lifts with Cable Hoisting Gear

The lifting capacity of lifts with a cable hoisting gear usually is below 600 kg.

Examples of lifts with a cable carriage hoisting drive are shown in Figs. 14.58, 14.60 and Table 14.2.

A lift with a capacity of 200 kg (Fig. 14.58) is made up of the following structural units:

Table 14.1 Classification of material lifts

Classification criterion	Lift definition
Platform drive design	Material and equipment lifts with cable hoisting gear
	Material and equipment lifts with rack-and-pinion hoisting gear
Platform track supporting structure	Material and equipment mast lifts
	Material and equipment shaft lifts
Base stability securement	Free-standing material and equipment lifts
	Anchored material and equipment lifts

- A base
- A multisectional mast
- A head with cable pulleys
- A drive unit-cable winch
- A carriage

The carriage moves along the mast, which is secured to the base. The mast is made from sections and has a segmental structure. It can be extended by adding more sections. The mast may be a free-standing structure or a structure anchored by means of special elements to the building's wall or window openings. The carriage is hoisted by a cable system. The winch's cable is guided to the mast's head, where there are cable pulleys through which the cable winds. The cable's end is secured to the carriage, which is equipped with rollers. The carriage suspended on the cable moves along the mast's guides. Accessories for transferring different materials are fixed to the carriage (Fig. 14.59). The carriage can slew around the mast by an angle of about 90°, which improves operating safety during the unloading of materials.

To facilitate the transport of the lift, its base is equipped with vehicle wheels.

Another 500 kg-capacity lift with a cable working platform raising drive is shown in Fig. 14.60.

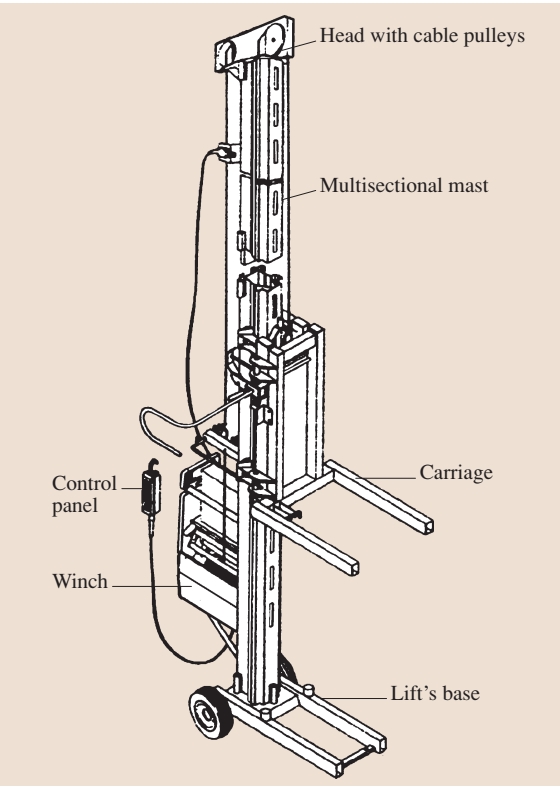

Fig. 14.58 Two-hundred-kilo-capacity lift with cable hosting drive

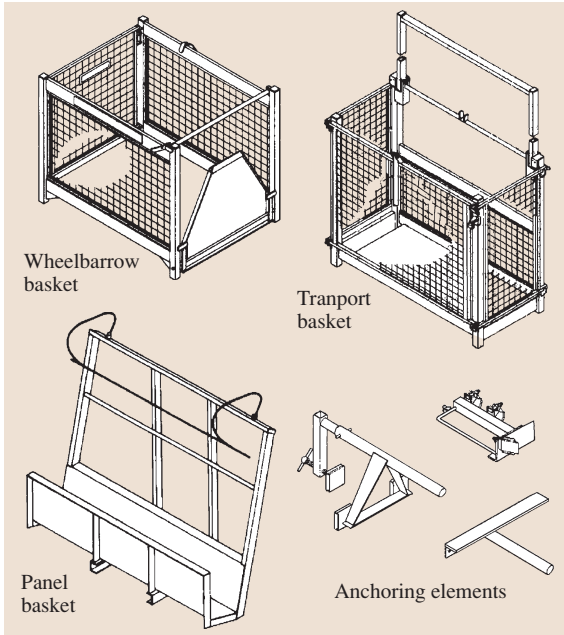

Fig. 14.59 Lift accessories

The lift consists of the following structural units (Fig. 14.60):

- A base
- A cable winch
- A transport basket
- A carriage
- A multisectional mast
- A head with cable pulleys

The basket can slew around the mast by 90°.

The lifts are self-assembled using the provided accessories.

Lifts with a cable hoisting drive are equipped with the following control and safety systems:

- Gripping devices activated when the limit speed is exceeded
- Limit switches making it possible to stop the lift at set stop levels
- A carriage (with the platform installed) upper position limit switch
- A supply-failure emergency carriage lowering system
- Stops in the lift's base

Ladder Lifts

Ladder lifts are cableways for transferring a load simultaneously in the vertical plane and in the horizontal plane. They are employed in the construction and repairs of residential buildings up to 30 m high and are used for roof and indoor work. Ladder lifts enable the transfer of building materials and the removal of waste materials. A typical ladder lift is shown in Fig. 14.61 and Table 14.3.

The ladder lift's main components are: a cable winch, a track, and a carriage.

A cable winch (Fig. 14.61) with a 230 V single-phase, squirrel-cage electric motor is the most popular drive unit used in ladder lifts. The winch includes the following assemblies: an electric motor, a roller gear, a cable drum with a cable, and an electrical system (contactors, relays, overload protections, 230 /24 V transformers).

Winches are mounted on frames attachable to a track segment. They are usually mounted between the truck's two lowest rungs. The drive unit is controlled via a portable control panel. The drive units employed in ladder lifts are very similar to the portable winches described in Sect. 14.6.2.

The main unit of ladder lifts is the track set at an angle for work (Fig. 14.61) It rests against the ground at the bottom and against a structural member (a window frame, the roof's edge) of the building at the top. When a ladder lift is to be used on a sloping roof, a track bend (Fig. 14.61) whose inclination can be adjusted is incorporated and then the track end segments (Fig. 14.61) that are to rest on the roof are attached. The track's section from the base to the building's structural member is supported by an oblique strut. The structural members of the base and the track segments are usually made as ladders whose sides constitute a raceway for the carriage's vehicle wheels. The track is typically made of aluminum alloys, but track members made from tubular steel sections are also commercially available.

Table 14.2 Specifications of cable-driven material and equipment lifts shown in Figs. 14.58 and 14.60

Parameters		
Lifting capacity (kg)	200	500
Lifting speed (m/min)	27	
Maximum lifting height (m)	80	60
Mast section length (m)	2.0	2.0
Mast section weight (kg)	16	30
Distance between anchors (m)	4	4
Gripping device	Yes	Yes
Platform's dimensions		
– Height (m)	max. 1.95	1.0
– Width (m)	0.5–0.75	1.0
– Length (m)	1.15–1.25	1.5
Electric supply (V/Hz)	Single-phase current 230/50	Three-phase current 400/50
Winch motor power (kW)	1.5	3.5
Total mass of lift (kg)	20 m high lift – about 500	20 m high lift – about 775

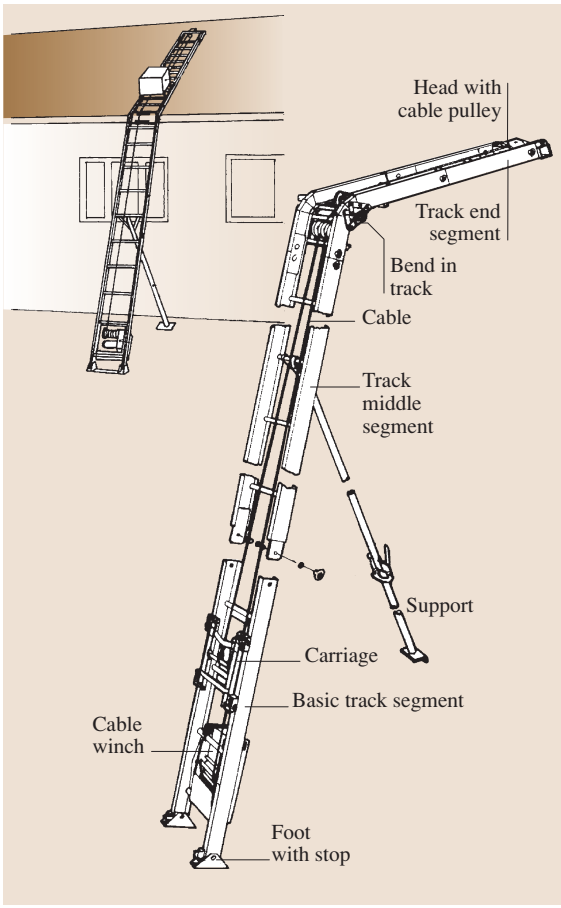

Fig. 14.61 Ladder lift

Within the track structure one can distinguish (Fig. 14.61):

- A base segment
- Middle segments
- A head
- An optional end segment

The base member ends with two hinged feet or a cross-bar with wheels, enabling the ladder lift to be rolled without it being necessary to disassemble it.

The middle segments are equipped with locking connectors inserted into adjoining segments and fixed with bolts and nuts.

The track bend has a link mechanism that allows it to be inclined. It also has cable-guiding pulleys.

Another cable-guiding pulley is situated at the end of the track.

The track's accessories include a strut to support its end passing through a window opening.

In some models, the track can be used as the lift's mast for the vertical transport of materials.

The carriage (Fig. 14.61) is the lift's vehicular unit. It is in the form of a frame with vehicle wheels. A cable with a hook, led from the winch to the carriage, runs along the guide and is directed by intermediate cable pulleys and the pulley in the cable track's head. As a rule, the carriage is equipped with an automatic gripping device actuated when the cable breaks.

Accessories for fastening loads are shown in Fig. 14.62. The accessories are mounted on the carriage. They enable efficient and safe materials handling.

Table 14.3 Specifications of model ladder lifts

Parameters	
Lifting capacity (kg)	150–200
Length of track (m)	13–30
Speed of platform (m/min)	18–40
Guide bend angle adjustment (°)	20–45; in some ladder lifts: 0–70
Number of guide sections	9 to 15
Electric supply (V)	230 single-phase alternating current
Motor power (kW)	0.75–1.5
Control	Electrical – through control buttons
Mass of drive unit (kg)	40–55
Mass of guide section (kg)	≈ 10
Total mass of ladder lift (kg)	160–210

Mast Material and Equipment Lifts with Rack-and-Pinion Hoisting Gear

In material and equipment lifts with a rack-and-pinion hoisting gear the platform used for transporting materials climbs a rack running along the mast.

The lift consists of a platform and a mast with a base. The mast structure is segmental. The individual segments have the form of a cuboidal truss structure with a rack attached to one side. Thanks to its segmental structure and the use of appropriate assembly accessories the lift is a self-assembly device. The mast is extended by adding and joining mast sections. The mast is anchored, usually by means of tubular elements, enabling the adjustment of its position relative to the wall of a building. The drive unit mounted on the platform typically consists of an electric motor with a built-in electromagnetically released spring brake, a flexible clutch, a worm gear, and a rack wheel that mates with the mast's rack. In the case of two-mast lifts, two drive units are employed. Examples of material lifts with a platform raising rack-and-pinion hoisting gear are shown in Figs. 14.63, 14.64 and Table 14.4.

The handled materials are loaded and unloaded at stops with transport stages. The mast's base is enclosed by fencing with a control box attached to it. There is an electrically controlled pivoting gate in the fencing. On the entry side all platform stops have sliding barriers which may be equipped with an electric barrier-opening monitoring system for additional protection, so that persons at the stop cannot fall out. Similarly as ca-

ble lifts, lifts with a rack-and-pinion lifting gear may be equipped with a set of wheels to enable them to be easily transported to a new work site. Instead of the platform for handling lump and sacked materials, a special bucket for transporting concrete mix can be installed.

A comparison of lifts with a rack-and-pinion hoisting gear with lifts with a cable hoisting gear shows that the former lifts have several advantageous properties such as: greater lifting height, easier and safer assembly, and simpler operation.

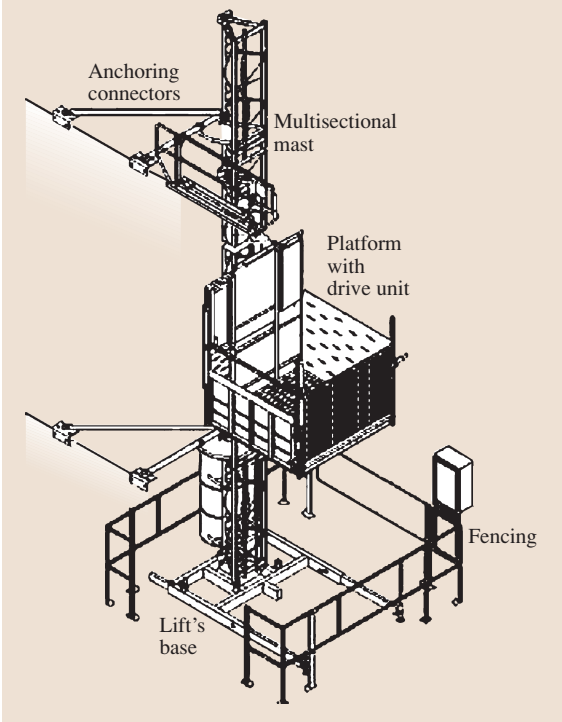

Fig. 14.63 Single-mast material and equipment lift with rack-and-pinion hoisting gear

Total mass of 15 m- and 70 m-high lift, respectively (kg)	2300–10 000

Shaft Material and Equipment Lifts

Shaft material and equipment lifts (Fig. 14.65) are used for the vertical transport during the construction of medium- and high-rise building structures.

A shaft lift consists of the following main parts (Fig. 14.65 and Table 14.5):

- A shaft
- An upper beam
- Guides
- A bottom cable pulley
- The platform's upper beam
- A platform
- A winch (typical lifting winches with an electric or diesel drive can be used)

The shaft has a spatial truss structure. The load-bearing platform is made of steel sections. The cable is guided by the bottom and top cable pulleys. The end of the cable is fixed to the upper beam (Fig. 14.65).

There is also a shaft lift design in which the shaft is made of only flat frames anchored to the building's wall. Shaft lifts are equipped with similar safety devices as other material lifts.

Material lifts are equipped with the following safety devices:

- A gripping device which stops the platform as it descends whenever it exceeds the maximum allowable rate of descent.
- Protection against disengagement of the drive wheel from the mast's rack. As standard, sliding guides are used. They keep the load platform on the mast even if the roller guides fail.
- An emergency lowering system used in the case of a prolonged power failure. Some lifts are equipped with emergency lowering systems with speed self-stabilization – the speed stabilizes below the speed at which the gripping device is actuated.
- The upper and lower limit switches, automatically stopping the platform at the mast's highest and lowest levels.
- Switches and locks for stop doors or barriers, preventing their accidental opening when the platform is outside the stop zone or in motion.
- Stops to ensure that the platform will be brought to a stop if the limit switches fail.
- An induction sensor that monitors mast presence during mast assembly.
- A sound system signalling the start of a platform ride.
- Protection against electric shock.
- Overload protection of the electric motors.
- Switches actuated when the working platform skews in two-mast lifts.

The operation of the cable-driven material lifts described above typically consists of the control of the movement of the carriage by pushing buttons on the control panel at the lower station. It is also possible to switch to control from the platform during assembly and maintenance of the lift.

14.4.2 Material and Equipment Lifts with Access to Personnel

Material and equipment lifts with access to personnel are intended for the vertical transport of persons and materials during construction/assembly works and repairs of mainly high-rise buildings in housing and industrial construction. Their design is usually similar to that of material and equipment lifts with a rack-and-pinion hoisting gear.

A person and material lift consists of a cabin with a rack-and-pinion drive, moving on a mast secured at the bottom to the lift's base and anchored to the building's wall, and transport stages (stops) between which transport takes place. The mast has a segmental structure and can be extended by adding mast sections. It is anchored by means of a system of tubes, which makes it possible to adjust the mast's position relative to the building's wall.

The lift can have two cabins, each with its own drive system, whereby the transport of persons and materials can be doubled. The lift's cabins move on a common mast independently of each other. Examples of person

Table 14.6 Specifications of selected person and material and equipment lifts

Parameters	Single-cabin lifts	Two-cabin lifts
Lifting capacity (kg)	1200–2000	2×1200–2×2000
Maximum lifting height (m)	150–300	150–300

and material lifts with a rack-and-pinion, platform lifting gear are shown in Figs. 14.66, 14.67 and Table 14.6.

The development of high-rise construction created a need for high-lifting-speed vertical transport equipment. For this purpose fast lifts with a lifting speed of up to 1.8 m/s are employed. These are used for the vertical transport of persons and materials and equipment in industrial construction, for building reinforced concrete chimneys, silos, television towers, and similar structures. One- and two-mast high-speed construction lifts are available.

These lifts incorporate electrohydraulic drive systems whose basic unit is a hydrostatic gear. The hydraulic engine's output shaft is connected by a cou-

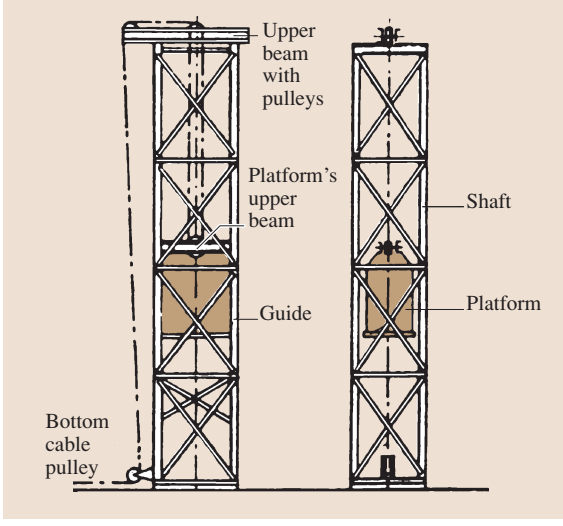

Fig. 14.65 Shaft material and equipment lift with cable hoisting gear

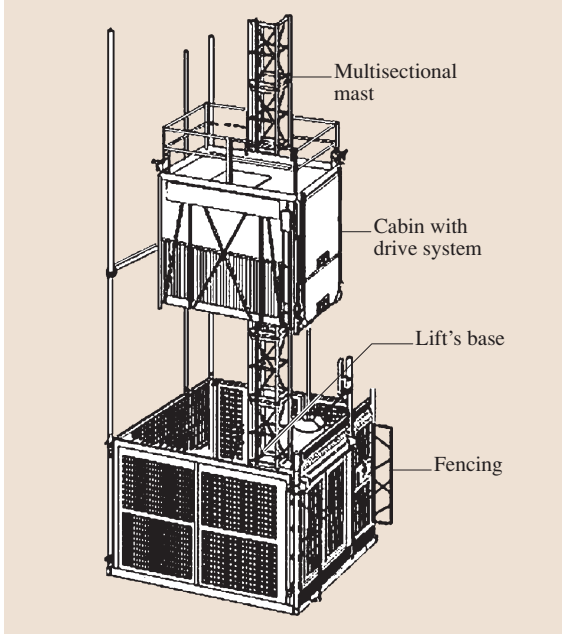

Fig. 14.66 Single-cabin person and material lift with rack-and-pinion hoisting gear

pling to the shaft of a worm gear assembly on the output shafts of which cylindrical gears mating with the mast's rack, and so making the cabin move up or down, are mounted. The weight of the loaded cabin is counterbalanced by a counterweight connected to the cabin by a steel cable passing through pulleys fixed to the top of the mast.

The safety of persons in person and material lifts is ensured by appropriate guards around the traffic way and the stop platform access. Person and material lifts can be controlled from the moving cabin as well as from any stop level. The lift's base (the bottom stop) is fenced in to a height not less than 2.0 m. The access areas are protected by stop doors with a minimum height of 2.0 m, equipped with safety locks.

Entrances to the person and material lifts' cabins are protected by doors. The cabin door is equipped with mechanical bolting devices and safety cutout switches, preventing the door from being opened as the cabin is moving when the cabin's floor is not within about ±0.25 m from a stop landing or when the door is not closed and the bolting device is not in the closed position.

In addition, person and material lifts are fitted with similar safety devices as those used in rack-and-pinion material and equipment lifts, i. e.:

- Gripping devices actuated at an excessive speed of descent
- Protection against disengagement of the drive toothed wheel from the mast's rack
- An emergency lowering system
- Limit switches
- Working platform skewness switches in two-mast lifts
- Protection against electrical failures in the case of no voltage, voltage decay, or voltage drop
- Electrical devices protecting:
  - Closed stop gate position
  - Stop gate bolting device position
  - Closed cabin or platform gate position
  - Bolted emergency hatch or door position

Modern rack-and-pinion person and material and equipment lifts are characterized by:

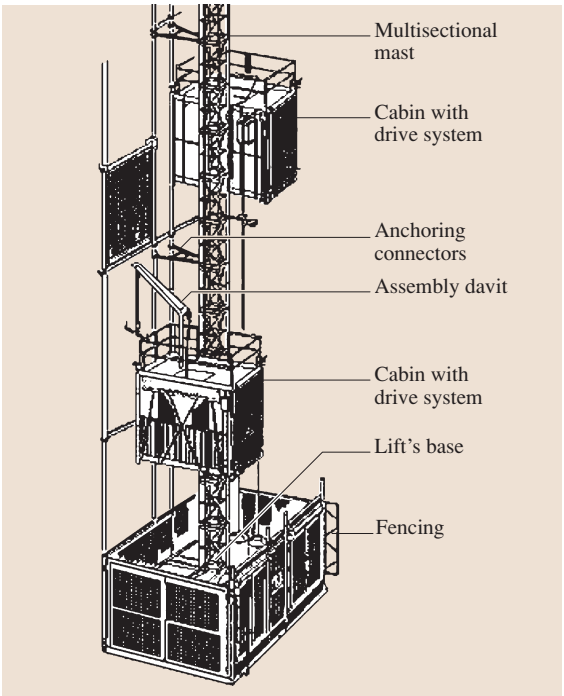

Fig. 14.67 Two-cabin person and material lift with rack-and-pinion hoisting gear

- A great lifting height: up to 300 m
- Easy and quick assembly
- A high lifting capacity: 2000 kg per cabin
- Automatic stopping of the cabin at the terminal stops
- The possibility of programming at which stops the cabin should stop
- Completely safe operation owing to the use of appropriate protective measures
- Easy operation and simple maintenance
- An installation that enables audio communication between the cabin and the bottom stop
- An overload control system

Because of their advantages person and material lifts with a rack-and-pinion hoisting gear have gained a dominant position in the lift market.

14.5 Access Machinery and Equipment

14.5.1 Static Scaffolds

A scaffold is a temporary (usually bar) structure erected to provide safe access during construction, repair, maintenance, and demolition of all kinds building structures.

Scaffolds can be classified according to the different criteria specified in Table 14.7, and the main criteria for classifying scaffolds and the related terminology are described below.

One of the major criteria is the division of scaffolds with regard to their design and assembly method. Particularly important is the division into tube–coupler scaffolds and system scaffolds.

Tube–coupler scaffolds (Fig. 14.68) are constructed from steel tubes and couplers, and the stagings are made from boards or balks. In this type of scaffolds, the dimensions of the structural grid are not rigidly imposed by the dimensions of the components, e.g., by the length of the tubes. Workers assembling a tube–coupler scaffold according to a blueprint ascertain the positions of all the elements which determine the dimensions of the structural grid and the verticality of the uprights. The basic components of the tube–coupler scaffold are shown in Fig. 14.68.

In tube–coupler scaffolds, such elements as standards, transons, and bracings are joined eccentrically by right-angle or swivel couplers, as illustrated in Fig. 14.69.

A characteristic feature of *scaffolds made of prefabricated elements* (system scaffolds) is that their dimensions (or some of their dimensions) are determined by the dimensions of their components. All frame and modular scaffold systems belong to this class. A general view of system scaffold constructions is shown in Fig. 14.70. Modular scaffolds and frame scaffolds are shown on the left and right, respectively.

In the *frame scaffold*, the vertical structure is made up of prefabricated flat frames. The frame consists of two uprights permanently connected by transverse el-

Table 14.7 Classification of scaffolds

No.	Classification criterion	Name of scaffold
1	Intended use	Working scaffold Protective scaffolds Load-bearing scaffolds
2	Design and assembly method	Tube–coupler (bricklayer's) scaffolds Ladder scaffolds Scaffold made of prefabricated elements (system scaffold): Modular, Frame
3	External load-bearing mode	Standing scaffolds Suspended scaffolds Trestle scaffolds Outrigger scaffolds Cantilever scaffolds
4	Protection of scaffold against overturning	Anchored facade scaffolds Scaffolds secured to base by guy-ropes Free-standing scaffolds
5	Transferability	Immobile (stationary) scaffolds Mobile (portable) scaffolds
6	Operating mode	Scaffolds used for short periods, e.g., during working shift Permanent scaffolds used for prolonged periods without dismantling
7	Material from which scaffold load-bearing elements are made	Wooden scaffolds Aluminum scaffolds Steel scaffolds
8	Technical–organizational and formal-legal aspects	Scaffolds in typical version Individually designed scaffolds

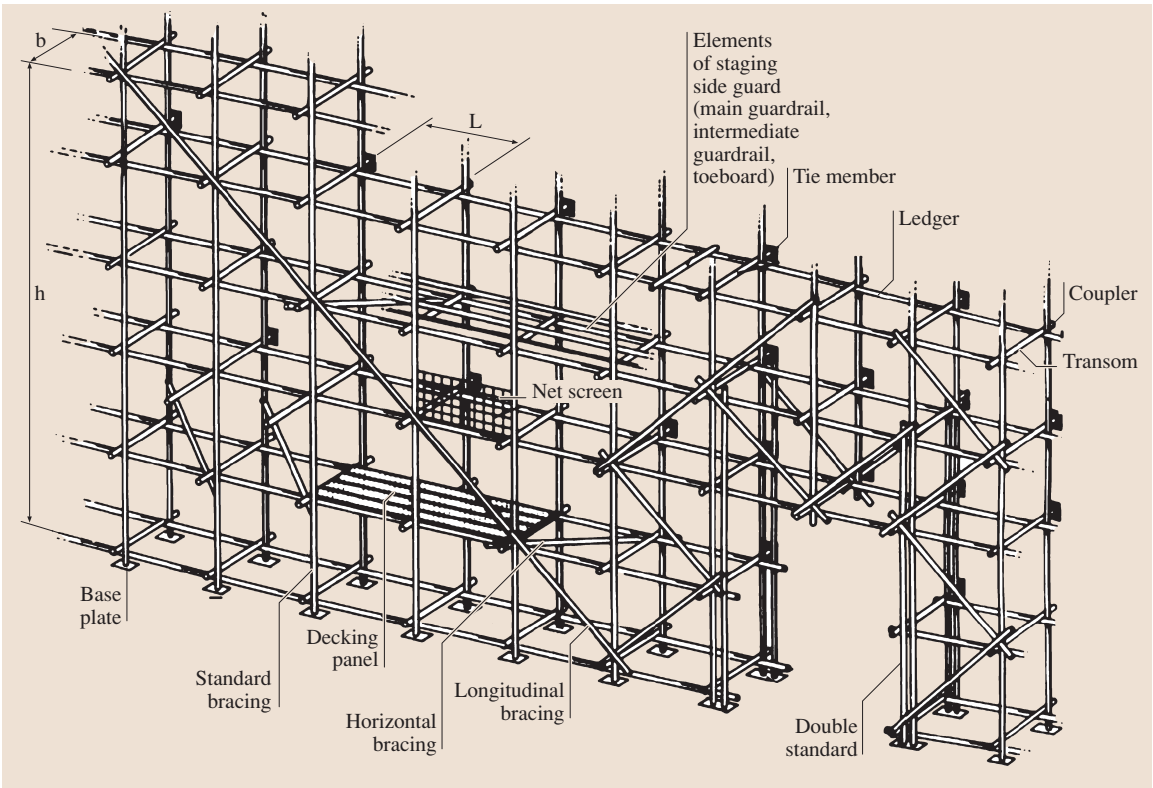

Fig. 14.68 Anchored facade tube–coupler scaffold (*b* scaffold width; *L* scaffold length; *h* scaffold height)

ements at the frame's top and bottom. The top cross member is used for fixing decking panels. The bottom member may prevent the disassembly of the decking panel while the scaffold is in service. In the vertical plane the scaffold is braced by diagonal bracings. In the horizontal plane it is braced by system decking panels.

In a modular scaffold, transoms, ledgers, and bracings are joined with standards at fixed nodal points spaced at regular intervals, usually every 0.5 m.

Modular and frame scaffolds made by one manufacturer are in most cases compatible and can be combined.

In frame system scaffolds, uprights are connected with crossbars by inseparable welded joints.

In *modular system scaffolds*, standards are joined with transoms at fixed nodal points.

Transoms and bracings can be attached to standards by means of coupling elements permanently fixed to the latter. The coupling elements (coupling heads) usually have the form of a disk or a flange and they are regularly spaced, usually every 0.5 m. The bracings and the transoms are tipped with coupling heads. Transoms and bracings are connected with standards, typically by cotter joints. As opposed to tube–coupler structures, in modular scaffolds the axes of the ledgers, the transoms, and the standards connected together intersect at one point. A modular scaffold joint is shown in Fig. 14.71.

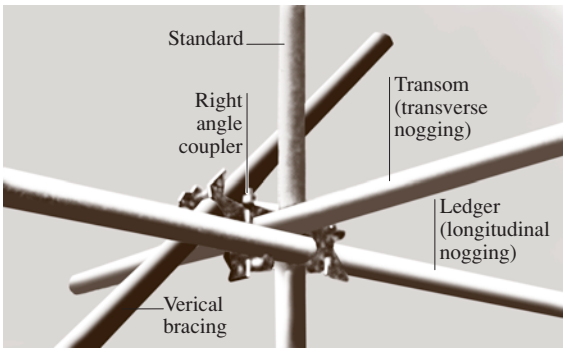

Fig. 14.69 Tube–coupler scaffold joint

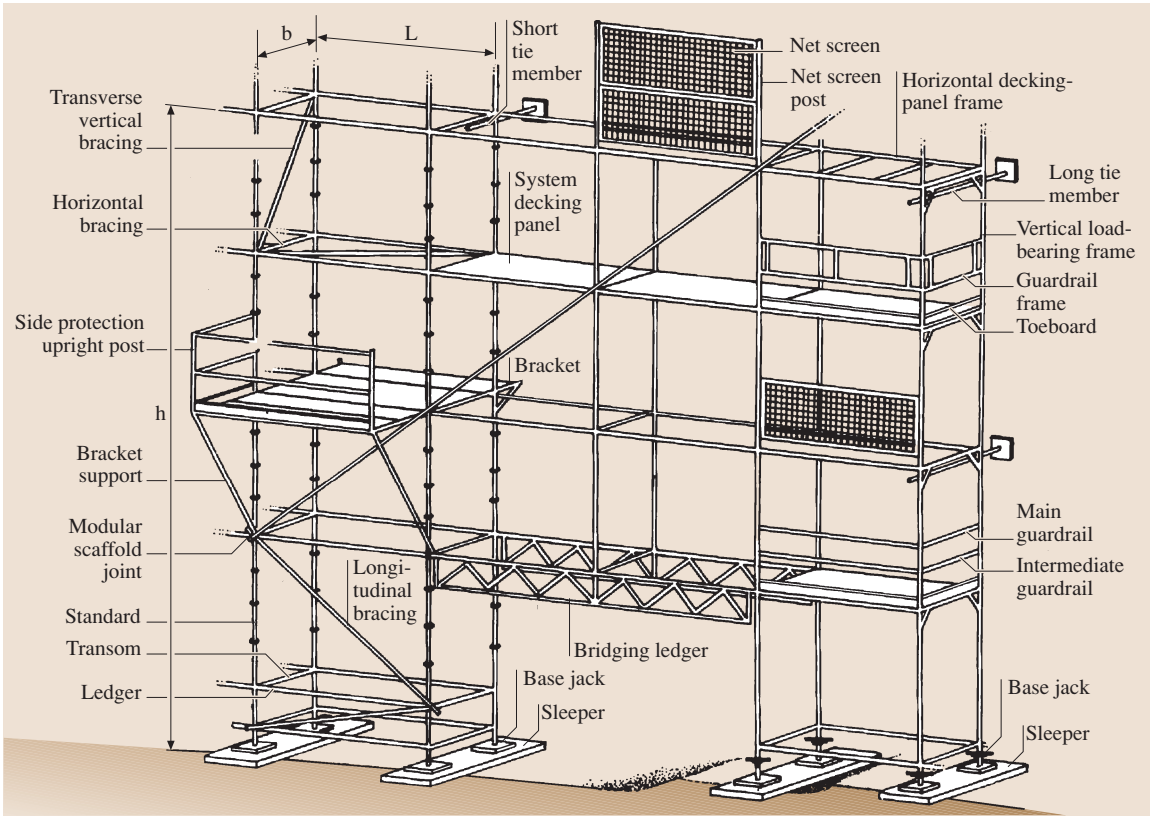

Fig. 14.70 Anchored facade system scaffolds frame scaffold (*right*) and modular scaffold (*left*) (*b* scaffold width; *L* scaffold length; *h* scaffold height)

System scaffolds have several advantages over tube–coupler scaffolds:

- Much easier, quicker, and safer assembly
- Higher load capacity at similar or identical scaffold geometrical or material specifications
- Lower and easier to assess variability of the scaffold structure's random parameters such as geometric imperfections, the load capacities of the individual elements, and the characteristics of the joints
- Possible greater standardization of typical designs

For these reasons tube–coupler scaffolds are being supplanted by system scaffolds.

Another major criterion according to which scaffolds are divided is their intended use. This is connected with the character and magnitude of the loads acting on the assembled structure. Two basic uses can be distinguished:

- Working scaffolds – structures capable to carry worker, material, and equipment loads.
- Load-bearing scaffolds – support structures which, during the construction of a building, can be loaded with the weight of its individual elements or units; one should note that the reliability of scaffolds of this type is a necessary condition for the proper course of a construction process (e.g., concreting). The construction and use of load-bearing scaffolds is subject to separate regulations.

Another major scaffold classification criterion is connected with technical–organizational and formal–legal aspects and with the standardization of scaffold designs and applications.

In legal instruments scaffolds are divided into:

- Scaffolds in a typical version
- Individually designed scaffolds

Table 14.8 Specifications of typical portable single-mast climbing platforms

Parameters				
Platform's length/lifting capacity (m/kg)	4.1/1300 7.1/800 10.1/500	4.2/1300 7.4/1000 10.5/700	4.2/2000 7.4/1700 10.5/1400 12.5/1200	4.2/2700 7.3/2300 10.5/1900 13.7/1500 16.9/1000

A scaffold in a typical version means an assembly version of the scaffold which covers the most frequent applications of the scaffold structure. It is assumed that the manufacturer has provided a proof of the scaffold's static strength and neither its user nor the company assembling it has to provide such a proof in order to certify the scaffold fit for use on the construction site. Also in the case when the assembly version has been realized in accordance with a generally recognized assembly standard the proof does not have to be provided. The generally recognized assembly standard may be defined in assembly norms or instructions issued by the manufacturer of the given type of scaffold.

Scaffolds in a typical version are anchored, facade, working scaffolds with a height of up to 24 m and access working towers erected to a height of 8 m outdoors and to a height of 12 m indoors.

Typically, a useful load of 2 kN/m^2, sometimes 0.75, 1.5, 3, 4.5, and 6 kN/m^2, is assumed for stagings.

Examples of scaffolds in their typical versions are shown in Fig. 14.72.

Each scaffold that is not in a typical version should be individually designed and its statics tested. The range of the structural analysis depends on the complexity of a given scaffold structure. Examples of atypical scaffolds are shown in Figs. 14.73–14.77.

Competent construction design companies, usually connected with equipment manufacturers, should be entrusted with the design of atypical scaffolds. When selecting scaffolds the user should take into account the following:

- The construction site's location (a wind load zone, power lines, traffic routes, etc.)
- The kind of terrain and the lay of the land on which the scaffold is to be founded

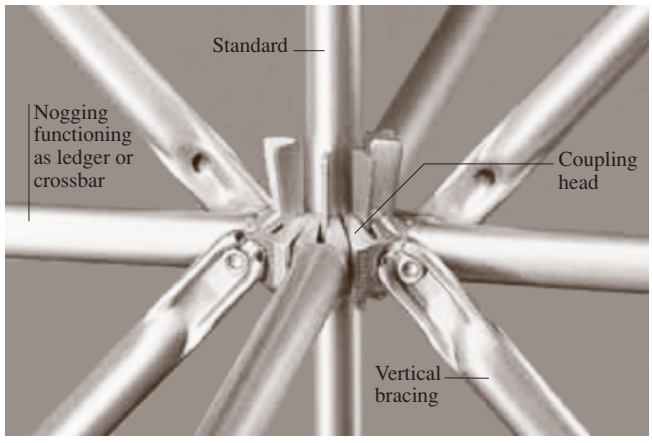

Fig. 14.71 Modular scaffold joint

- The bearing capacity of the base on which the scaffold is to be founded
- The building's height and the shape of the elevation
- The kind and type of scaffold
- The intended use of the scaffold
- The magnitude of the loads originating from people and equipment
- Easy anchoring of the scaffold
- The number and layout of traffic routes
- The transport of materials onto the scaffold
- Canopies

14.5.2 Elevating Work Platforms

General

Elevating work platforms form a wide class of cranes for elevating persons and equipment for repair, maintenance, and assembly purposes. Depending on their design and application, elevating work platforms can be divided into the following groups:

- Portable mast-climbing platforms
- Mobile (mounted on special chassis) elevating work platforms
- Hanging scaffolds

Portable Mast-Climbing Platforms

Portable mast-climbing platforms are used for masonry plastering, assembly, insulation, and facade works in housing and industrial construction. Portable mast-climbing platforms (Figs. 14.78 and 14.79 and Tables 14.9 and 14.10) are made up of the following units:

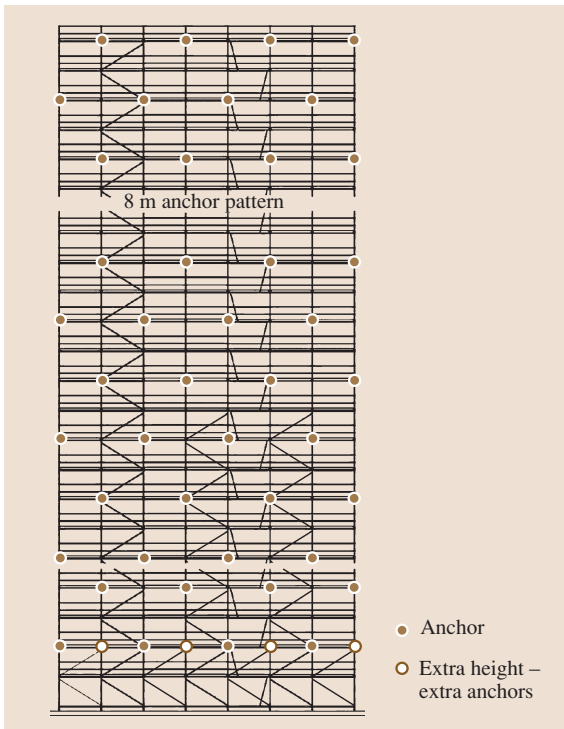

Fig. 14.73 Anchored, facade, frame scaffold in atypical version. The atypicality consists of the considerable height of the scaffold

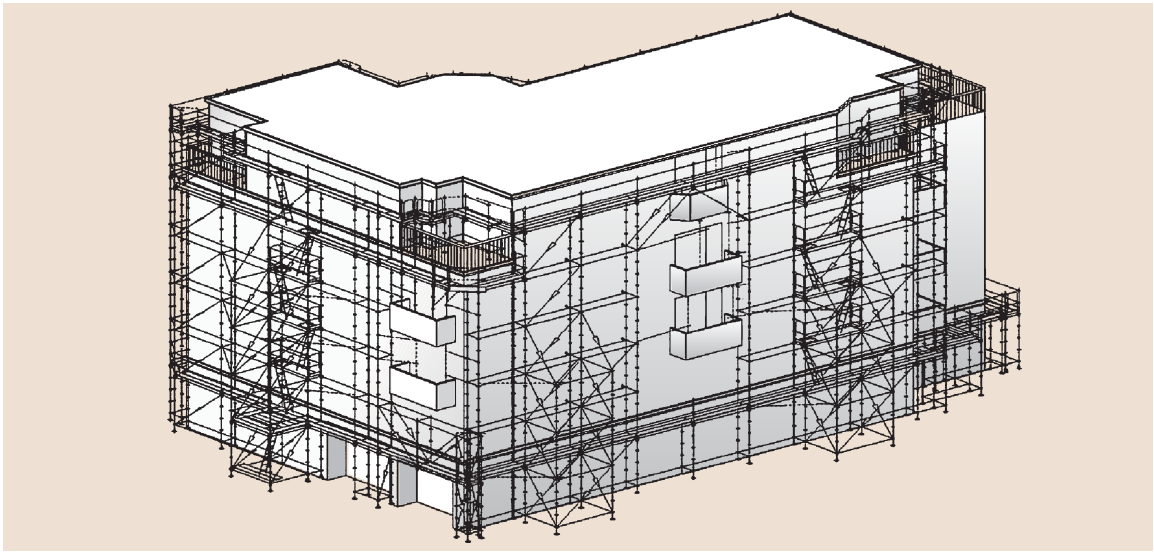

Fig. 14.74 Facade, frame scaffold in atypical version. The atypicality consists of the lack of anchoring

- A base
- A mast or multisectional masts
- A work platform lifting unit
- A work platform

The work platform moves on a mast fixed to a base and anchored to a wall of a building structure. The mast is

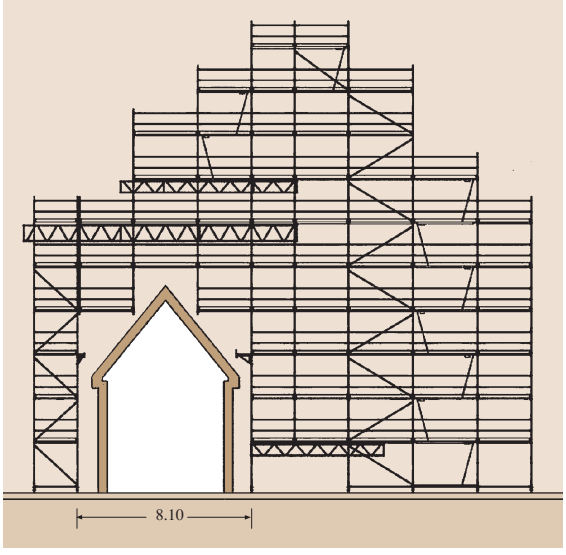

Fig. 14.75 Anchored, facade, frame scaffold in atypical version. The atypicality consists of the part of the scaffold suspending on girders

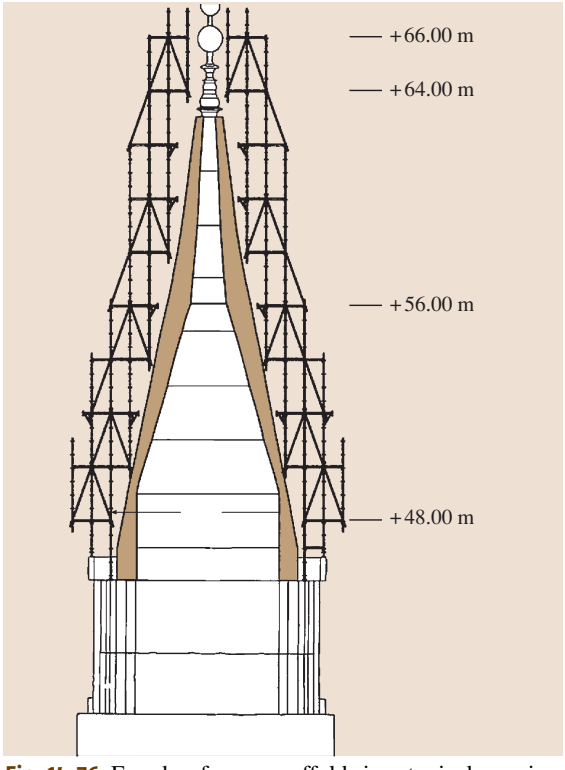

Fig. 14.76 Facade, frame scaffold in atypical version. The atypicality consists of the shape of scaffold support scheme, which differs greatly from the typical version

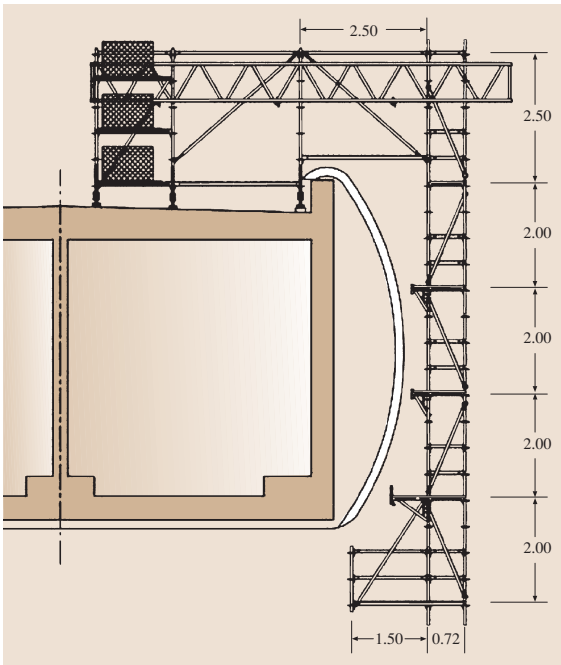

Fig. 14.77 Atypical suspended scaffold. The atypicality consists of the suspending main part of scaffold

made up of sections added up to the required height. In the case of a free-standing mast, the work platform can be usually lifted to a height of 20 m. The mast's base can have the form of a carriage or be stationary. If a carriage is used as the base, the free-standing mast-climbing platform can be moved without it being it necessary to disassemble the mast completely. The carriage can be towed by a tractor or be self-propelled and so able to move along the wall of the building structure. A small-sized stationary base is used when the space for the mast-climbing platform is restricted and no carriage can be employed, e.g., in a street with a narrow pavement. The work platform is elevated by a rack-and-pinion gear. Thanks to its sectional design the mast-climbing platform can be configured to fit the building structure's shape.

In addition, protractible struts, with length adjustable from 0 to 2500 mm, can be attached to the mast-climbing platform's sections. Planks or wooden boards are placed on the beams, thereby creating additional working surface. The combination of the mast-climbing platform's sectional structure and the system of protractible struts makes it possible to obtain work access on walls of any shape (straight, curved, and with slants and bevels) and architectonic form (balcony,

loggia, niche, bay). The whole mast-climbing platform is fenced in with railings to protect persons working on it from falling out. It is also possible to combine two single-mast climbing platforms to form one platform (up to 40 m long) climbing two masts (Fig. 14.79 and Table 14.10). In many cases, mast-climbing platforms may replace stationary construction-assembly scaffolds.

Similarly to material hoists and person and material hoists with a rack-and-pinion drive, mast-climbing platforms are equipped with the following safety devices:

- An emergency lowering system
- A braking device
- A safety device preventing the driving gear wheel from disengaging from the mast's gear rack
- Electric-shock protection
- Overload protection for the electric motors
- Work-platform-slanting cutouts (in two-mast climbing platforms)
- Work platform terminal position cutouts
- Sensors signalling a platform loading which may result in overturning of the mast-climbing platform or its damage

Mobile Elevating Work Platforms

Mobile elevating work platforms have a similar range of applications (elevating persons and equipment) as the portable mast-climbing platforms described above, except that their use in one work place is short.

Mobile elevating work platforms form a class of devices varied in their design. The basic types of mobile elevating work platforms are listed in Table 14.10.

Mobile elevating platforms are usually equipped with protractible struts. Truck-mounted platforms are the most popular mobile elevating work platforms used in construction.

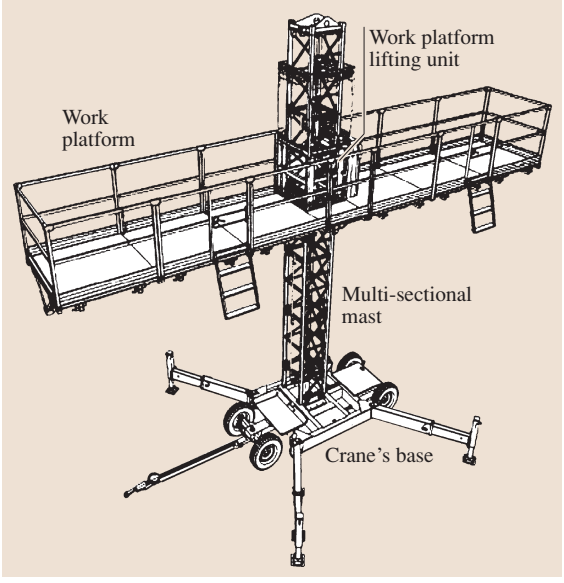

Fig. 14.78 Portable single-mast climbing platform with rack-and-pinion lifting gear

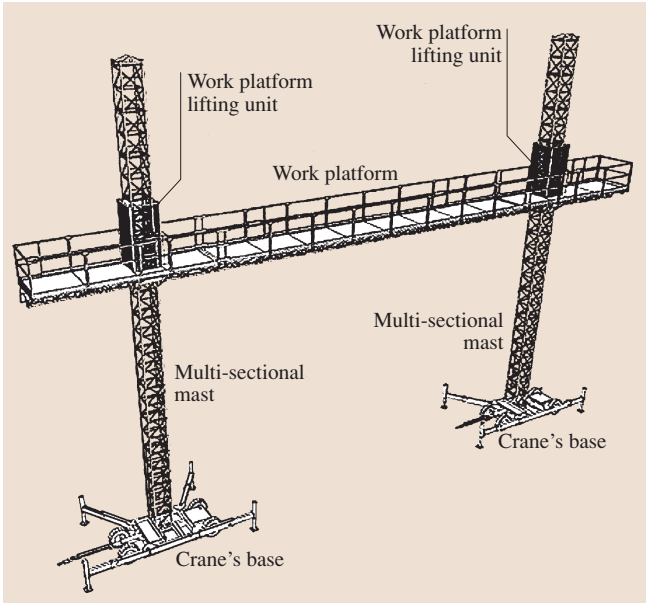

Fig. 14.79 Portable two-mast climbing platform with rack-and-pinion lifting gear

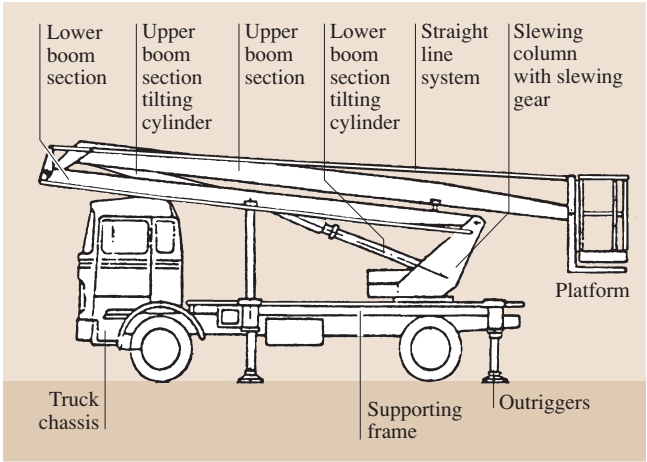

Fig. 14.80 Truck-mounted elevating platform

Table 14.10 Types of mobile elevating work platforms

Description of mobile elevating work platforms	Design schematics
A mobile elevating work platform featuring a telescopic boom. The boom can be raised, lowered, and slewed relative to the vertical axis.	A platform mounted on a telescopic column or a hydraulic servomotor. The working motions are: the raising and lowering of the platform in the vertical plane.	A mobile elevating platform with a scissor extending structure.	A truck-mounted elevating platform whose extending structure is usually in the form of a two-stage boom. The elevating platform performs the following motions: • Raising and lowering • Slewing relative the vertical axis perpendicular to the base	Key: 1 platform; 2 extending structure; 3 chassis; 4 struts	

Truck-Mounted Elevating Platform

The truck-mounted elevating platform consists of the following parts shown in Fig. 14.80.

The supporting frame is a body to which protractible struts, a hydraulic feeder, and a slewing gear are fixed. The supporting frame is secured to a truck chassis.

Table 14.11 Specifications of selected truck-mounted elevated platforms with elevation up to 15, 21, and 40 m

Specifications	Platforms with elevation of 15 m	Platforms with elevation of 21 m	Platforms with elevation of 40 m
Max. working elevation (m)	10.0–15.0	16.0–21.0	25.0–40.0
Max. horizontal radius (m)	4.2–7.4	5.5–11.0	11.6–21.9
Lifting capacity (kg)	120–200	200–300	265–365
Weight (without chassis) (kg)	950–2300	1620–5900	5200–13 400
Length in transport mode (m)	5.3–7.45	6.8–10.2	7.8–11.4
Width in transport mode (m)	1.9–2.1	2.1–2.5	2.5
Height in transport mode (m)	2.0–3.6	2.6–3.35	3.5–3.8
Slewing angle (°)	330 or 360	360	360

The slewing column is attached to the supporting frame through a crown-bearing. The column is a slewing welded-construction frame with a transmission gear and a brake mounted on it. The lower boom stage and the cylinder are attached to the column by articulated joints.

The boom consists of two stages connected by an articulated joint. Each stage is a welded box structure.

The work platform consists of a floor made from thin-walled steel sections, railings, and curbs.

The straight-line system is a tension-member structure which keeps the work platform in a horizontal position regardless of the angles at which the boom's stages are positioned.

The work platform positioning system consists of a pump, filters, distributors, valves, steel pipes, hoses, and hydraulic cylinders. The hydraulic pump is powered from the truck's gearbox via a lay shaft. Oil is supplied to the working cylinders through a rotary joint. The struts are controlled through distributors mounted on the supporting frame. The boom's cylinders and slewing can be controlled through a distributor mounted near the slewing column or on the work platform. The system is protected against the eventuality of simultaneous steering of the struts and the boom's cylinders. The boom's cylinders and those of the struts are equipped with valves to prevent a pressure failure and the resulting uncontrolled shift of the piston rod.

The maximum angle of elevation of the boom's upper stage is limited by a limit switch in the form of a hydraulic valve controlled by a cam on the boom. The hydraulic system's circuits are protected against excessive pressure rise by overflow valves.

In elevating platforms capable of large elevations (20–40 m), proportional control, ensuring that the working motions controlled by the operating lever are fluid and quick, is used instead of the typical hydraulic control.

Truck-mounted elevating platforms have the following safety measures:

- Limit switches preventing the boom's upper section from being excessively raised and the boom's lower stage from being lowered while the boom's upper stage is maximally raised
- A hydraulic system lock preventing the working circuit and the struts from being simultaneously fed
- Overload protection in the form of overflow valves

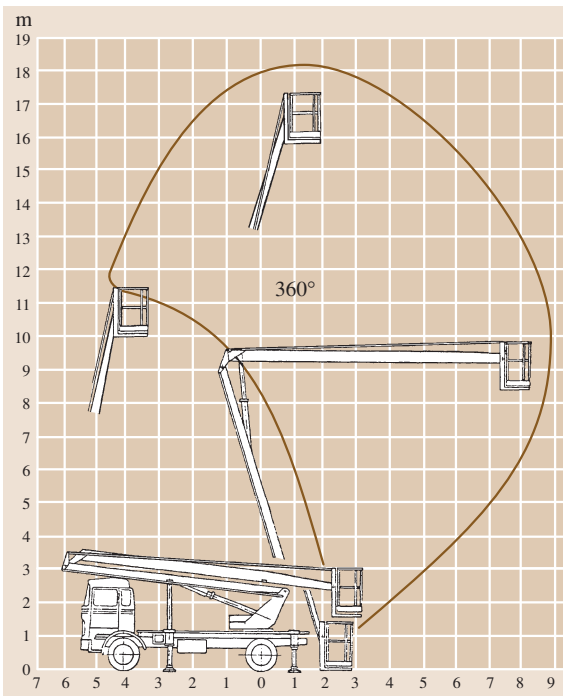

Fig. 14.81 Work area of truck-mounted elevating platform with elevation of 18 m and radius of 8.7 m

- Emergency lowering of the cradle while the pump drive is switched off

The truck-mounted elevating platform's basic operating parameters are:

- Lifting capacity
- Maximum elevation
- Maximum radius
- Work area, specifying the allowable position of the elevating platform in the vertical plane
- Angle of rotation of the body

The work area with specified positions of the work platform in the vertical plane is shown in Fig. 14.81.

Mobile elevating platforms can be mounted on mass-produced truck chassis. The type and size of chassis depends on the specifications of the elevating platform. The characteristics of selected chassis for the particular groups are detailed in Table 14.11.

14.5.3 Hanging Scaffolds

Hanging scaffolds are intended for use in both housing and industrial construction. They are used for finishing works such as painting work, plaster work, insulation work, and window glazing. In many cases, hanging scaffolds may replace stationary construction-assembly scaffolds.

Hanging scaffolds can be divided into the following kinds:

- Stationary, hand-driven, single-person (cradle) scaffolds
- Stationary, hand- or electrically driven scaffolds
- Mobile, hand- or electrically driven scaffolds
- Stationary, hand- or electrically driven sectional scaffolds

Stationary, single-person hanging scaffolds are cradles with a single-person workstation. The cradle is suspended by a hoisting cable from a boom placed on the roof of a building. The vertical motion of the scaffold is effected by means of a two-crank hand winch operated by the person in the cradle. There are containers for materials and tools on both sides of the cradle.

A single-person hanging scaffold is shown in Fig. 14.82.

Specifications of single-person hanging scaffolds are listed in Table 14.12.

Table 14.12 Typical specifications of single-person hanging scaffold

Parameters	Value
Hoisting capacity (kg)	100
Elevation (m)	35
Hoisting speed (m/min)	1.35–2.2
Type of drive	Hand
Crank force (N)	150
Diameter of steel cable (mm)	8
Mass of movable part (kg)	148
Mass of counterweight (kg)	270

Stationary Hanging Scaffolds

These are scaffolds in which the work station is a platform with winches, suspended on cables. Hand-driven and electrically driven hanging scaffolds are used.

A stationary hanging scaffold with a hand drive is shown in Fig. 14.83.

The hanging scaffold shown in Fig. 14.83 consists of three main units: a platform, two winches with a hoisting cable, and a boom. The platform is a steel frame (lined with boards) with a take-down guardrail. The platform is equipped with roller fender beams guiding it on the building's wall during hoisting and lowering. The hanging scaffold is hoisted and lowered

Total weight of scaffold (kg)	900	1770	2500	3610

by means of two hand winches suspended on suspension rods and hoisting cables. The following winch types are used for hand driving hanging scaffolds:

- Typical drum winches with the end of the cable fixed to the drum
- Frictional winches with loading of the lower end of the cable by means of a weight or spring load
- Lever pull hoists

In drum winches a pawl on the winch's ratchet and a frictional mechanism prevent the scaffold from unintended descent. The scaffold is suspended from two booms joined together by pipe connectors. The scaffold is for two persons, each operating one winch during the hoisting and lowering of the platform.

A stationary hanging scaffold with an electric drive is suspended in a similar way to the hand-driven scaffold. The vertical motion of the scaffold is effected by two drum winches with gears. The turns of the winches are synchronized through a cardan shaft connection between the driving electric motor and the winches. Scaffolds of this type are equipped with a hand-operated lowering gear used in the event of failure of the electric drive.

The specifications of hand- and electrically driven hanging scaffolds are shown in Table 14.13.

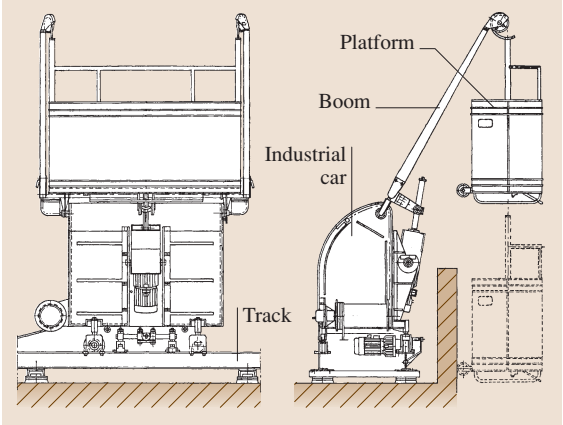

Fig. 14.87 Mobile hanging scaffold with electric drive

Stationary Sectional Hanging Scaffolds

This group includes: straight, angular, and arched hanging scaffolds, which are intended for housing and industrial construction applications, mainly facade works. Similarly to the case of the two-person scaffolds described above, the platform is suspended by steel cables from booms laid on the roof and secured with a ballast or anchored in the roof.

The scaffold consists of 3–4.5 m long 1.5 m wide segments adding up to a desired length. A schematic of the sectional hanging scaffold is shown in Fig. 14.84.

Thanks to the platform's sectional design, hanging scaffolds of different shapes (angular and arched) can be formed, as shown in Fig. 14.85.

The vertical motion of the scaffolds is effected by an electric motor, cardan shafts, and winches.

The possible ways of anchoring the booms are shown in Fig. 14.86, and the specifications of sectional hanging scaffolds are listed in Table 14.14.

Mobile Hanging Scaffolds

Mobile hanging scaffolds can be moved horizontally on an industrial car without disassembling and reassembling the booms from which they are suspended.

A typical mobile hanging scaffold design is shown in Fig. 14.87.

The vertically moving work platform is suspended by steel cables from booms mounted in a swinging mode on an industrial car. Drives for traveling on a track laid on the roof of a building and for hoisting the platform are installed on the industrial car. The scaffold can be steered from both the platform and the roof. Scaffolds of this type usually have a hoisting capacity of about 300 kg and are capable of an elevation of 100 m.

14.6 Cranes

14.6.1 Mobile Cranes

Mobile cranes are intended for lifting and lowering loads and transferring them in the horizontal plane [14.23, 32]. Mobile cranes find wide application in the assembly of steel and reinforced concrete structures, repairs and materials handling. Their advantage is their mobility, high traveling speed, and quick setup on a construction site.

As regards their undercarriage, mobile cranes are divided into:

- Truck cranes
- Terrain-wheeled cranes
- Crawler cranes

Mobile cranes are typically truck-mounted. Cranes with a maximum lifting capacity of up to 20 t are usually mounted on mass-produced truck chassis, whereas high-capacity cranes are mounted on special undercarriages. The latter may have all their wheels driven and turnable, making them highly manoeuvrable and able to move over rough terrain.

Modern hydraulically driven cranes have replaced cranes with mechanical and pneumatic steering. A modern truck crane with electrohydraulic drives and steering is shown in Fig. 14.88.

The crane's base is a frame which, depending on the crane's design and hoisting capacity (maximum 20 t), may constitute a separate subassembly mounted on a typical truck chassis or be an integral part of a special truck chassis (high-capacity cranes). Mobile cranes are usually driven by internal-combustion engines, although some terrain-wheeled cranes and their working tools are driven by hybrid combustion–electric drives. In high-capacity cranes usually two driving motors are used: one for driving the vehicle and the other (situated in the slewing body) for driving the working tools.

The crane's frame incorporates four struts, with hydraulic lifts attached to their ends, extended by two hydraulic servos. For work the struts are protracted horizontally and then the whole crane is jacked up by the hydraulic lifts to such a height that the road wheels do not touch the ground. Some cranes can operate on their road wheels.

The slewing body with the operator's cabin is connected with the chassis frame through a crown bearing. All the working fittings are mounted on the crane body. The jib consists of a stationary section and two to six protractible sections. The jib's sections are usually protracted synchronously. The winch is mounted at the origin of the telescopic jib's stationary section. A significant number of cranes are equipped with an auxiliary jib which in its working mode can be attached to the telescopic jib's head in order to increase the crane's radius. In the traveling mode the auxiliary jib is attached to the side of the permanent telescopic jib. A counterweight is mounted at the rear of the slewing body.

The principal working gears and systems of telescopic-jib cranes are:

- *A jib-protracting gear* driven by two reversible hydraulic cylinders. As a rule, the jib's members are protracted synchronously.
- *A crane radius changer* driven by a reversible hydraulic cylinder. In high-capacity cranes sometimes two hydraulic cylinders are used for this purpose. The crane radius changer typically allows one to set the jib at an angle of 0–75°.
- *A slewing gear* driven by a hydraulic engine, a planetary gear, and a crown bearing with outer meshing. The slewing gear is equipped with an automatically controlled multiple disk brake.
- *A lifting gear* consisting of cable drum winch, a cable, pulleys, and a pulley block. The cable drum is driven by a hydraulic engine and a planetary gear. As a rule, the winch's pull force is much weaker than the crane's maximum lifting capacity. Hence it is necessary to use multistrand blocks to reduce the forces in the cable.

All the working gears and the gear that extends the struts are hydraulically driven. In truck-mounted low-capacity cranes equipped with one internal-combustion engine, the hydraulic oil tank and the hydraulic pumps are mounted in the crane's undercarriage. Hydraulic oil is fed into the body's working circuits through a hydraulic rotary joint. In cranes with two internal-combustion engines, the hydraulic pumps of the crane's working circuits are driven by the engine mounted in the slewing body.

The following working motions of the crane are controlled:

- Body slewing
- Change of jib length
- Inclination of jib
- Lowering and raising of the hook
- Traversing gear motions (for terrain crawler cranes and some wheeled cranes in which traveling with a load suspended from the hook is allowable)

These working motions are typically controlled from the operator's cabin. A system of control levers, which can limit the linking of the particular working motions, ensures proper control of the latter. The recommended systems and directions of motion of the control levers are shown in Fig. 14.89.

All cranes are equipped with the following safety devices:

- *A load limiter* – usually a microprocessor unit signalling that the hook block is reaching the rated load and disabling the crane's working motions when the rated load is exceeded. A signal indicating that the hook block is approaching the rated load is activated at 0.9–1.0 of the nominal load: an orange indicator light comes on in the control panel in the operator's cabin and an audible warning is produced. Overload is signalled by a red indicator light and disabling of the working motions, except for downward motion of the lifting gear. The signalling system is activated and motions are disabled when the crane block load is in the range of 1.0–1.1 of the rated load. The load limiter should be calibrated for a given hoisting capacity characteristic. Each load limiter should be equipped with an interlock for disabling the limiter in an emergency:
- *A block upper position limit switch* – disengages the winch's drive when the block finds itself at a certain distance from the jib's head.
- *Slewing gear limit switches* – are used in cranes that cannot turnaround completely, e.g., an allowed rotation angle of 270°. These protect the crane against the situation in which the slewing column and the jib reach an out-of-specification position relative to the chassis.
- *Cable unwinding limit switch* – protects against complete unwinding of the cable from the winch drum. The limiter is actuated when there are only a few coils of cable left on the drum.
- *Emergency jib retracting and lowering system* – enables the retracting and lowering of the jib to a safe position in the case of a failure of the hydraulic system.
- *Hydraulic system protections* – enables the automatic return of the piston rods of the struts', the radius changer's, and the lifting gear's cylinders.

The basic parameters characterizing the operating properties of mobile cranes are:

- Hoisting capacity
- Radius
- Hoisting height

The values of these parameters are usually presented in the form of diagrams representing hoisting

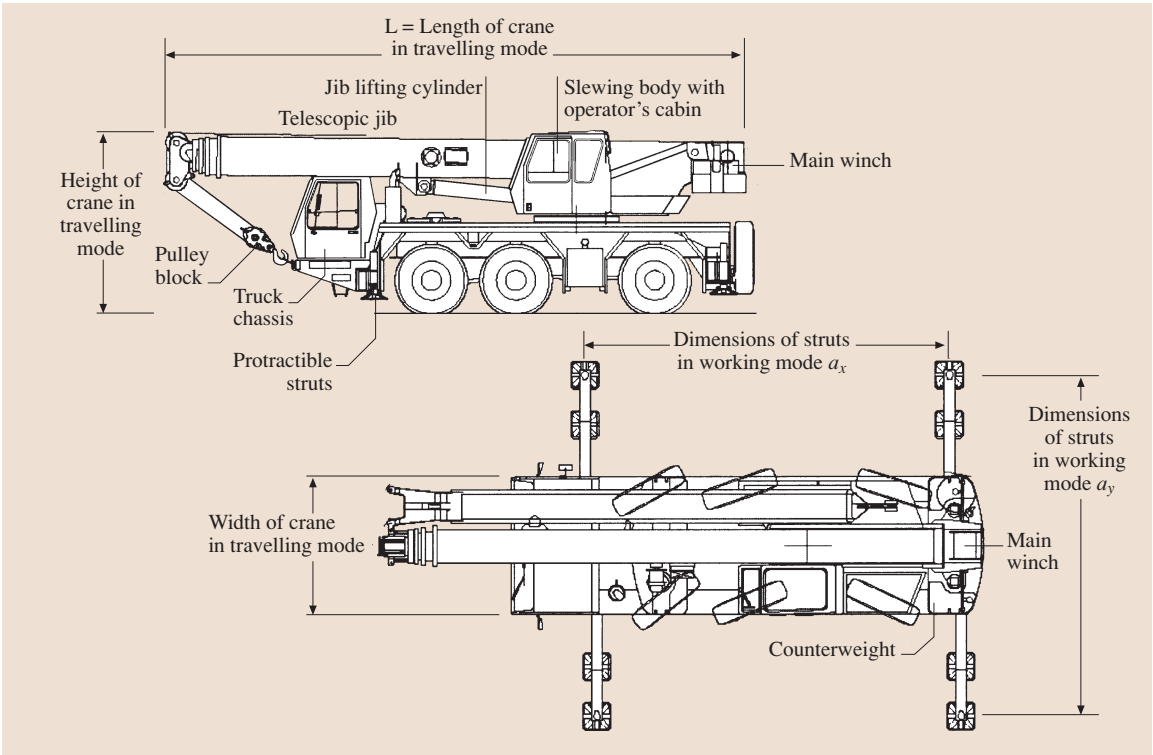

Fig. 14.88 Mobile crane mounted on a special truck chassis in traveling mode (a_x and a_y dimensions of struts in working mode)

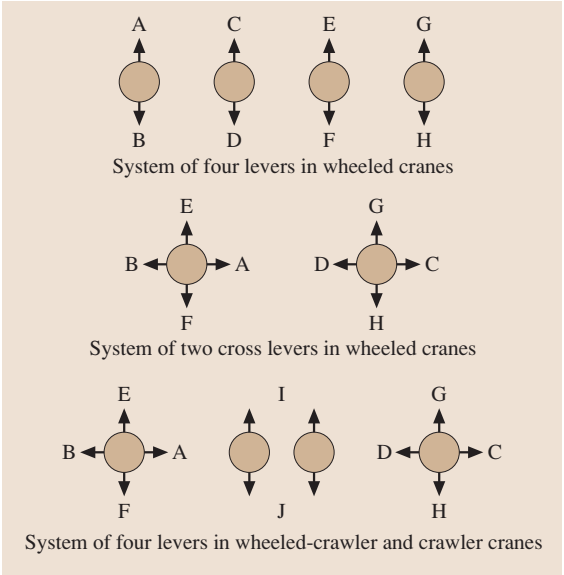

Fig. 14.89 Systems and directions of control lever motions in mobile cranes

capacity versus radius and jib length. Exemplary diagrams for truck-mounted mobile cranes are shown in Figs. 14.95–14.98.

Hoisting capacity diagrams specify calculated and experimental crane load values which take into account the crane's position stability and its structural strength.

Mobile cranes very considerably in their basic operating parameters. The hoisting capacity of currently manufactured cranes ranges from 5 to 550 t. Their basic specifications are listed in Table 14.16.

When selecting a crane for a given range of works one should consider the following:

Table 14.15 Symbols used in Fig. 14.89

A	–	turn right	G	–	lower hook
B	–	turn left	H	–	raise hook
C	–	protract jib	I	–	travel forwards
D	–	retract jib	J	–	travel backwards
E	–	increase radius	F	–	decrease radius

- The maximum hoisting capacity is given for the retracted main jib and a small radius of about 3 m and so is of little practical value. Hoisting capacity at larger radii decreases markedly.
- One should aim at operation at the smallest possible radii and hoisting heights so that a rational choice of a crane can be made and the crane's useful properties be effectively exploited. The use of large radii and hoisting heights should be technologically justified.
- One should take into account the travel of the crane to the working area and the bearing capacity of the ground on which the crane is to be set up. The bearing capacity of the ground should be appropriate for the anticipated loads acting on the struts.

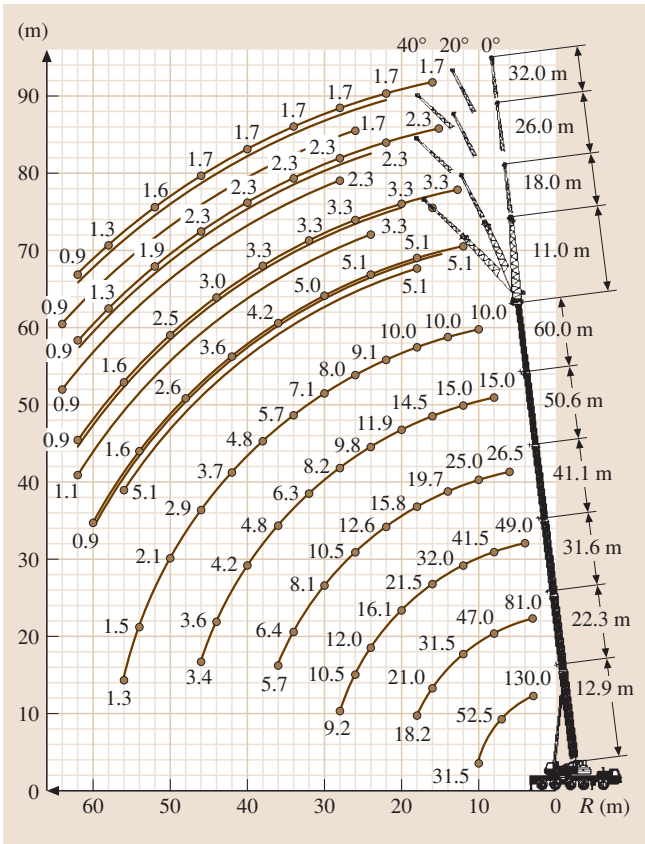

Fig. 14.91 Diagram representing hoisting capacity of crane with maximum capacity of 130 t. Note: The characteristic is determined for the main jib and the auxiliary jib. The *numbers* above the curves specify the allowable hoisting capacity for a given jib and hoisting height

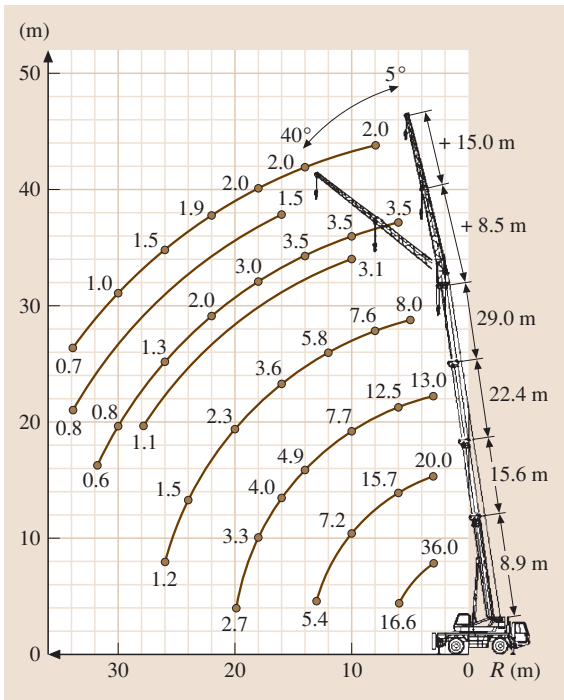

Fig. 14.90 Diagram representing hoisting capacity of crane with maximum capacity of 35 t. Note: The characteristic is determined for the main jib and the auxiliary jib. The *numbers* above the curves specify the allowable hoisting capacity for a given radius and hoisting height

14.6.2 Small Capacity Portable Cranes, Gantries, and Winches

A range of portable machines, based on winches and other accessories, for handling materials and transferring light equipment on construction sites has been developed.

This machinery includes:

- Scaffold cranes mounted on scaffolds (Fig. 14.92 items 5 and 6, and Fig. 14.95)
- Portable cranes (Fig. 14.92 item 4, and Figs. 14.96, 14.98) fixed to steel supports installed between floors, in window openings or on the roof (Fig. 14.97, basic parameters are shown in Table 14.17)
- Gantries mounted on the roof (Fig. 14.92 item 3), in an opening in the building's elevation (Fig. 14.92 item 2) or on a scaffold (Fig. 14.89 item 1)

The main component of the above machines is a universal winch that can work in tandem with various accessories.

Figure 14.92 shows the use of scaffold cranes, portable cranes, and small-capacity gantries during building erection.

Machinery of this type is intended for lifting and transferring loads of up to 200 kg to a height of 80 m. The design and technical specifications of these winches make them a highly effective means of vertical transport in construction work involving scaffolds as well as the assembly and disassembly of scaffolds.

Winches in scaffold cranes can be mounted in two ways:

- Outside the crane, to the lowest (from the ground) scaffold upright (Fig. 14.93)
- On the crane's boom (Fig. 14.92 item 5, and Fig. 14.94)

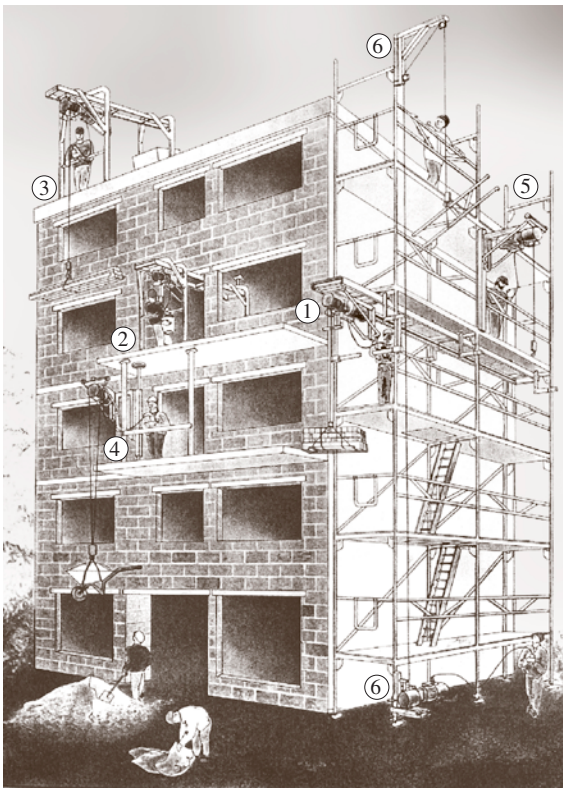

Fig. 14.92 Use of scaffold cranes, portable cranes, and small-capacity gantries during erection of building (items 1–6 are explained in the text)

In the case of winches mounted using the former method, a limit switch, functioning also as a load limiter and a block upper position switch, is incorporated into the winch's housing.

The way in which a winch is mounted onto the boom is shown in Fig. 14.94 and Fig. 14.92 item 6.

The working radius of the boom with a mounted winch can be changed by protruding the load-bearing tube. There is a series of holes in the inner tube for a blocking pin. The boom with the winch can be attached in a slewing mode to all kinds of support elements (Figs. 14.95–14.98).

The advantage of winches mountable on booms is their simple design and assembly owing to the

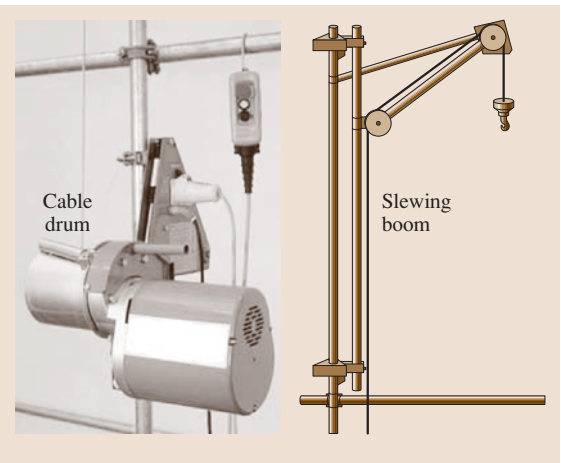

Fig. 14.93 Scaffold mountable winch

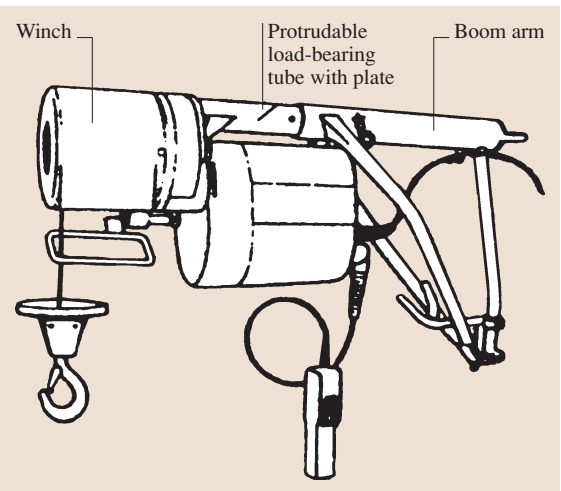

Fig. 14.94 Winch mounted on boom

Table 14.16 Specifications of selected mobile cranes with telescopic jib

Rated hoisting capacity	8	25	50	90	130	450
Minimum radius of main jib (m)	3	3	3	3	3	3
Maximum radius of main jib (m)	12	26	34	37	56	56

Dimensions in traveling mode (mm)						
• Length	9050	10 225	11 020	12 795	14 980	19 622
• Width	2500	2500	2500	3000	2750	3000
• Height	3500	3450	3480	3795	3910	3990
Spacing between struts						
a_x (mm)	4450	6325	6625	8100	7800	8760
a_y (mm)	4136	6200	6200	7000	7500	8900
Maximum traveling speed	40	75	85	79	80	85

elimination of intermediate cable pulleys. Their disadvantage is the unfavorable weight and load distribution along the boom's end, resulting in the increase in the forces needed to slew the loaded boom and in heavier loading of the load-bearing structure.

The structure of winches with a hoisting capacity of 60–200 kg, employed in portable cranes and gantries, is shown in Fig. 14.99. The characteristic feature of such winches is the use of an electric motor with a built-in brake and the integration of all the units, i. e., the electric motor, the toothed gear, the drum, and the electric control system.

The drive units of modern winches commonly incorporate:

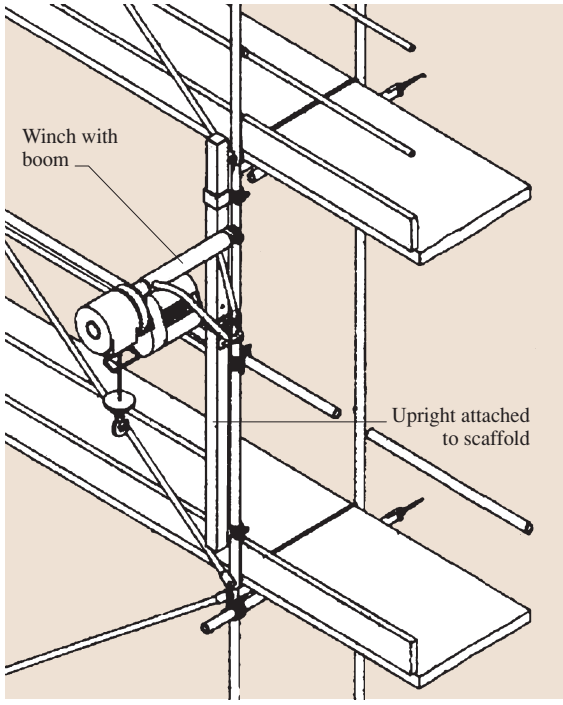

Fig. 14.95 Scaffold crane

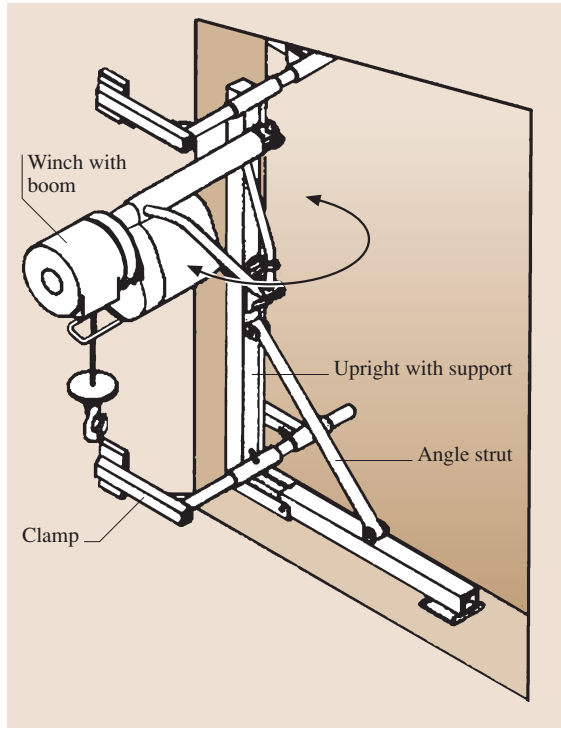

Fig. 14.96 Portable crane mounted in window opening

- Clutchless connection between the motor and the gear transmission – a gear wheel interacting with the transmission gear's toothed wheel is mounted in the rotor shaft's end.
- The cable drum is equipped with bearings internally whereby the transmission and the cable drum are compact.

Modern winches are intended for vertical transport for a wide range of construction works. Hence the range of handled construction materials is highly diverse as regards kind, shape, dimensions, and so on.

For this reason the manufacturers of light cranes offer a wide range of accessories for securing the load. Examples of accessories for handling different kinds of materials are shown in Fig. 14.100.

The use of such elements greatly increases work effectiveness and improves operational safety.

14.6.3 Tower Cranes

General Information

Tower cranes are commonly used in civil engineering for short-distance transport of loads and for erecting reinforced-concrete, steel, and masonry structures. Tower cranes owe their universality to the ease with which their structural-operating specifications (hoisting height, radius, and lifting capacity) can be adapted to the needs of construction sites. Such adaptation is possible thanks to the modular structure of tower cranes.

Tower cranes are classified according to the design of their basic units, e.g., the kind of slewing gear, the method of relocating and setting up, the jib design, and the tower design.

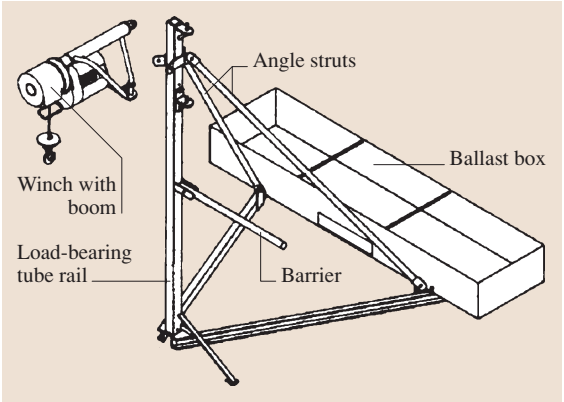

Fig. 14.97 Portable crane mounted on building's roof

Table 14.17 Technical specification of portable cranes

Lifting capacity	60–200 kg
Boom's radius (accessories)	About 1 m
Lifting height (max)	75–80 m
Lifting speed – first gear	15–20 m/min
Lifting speed – second gear	40–60 m/min
Accessories boom slewing	Manual
Power supply	230 V single-phase AC
Motor's power	0.3–1.1 kW
Control	Control panel
Drive unit mass	35–60 kg

According to the slewing gear design, two kinds of tower cranes: *high-* and *low-slewing* (with a non-slewing tower and a slewing tower) can be identified. The typical components of *high-slewing tower cranes* are: a stationary vertical tower resting on a base or a foundation anchor and a slewing part consisting of a rotary ring, a turret, a jib, and a counterjib. The typical components of *low-slewing tower cranes* are a slewing vertical tower resting on a base and a jib.

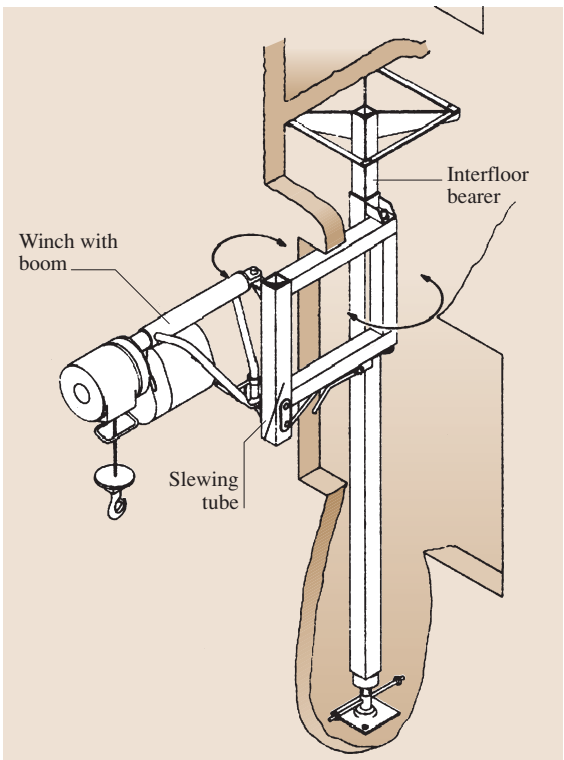

Fig. 14.98 Portable crane fixed to steel support

Each tower crane mounted on a base can be additionally equipped with a traversing gear to enable it to move on a straight or curvilinear track.

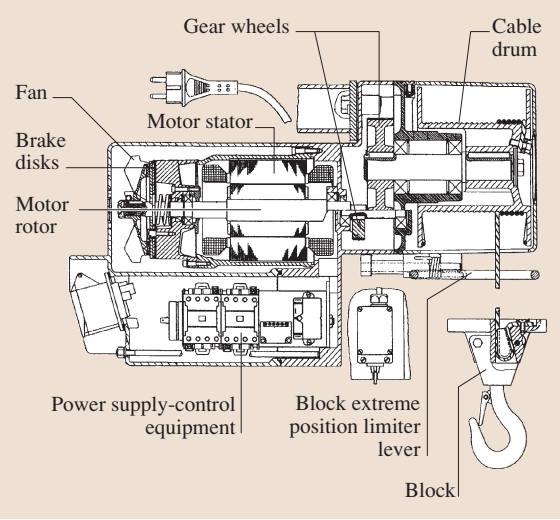

Fig. 14.99 Structure of winch used in portable and scaffold cranes and small-radius gantries

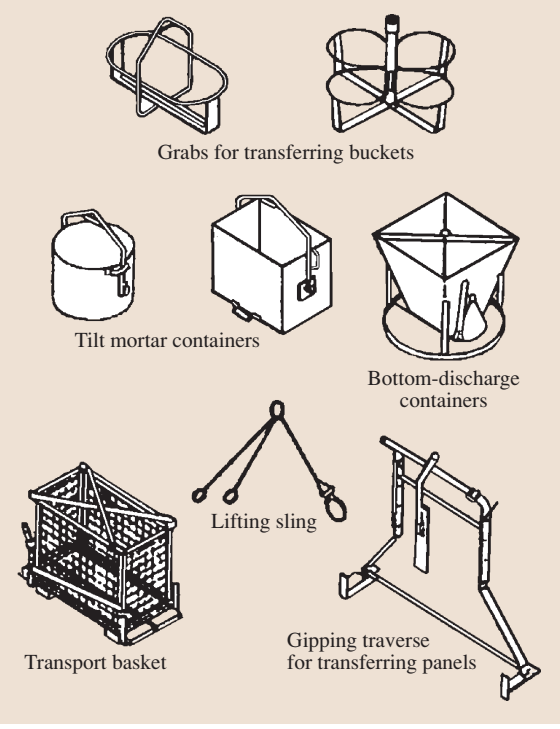

Fig. 14.100 Examples of accessories for handling materials by portable cranes, gantries, and winches

The tower and jib of modern cranes have a modular design. The tower's height and the jib's length can be adjusted by changing the number of tower or jib modules (sections). As a result, the basic operating specifications of tower cranes (hoisting height, radius, and hoisting capacity) vary greatly, not only within the particular kinds of cranes but also within a given crane model.

The main operating specifications of the most common type of cranes, i. e., *high-slewing cranes*, are as follows:

- Autonomous hoisting height: up to 100 m (at a 2.45 m × 24.5 m tower cross section)
- Maximum hoisting capacity: 50 t (4–16 t in housing construction)
- Radius: 20–80 m

Besides the above most common cranes, there are also cranes made to order, e.g., a crane with a hoisting capacity of 225 t, a radius of 80 m, and a hoisting height of 130 m. The crane is equipped with a computer system that controls the position of the jib counterweight to counterbalance the bending moments acting on the tower and it has a lift for transporting the operator to the control cabin.

The basic operating specifications of *low-slewing cranes,* as an option, are as follows:

- Maximum hoisting height: up to 50 m
- Maximum hoisting capacity: 2–8 t
- Radius: 10–50 m

Most of the currently manufactured *low-slewing trolley cranes* can operate with the jib raised at a certain angle (usually 8–30°).

A classification of tower cranes according to their design features such as:

- Movability relative to the erected building structure
- Jib design
- Tower design

is detailed in Tables 14.18–14.20.

Cranes with a horizontal trolley jib are most commonly used in construction. Cranes with inclinable jibs find many fewer applications; they are used mainly on construction sites with restrictions on the crane's work radius because of the site's location and its organizational-legal conditions (e.g., in places where charges for the area over which the crane's jib passes are levied).

Table 14.18 Classification of tower cranes according to their movability

Type of crane	Description	Sketch
Stationary crane	Mounted on foundation anchor	Floor crane (moving up with erected building structure)	Mounted on erected building structure and jacked up as successive storeys are built	Track crane (moving on track)	Mounted on base equipped with traversing gear enabling traveling on track	Mobile	Truck-mounted or wheeled, partially or fully folded during transport	
Cranes with Trolley Jib

As mentioned above, tower cranes with trolley jib are currently most commonly used on construction sites. A typical design of such a crane is shown in Fig. 14.101.

The crane's structure consists of basic units: a base, a tower, a slewing head, and a jib.

Base. Depending on the site's requirements, the crane's base can also be mounted on:

Table 14.19 Classification of tower cranes according to jib design

Type of crane	Description	Sketch
Crane with horizontal trolley jib	Jib operating in horizontal plane; radius is changed through movement of trolley along jib; jib can be attached to tower with or without tie rods. In some cranes, jib can be raised at angle of 8–30°	Crane with inclinable jib (without trolley)	Jib can be inclined in vertical plane; radius is changed through inclination of jib	
Table 14.20 Classification of cranes according to tower design

Name of crane	Description
High-slewing tower cranes (cranes with nonslewing tower)	Crane's tower does not slew. Jib can slew thanks to slewing towerhead connected with tower via rim bearing
Low-slewing tower cranes (cranes with slewing tower)	Crane's tower slews. Tower is connected to crane's base via rim bearing

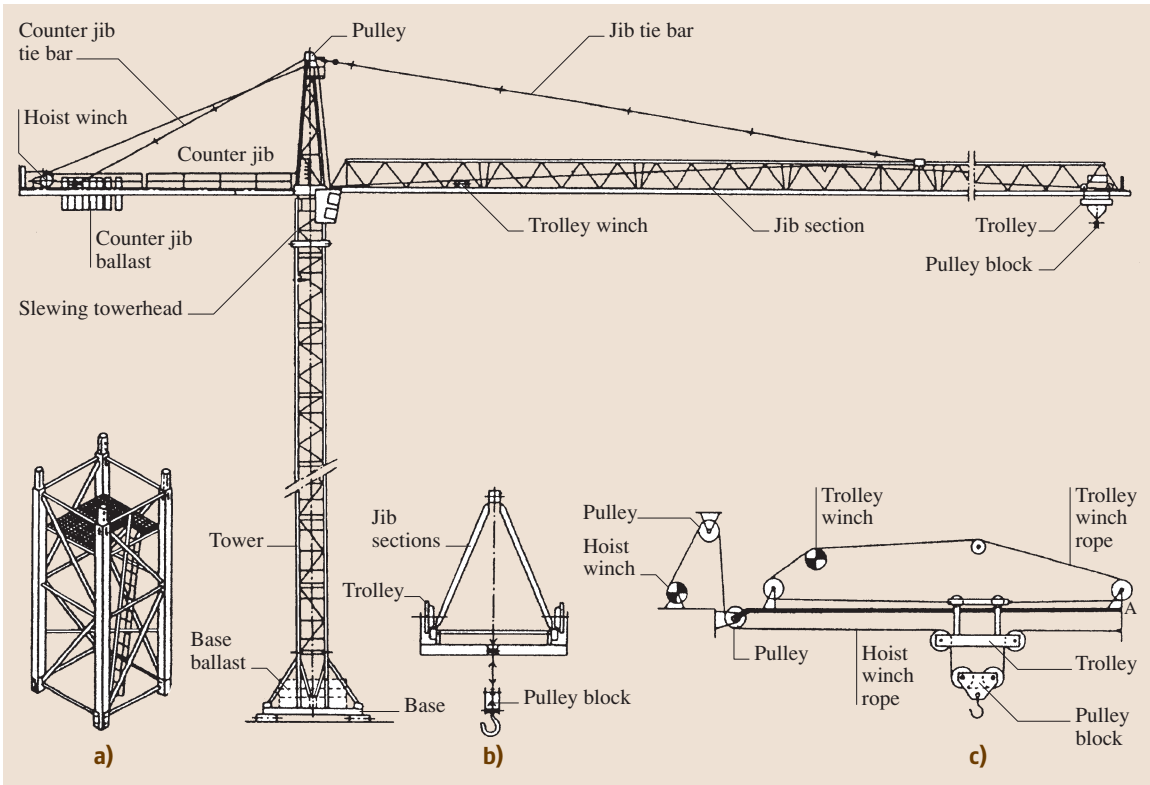

Fig. 14.101a–c Tower crane with trolley jib – main parts. **(a)** Tower's section. **(b)** Jib and trolley's cross section. **(c)** Kinematic diagram of trolley and pulley block winch hoist drive

- Supports provided with foundation plates (Fig. 14.102a)
- Trucks traveling on a rail-track (Fig. 14.102b)
- Supports on a concrete foundation (Fig. 14.102c)
- Feet embedded in foundation concrete (Fig.14.102d)

In most modern high-slewing cranes, the tower can be also mounted directly on the building structure being erected and goes up with it. For the assembly and disassembly of cranes three special frames are used. The tower is fixed by means of two frames to the erected building structure's members (usually a floor) (Fig. 14.103). A third frame is used to jack the crane up to a higher storey.

The *tower* is a metal structure usually in the form of a space truss with columns open or closed in cross section. The tower functions as a support for the jib which can be mounted on it at the appropriate height. In cranes with a nonslewing tower, a head is attached, via a rim bearing, to the tower's top. The tower is made as a welded construction or from sections joined by fasteners. Typically, 2.8–6 m-high (for the telescopic self-erecting model) sections square in their cross section or 6–12 m-high (for a crane set up using a truck crane) ones are used. The sections are fastened together with bolts or pins. In high-slewing cranes, a slewing head is mounted onto the stationary tower's top and a jib and a counterjib (with its ballast) are attached to it. The slewing head assembly usually incorporates a slewing gear drive.

In most cranes, the height of the tower can be increased without it being necessary to partially disassemble the crane. This is done using a telescopic cage by means of which the crane can be raised and additional tower sections can be inserted.

The *jib* is a space framework fixed to the tower (slewing-tower cranes) or a slewing towerhead (nonslewing tower cranes), making it possible to obtain a proper radius through the shift of the trolley. Jibs usually consist of several sections to facilitate their transport and assembly. The trolley moves on the jib's bottom flanges (Fig. 14.101b).

Pulley block hoisting gear. A hoist winch rope (Fig. 14.101c) passes from the hoist drum (Fig. 14.101c) via two pulleys (Fig. 14.101c) attached to the tower and then along the jib (Fig. 14.101) through the trolley (Fig. 14.101c) and the pulley block (Fig. 14.101c) to a securing point (Fig. 14.101c) at the jib's tip. As the rope winds on (unwinds from) the hoist drum, the pulley block is raised or lowered.

Trolley traversing gear. The trolley is shifted along the jib by a closed rope system (Fig. 14.101c) driven by a hoist winch (Fig. 14.101c).

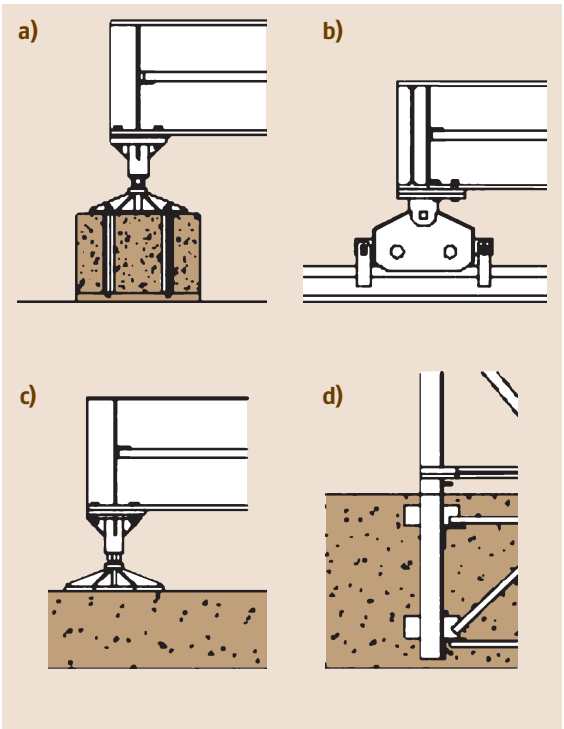

Fig. 14.102a–d Alternative ways of mounting tower crane with trolley jib **(a)** on supports provided with foundation plates; **(b)** on rail trucks (mobile version); **(c)** on supports and foundation plate; **(d)** on feet embedded in foundation concrete

Legend:
A – base mounted on feet
B – base with suspension system enabling traveling on rail-track
C – tower mounted directly on feet embedded in foundation concrete
D – mounted on building structure under construction and jacked up as successive storeys are erected

A hoisting speed proper for the hoisting capacity is selected by a remote-controlled gear switch. The speed can be as high as 125 m/min. The maximum trolley traversing speed is 80 m/min. The pulley block hoisting gear and the trolley traversing gear are driven by squirrel-cage motors or slip-ring motors equipped with electromagnetic brakes. Hydrostatic drives or electric motors with controlled speed are also used.

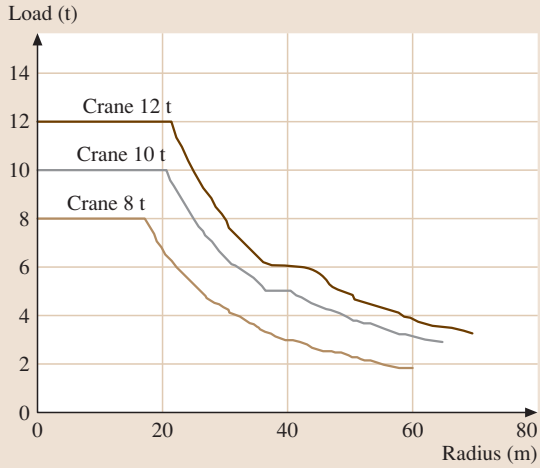

Fig. 14.104 Load–radius curves for 8 t, 10 t, and 12 t cranes

The crane's work motions are controlled from the operator's cabin using the controllers installed there, or they are radio-controlled. The operator's cabin can be equipped with a hoisting gear by means of which it can be hoisted to the appropriate height.

In the case of track-mounted (mobile) cranes, trackways made from traffic rails, (wooden or concrete) sleepers, ties, and stops, laid on a subgrade, are used. The track can be laid on a soil subgrade or a structural subgrade (a support structure, a building floor, a hard road surface). Usually railway rails are used for the tracks. The rails should be fixed to sleepers laid on a subgrade. The tracks should have protective groundings and lightning conductors. The tracks are equipped with the following protections:

- *Stationary and movable bumping blocks*: Stationary bumping blocks are usually situated at a distance of 1.5 m from the end of the track rails and movable bumping blocks at a distance of 1.2–1.5 m from the stationary ones.
- *Travel stops*: Devices switching off the crane's traversing gear when the gear's tripper runs into

a cam. Cams are mounted at the end of the crane track before the movable bumping blocks. The cams are positioned in parallel to the track so that the lever of the traversing gear tripper mounted on the crane's carriage can run into them.

After work, mobile cranes are secured to the trackway by means of clamps (fastening the carriage to the rails) preventing wind pressure from shifting the crane from its work position.

Tower cranes are equipped with the following protections:

- *Hoisting capacity limiter*: A device protecting the crane from lifting too heavy a load for a given radius. The protection acts in two stages. The reaching of the nominal hoisting capacity or moment is signalled acoustically and visually starting at 90% of the nominal values. The loading of the crane with a load amounting to 100–115% of the nominal hoisting capacity or with a moment amounting to 100–125% of the nominal moment results in the shut down of all the drives of all the gears except for the hoisting gear's lowering function. Each load limiter should have an interlock so that it can be switched off in an emergency situation.
- *Moment limiter*: Functions similarly to the hoisting capacity limiter.
- *Pulley block top hoisting position tripper*: Shuts down the hoisting winch's drive when the pulley block comes very close to the jib's trolley.
- *Rope unwinding tripper*: Prevents the rope from unwinding completely from the hoisting drum. The tripper is activated when only a few coils of rope are left on the drum.
- *Trolley extreme position tripper*: Stopping the traversing of the trolley in one direction in its extreme positions.
- *Slewing tripper*: Stops the slewing motion of the crane when the crane's angle of rotation in one direction exceeds 1.5 turn (540°) to prevent the machine's feeder cables and control cables from being damaged (this applies to cranes without a rotary joint enabling unlimited slewing).

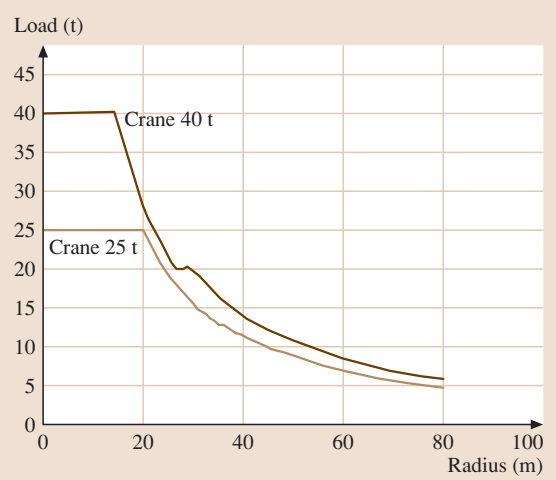

Fig. 14.105 Load–radius curves for 25 t and 40 t cranes

Since there is a wide range of tower cranes with a horizontal trolley jib, one can select the crane best suited to the construction site's conditions. It is common practice that several tower cranes with different hoisting elevations and capacities are so arranged around the structure under construction that they are complementary to one another. In such cases, particularly when the cranes' work areas overlap, it is extremely important that their simultaneous work is properly synchronized.

The basic structural-operating specifications of 8–40 t hoisting capacity cranes are shown in Table 14.21. For small radii the parameter which lim-

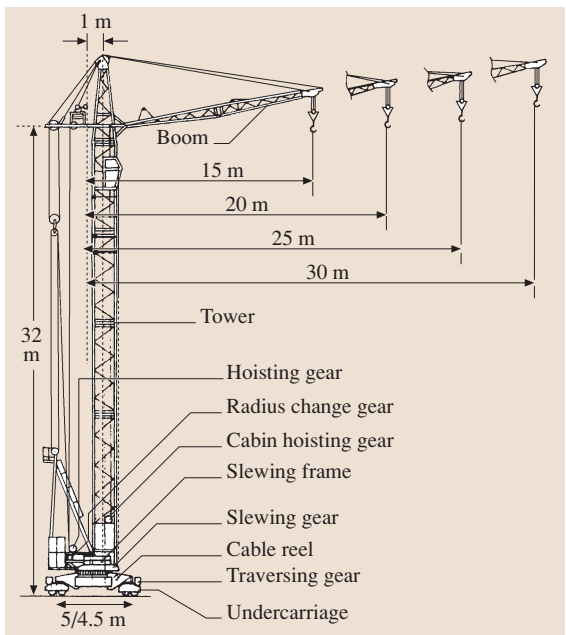

Fig. 14.106 Track tower crane with 10 t hoisting capacity with luffing boom

its the hoisting capacity of a tower crane is the strength of the load-bearing structure, while for larger radii the decisive parameter is the crane's stability. The crane's hoisting capacity characteristics specify the safe load values, calculated and experimentally determined taking into account the crane structure's stability and strength.

The load–radius curves for 8–40 t cranes are shown in Figs. 14.104 and 14.105.

Cranes with Luffing Boom

The structure of tower cranes with a luffing boom is described below using as an example a 10 t hoisting capacity track crane with a slewing tower (Fig. 14.106).

The crane's undercarriage consists of a welded box frame and cantilevers for mounting rail trucks. The undercarriage enables travel on straight and arched tracks. A rotary ring is attached to the undercarriage frame. A slewing frame with a hoisting gear, a radius changer, a slewing gear, and concrete ballast plates is mounted on the ring. The crane's tower and an installation cantilever are fixed to the slewing frame. The tower consists of segments, usually made from angle bars or steel pipes. An operator's cabin is attached to the tower, to which access is provided by a ladder secured to the tower. The crane's boom and a guy rope are attached to the tower's top segment. The boom is a welded lattice structure, quadrangular or triangular in cross section, made from high-strength steel sections. The boom consists of several sections (typically three ones) joined together by bolts. Cable pulleys, a hoisting gear tripper, and an overload tripper are mounted on the boom tip.

The crane's particular working motions are executed by the hoisting gear, the radius change gear, the tower slewing gear, and the traversing gear.

The hoisting gear consists of a motor, a coupling, a brake disk, a reduction gear, and a cable reel. Hoisting speed is changed by means of the reduction gear ratio lever. An additional drum for installing concrete counterbalance elements, is mounted on the hoisting gear's shaft.

The radius change gear consists of a hoisting winch and rigging. Drive is transmitted from the winch's motor via the flexible coupling working together with the brake and a thrustor to the reduction gear and the cable reel. The radius change reduction gear incorporates an additional friction–pawl brake. The cable system includes a stationary pulley block, a running pulley block, and guy-ropes. The slewing gear is secured to the slewing frame's front part. Drive is transmitted from the motor through the coupling with a brake disk and via a toothed gear to the rim bearing.

The traversing gear is made up of four rail trucks with double wheels, secured to the undercarriage's cantilevers. Drive from the motors is transmitted via couplings with brake disks, a reduction gear box, and an open-toothed gear to the wheels.

Similarly to cranes with a trolley jib, tower cranes with a luffing boom have the following protection devices:

- Load limiter
- Pulley block top hoisting position tripper
- Rope unwinding trippers
- Traversing limiters

The crane's working motions are controlled from the operator's cabin.

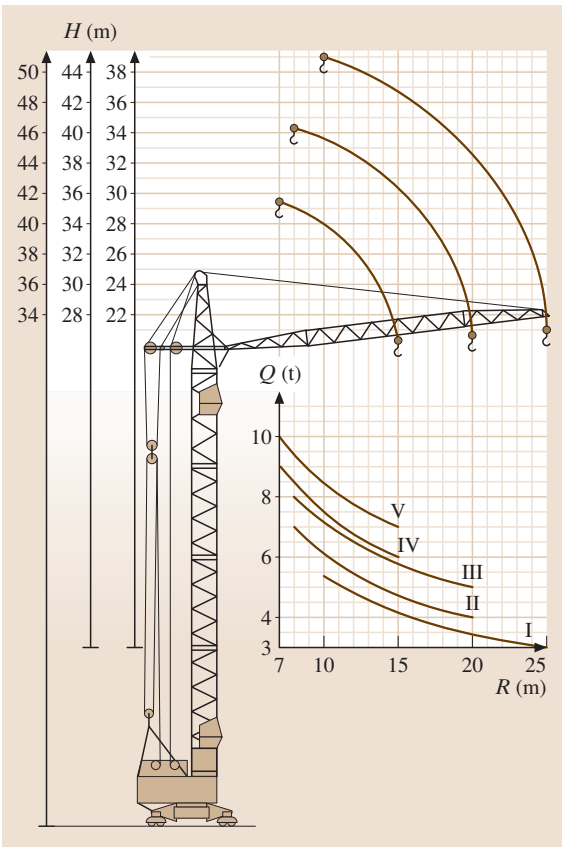

Fig. 14.107 Hoisting capacity as a function of radius and hoisting height for a 10 t-capacity crane with luffing boom

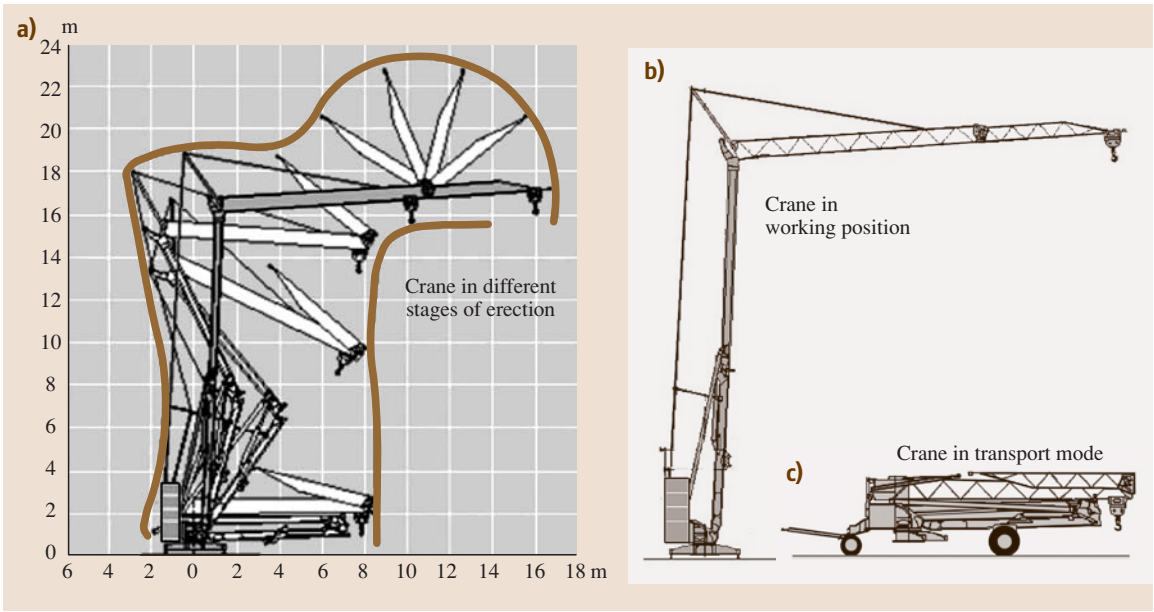

Fig. 14.108a–c Preparation of self-erecting crane for work: **(a)** crane in transport mode; **(b)** crane in different stages of erection; **(c)** crane in working position

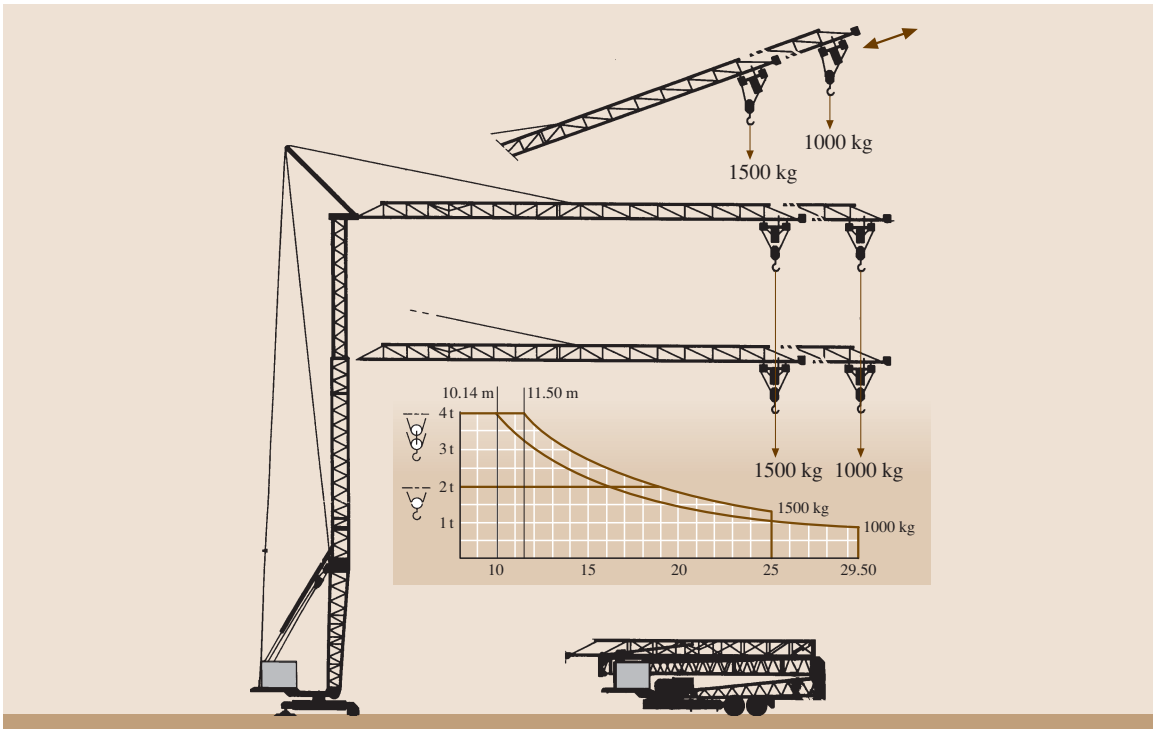

Fig. 14.109 Hoisting capacity versus radius for quick-assembling tower crane

A sample hoisting capacity–radius characteristic of a crane with a luffing boom is shown in Fig. 14.107.

Quick-Assembling (Self-Erecting) Cranes. Quick-assembling cranes form a separate class of tower cranes. Their characteristic feature is that they can be quickly assembled on a setup site. They do not require any other truck crane to be assembled, provided that the construction site has been properly prepared. The access road should be prepared such that the tractor towing the crane can reach the setup site and the latter should be practically at the same level as the access road. The setup site should be large enough for the vehicle with the ballasts to drive up close enough and for the crane to self-ballast (by means of its small auxiliary crane) and unfold. The crane is set up through the unfolding of the articulated mast and jib segments by its own drive units. During assembly the parts are connected by articulation but, once positioned, they are successively immobilized, forming a fixed load-bearing structure. The way in which self-assembling cranes are erected is illustrated in Fig. 14.108b, which shows four stages of assembly. Once the crane is properly set up, the jib's tip section is raised slightly. Then, using the crane's driving gears, its tower is put in a vertical position. Finally, the jib is completely unfolded.

Quick-erecting cranes are equipped with a trolley jib. They have a slewing tower which is secured to the base through a rim bearing.

An exemplary *hoisting capacity–radius* characteristic of a quick-erecting crane is shown in Fig. 14.109.

14.7 Equipment for Finishing Work

The aim of finishing work is to invest a structure with the design features and external and internal appearance. Finishing work includes:

- Roofing
- Outdoor (elevation) and indoor plastering
- Facing work
- Flooring
- Painting

The development of equipment for finishing work has been associated with the mechanization of the most labor-intensive and arduous activities. The first machines for finishing work were mortar pumps, followed by wood floor scrapers, parquet sanders, and mineral floor grinders. Later mechanical painting was introduced. Finishing work is carried out mainly on the construction site but efforts are made to move it to back-up facilities and transport ready-made elements to the site in order to increase work effectiveness. The range of finishing work is very wide in terms of both execution techniques and materials. The most commonly used equipment for finishing work is presented below.

14.7.1 Equipment for Roofwork

From the materials point of view the roofing used today can be divided into:

- Tar paper roofing mainly made from thermoweldable membrane
- Ceramic and stoneware tile roofing
- Bituminous shingle roofing
- Metal (zinc- and acrylic-coated steel sheet, rust-proof sheet, zinc sheet, titanium–zinc sheet, copper sheet, and other) roofing
- Polyvinyl chloride (PVC) panel and ethylene propylene diene monomer (EPDM) membrane roofing

Most roofwork is done using hand tools. For making *thermoweldable membrane roofing* devices equipped with liquefied petroleum gas (LPG) burners are used. There are two methods of making insulating coatings from thermoweldable membrane:

1. By means of a roofing machine and
2. Using only a set of burners

A roofing machine consists of the following units: a tar paper spreader, a battery of burners, a flexible gas hose, and an LPG cylinder. The burners' flames melt the layer of pitch on the tar paper and at the same time heat up the base. Under these conditions the tar paper is pressed against the base by a roller made of segments to ensure that the tar paper is pressed down along the entire width of the roll. On contact with the base the pitch cools quickly, forming a layer that bonds the tar paper to the base.

The set of burners includes a six-burner battery as well as a double burner and a single burner. The six-burner battery is secured to a steel frame equipped with two wheels. The single burner and the double burner are

used to lay tar paper strips that are narrower than the roll and in not easily accessible places.

All burner models are offered with a *sustaining flame* option, improving work safety. In recent years special burners for lap welding have been introduced.

Ceramic tile or bituminous shingle roofing is laid by hand.

Metal sheet roofing is hand-made from prepared elements. For the preparation of metal sheet roofing elements hand tools (shears, bending machines), or in the case of large-sized roofing work power-driven tools, are used. In the latter case, metal sheet is guillotined to the appropriate dimensions and formed using bending-flanging machines (Fig. 14.110). Roofing elements properly prepared in the site yard are transported to the construction site and built in.

Sometimes roofing is preceded by the laying of insulation materials. Insulation materials 20–27 mm thick are secured to concrete or steel bases by means of special nails and plastic elements (flanged bushes) driven in using cartridge-charged fixing tools. Nails and cartridge-charged fixing tools can also be used to secure PVC, EPDM, bituminous, and profile metal sheet roofing to bases.

14.7.2 Equipment for Plaster Work

Plastering machines are used for preparing, feeding, and rendering all kinds of plaster on the walls and ceilings of erected structures.

All of these activities can be performed by one machine, the so-called plastering unit, or a set of individual machines, consisting of a mixer, a mortar pump, distribution hoses, and a spraying nozzle. Hence in the machinery used for plaster work one can identify the following groups of equipment:

- Equipment for transporting prefabricated dry mortar from a silo to a plastering unit
- Mortar and plaster mix mixers
- Mortar and plaster mix pumps
- Plastering units

Equipment for transporting dry mortar from a silo to a plastering unit (Figs. 14.111 and 14.112) can be used to transport dry mortars with a bulk density of 0.5–2.0 Mg/m^3. The maximum distance over which the material can be fed is usually 200 m and depends on the compressor's capacity, the material's properties, and the lie of the transport conduits. The equipment operates as follows (Fig. 14.111): when the plastering unit's reservoir fill-up signalling system signals that there is no mortar, the silo closing valve opens and the pressure vessel fills up. Once it is filled, the valve closes and the compressor starts blowing compressed air through the aeration fabric into the vessel. Liquefied mortar is pumped through a hose from the vessel to the plastering

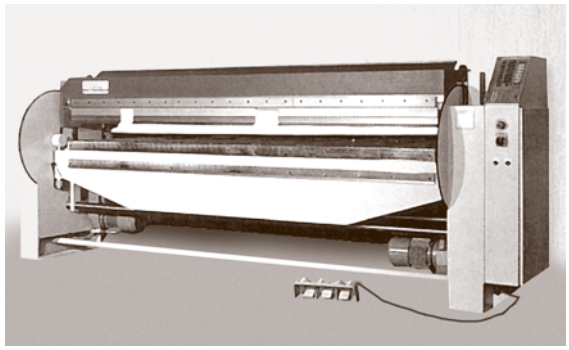

Fig. 14.110 Bending–flanging machine with roofing metal sheet profile programming

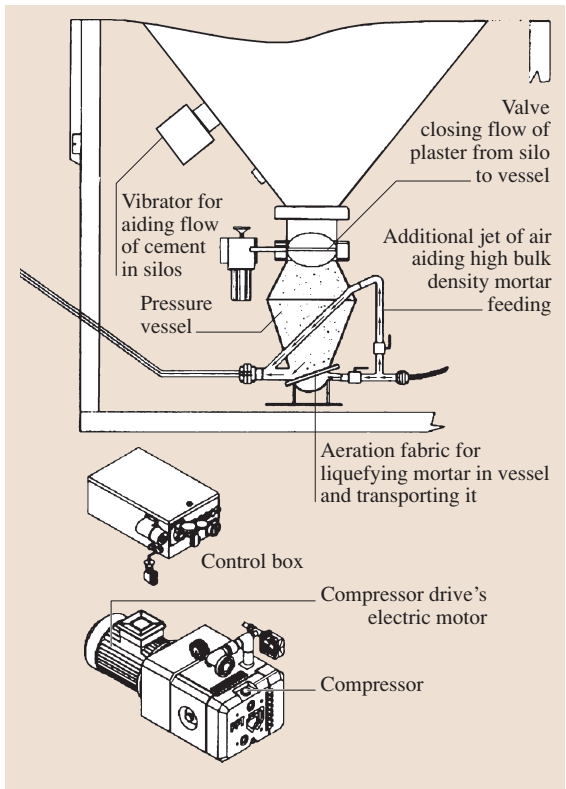

Fig. 14.111 Equipment for transporting dry mortar from silo to plastering unit

unit. If mortar with a high bulk density is to be pumped, the valve should be opened in order to aid the flow of mortar with an additional jet of air.

Portable equipment for transporting dry mortar, working in tandem with a plastering unit, is shown in Fig. 14.112. Besides a vibrator, an aeration unit is introduced in order to ensure proper flow of cement from the silo to the reservoir. The cement in the reservoir is liquefied by means of blow-in nozzles. The plastering unit's mortar reservoir is equipped with a lid with a fill-up signalling gauge and an air filter.

Dry mortar feeding systems can be made as mobile (equipped with a driving axle) or portable.

Mixers for Mortars and Plaster Mixes

Mixers for mortars and plaster mixes form a highly diverse class of plastering machines in terms of their size and principle of operation. The following kinds of machines are distinguished:

- Electrically driven, hand-operated mixers
- Continuous-type mixers
- Batch-type mixers

The machines are used for preparing masonry mortars, plasters, self-leveling mixtures, and so on.

Electrically driven, hand-operated mixers work by one or two electrically driven agitators that are manually introduced into a container to mix the contents.

Continuous-type mixers can be equipped with an open hopper (Fig. 14.113) or a dry mortar bin working with a dry mortar transport system (Fig. 14.112).

A diagram of a continuous-type mixer is shown in Fig. 14.113. In this mixer dry components are fed into the hopper and transferred by raking-out paddles and the feeding screw into the mixing unit, where water is added. The rate of flow of water into the mixer is controlled by a valve and a flowmeter.

Batch-type mixers perform the same function as continuous-type mixers, except that their operation is periodical and consists of the charging of components, their mixing, and discharging in succession. Their design is similar to that of concrete mixers. Pan-type mixers and paddle mixers are used. The most popular among the pan-type mixers are turbo mixers, planetary mixers, and turbo-planetary mixers. Among paddle mixers the most popular are mixers with a single helical agitator. Paddle mixers are discharged by tilting them or by opening a segment of the bottom.

It should be mentioned that also rotor mixers can be used to prepare gypsum mortars and mortars containing plastics. The components are mixed by setting them in rotary motion by means of a rotor.

Most mixers, both continuous and batch type, can work in tandem with mortar pumps.

Mortar pumps, when equipped with a mixer and a spraying gun, function as plastering units. The first mortar pumps were membrane pumps. Their maximum mortar pumping pressure was limited by the strength of

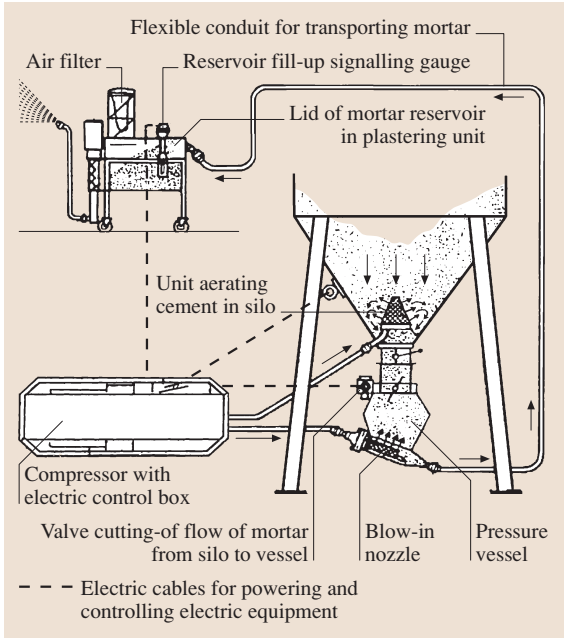

Fig. 14.112 Plastering unit working in tandem with equipment for transporting dry mortar

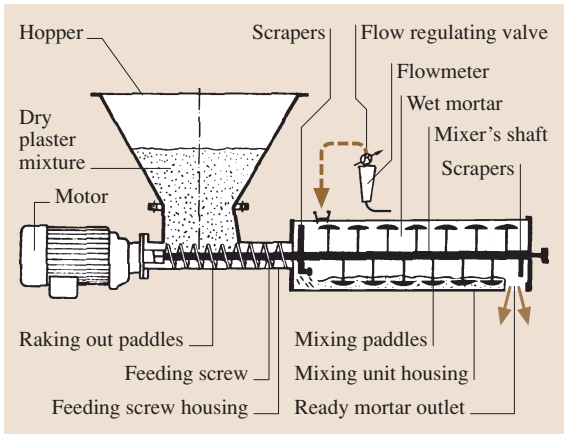

Fig. 14.113 Continuous-type mortar mixer with open hopper

the rubber membranes. As a result, the pump's lift was limited to about 20 m under average conditions. The desire to extend the reach of plastering and the required mortar forcing pressure has led to the development of piston pumps. The piston pumps currently produced by leading manufacturers can pump even heavy mortars to an elevation of 100 m at a forcing pressure of 6.0 MPa. The plaster feeding distances achieved depend on the forcing pressure, the mortar's composition, and the delivery rate. The delivery rate of piston pumps does not usually exceed 3.0 m^3/h.

A mortar pump design is shown in Fig. 14.114. The pump works such that, as the piston moves to the right, mortar is sucked through the suction valve into the working chamber. As the piston moves to the left the pressure of the mortar closes the suction valve and opens pressure valve. As the piston moves again to the right, mortar is sucked in again while the mortar on the piston's right side is forced into a pipeline. The pump makes it possible to minimize pressure fluctuations and therefore to maintain constant mortar spraying parameters and increase the fatigue strength of the mortar pipeline's flexible hoses. The travel of the pistons occurs as a result of the rotation of the cam pushing the roller during, respectively, the delivery stroke and the suction stroke.

The operation of a popular two-piston mortar pump with a cam drive is illustrated in Fig. 14.115. The function of the compensating piston is to equalize the mortar forcing pressure during the suction stroke of working piston. The suction stroke of the working piston is aided by a spring and the return stroke of the compensating piston results from the mortar pressure.

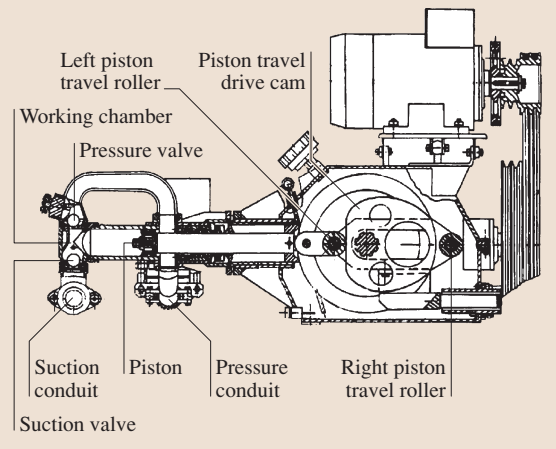

Fig. 14.114 Mortar pump with bilateral action piston

Besides piston pumps, screw pumps form another class of pumps. They are used for applying thin finishing coats of gypsum mortars, lime–gypsum mortars, and mortars with plastics. In recent years they have also been used for conventional mortars, competing with piston pumps. The principle of operation of the screw pump (Fig. 14.116) is to force mortar in the closed spaces between the helical surfaces of the rotor and sta-

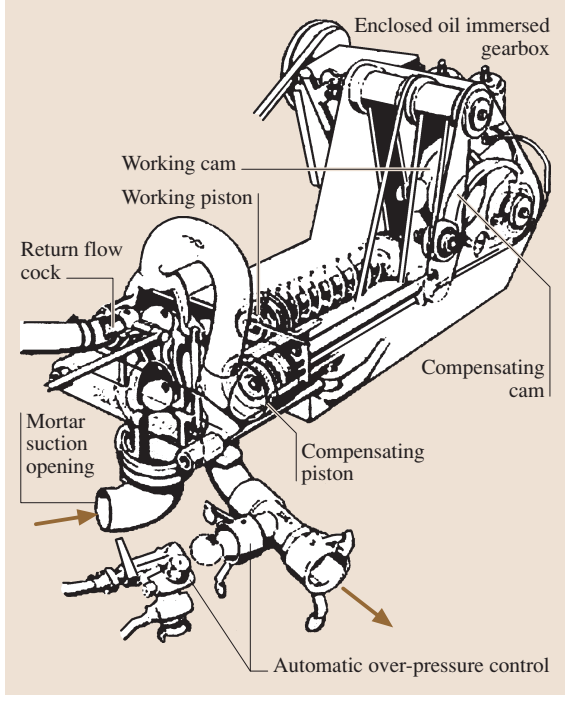

Fig. 14.115 Diagram of two-piston mortar pump with mechanical cam drive for the pistons

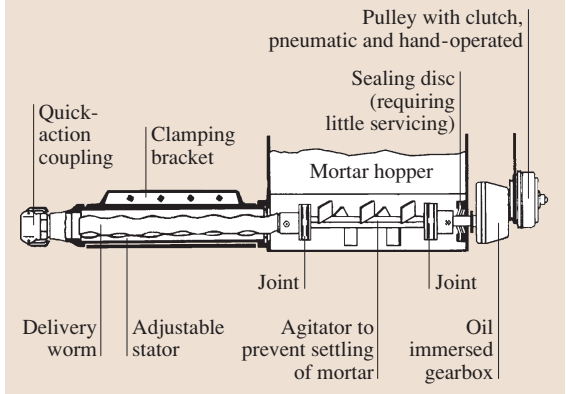

Fig. 14.116 Worm pump with adjustable stator

tor. The pump's stator is made of rubber that is resistant to compression and chemically aggressive liquids. The screw pump's efficiency decreases with operating time as a result of abrasive wear of the rotor and the stator. As the delivery of the pump decreases so does the forcing pressure. For the pump shown in Fig. 14.116 a decrease in pump delivery is counteracted by compensating the clearance between the rotor and the stator by means of a clamping bracket. Mortar is fed into the screw pump usually from the mortar hopper equipped with an agitator, which prevents the settlement of solid particles and the segregation of the material.

Plastering units are machines that mechanize the preparation and rendering of mortar. In the case of conventional cement–lime mortars, a plastering unit performs the functions:

- Charging of mortar components
- Mixing
- Straining
- Transport to rendering site
- Rendering on walls and ceilings

The introduction of plaster-like mixes and putties limited the activities connected with the preparation of mortar to only its transport or to mixing a dry mixture with water.

Depending on the plasters being made, plastering units can be divided into three classes that differ in their structural aspects:

- Plastering units for traditional lime and cement–lime mortars
- Plastering units for gypsum mortar
- Plastering units for plaster-like coats (PVC mortars)

A plastering unit for making traditional plasters from lime, cement–lime, and cement mortars is shown in Fig. 14.117.

In some plastering units, similarly to in concrete mixers, charging buckets are used in order to facilitate the loading of the components into the mixers. Plastering units are equipped with a remote control system for controlling the operation of the pump. If the spraying gun's air valve is closed, the pump's drive is automatically switched off and mortar feeding stops. The opening of the air valve results in the switching on of the pump's drive. As dry plaster mixes have become increasingly popular, plastering units for traditional mortars increasingly often feature screw pumps besides piston pumps.

A plastering unit for feeding and rendering mortars from ready-made dry plaster mixes is shown in Fig. 14.118. After refitting the pump and changing the mortar feeding hose, the plastering unit can also be used for self-leveling floor compounds.

A characteristic feature of the plastering unit shown in Fig. 14.118 is the reduced size of the mixer, whose function is performed by a mixing chamber with an agitator in the form of helical segments.

The rate of delivery of plastering units for traditional mortars is usually up to 3 m^3/h.

For feeding traditional plaster mortars, hoses that are 52–58 mm in diameter with tip elements 32–36 mm in diameter are usually used. For feeding and spraying special media, pressure hoses with increased strength are used.

Plastering units for traditional mortars can be adapted for spraying mixes to protect steel structures against fire, self-leveling mixtures, and similar materials.

Plastering units for gypsum mortars perform the functions of feeding, mixing, pumping, and pneumatic spraying of mortar onto a surface to be plastered. Their design is very similar to that of plastering units for dry plaster mixes. The structure of a plastering unit for gypsum mortars is shown in Fig. 14.119.

The mortar mixing chamber can operate in two positions: vertical and inclined. A vertical mixing chamber position is used for spraying ready-made gypsum plaster mixes. If the mixing chamber is inclined, a stroke pump can be used. For mounting and dismounting of the pump the mixing chamber is placed in a horizontal position.

A characteristic feature of plastering units for gypsum mortars is the common drive for the agitator and the pump, located in series.

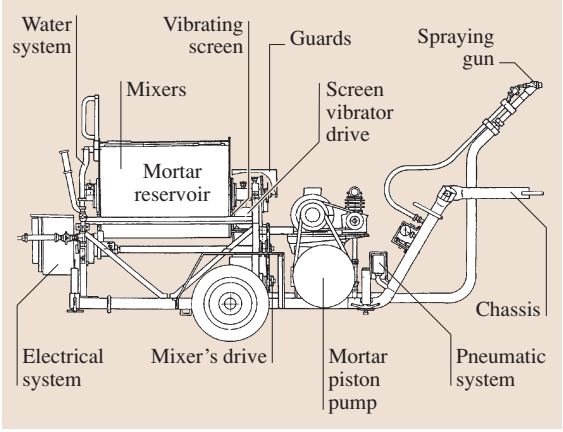

Fig. 14.117 Plastering unit for conventional plasters

In modern plastering units mainly screw pumps are used because of the following advantages:

- Pressure stability (practically no pressure fluctuations)
- Rate of flow can be adjusted by:
  - Changing the speed of rotation of the screw pump's rotor by controlling the speed of the driving motor
  - Adjusting the clamping pressure of the metal mantle on the stator (if the pump has such an option)

The rate of delivery can also be changed by replacing the pump with a unit with the desired flow rate.

Another useful feature of the screw pump is the possibility of changing the direction of flow by reverse pump rotation in the case of blockage of the pressure hose.

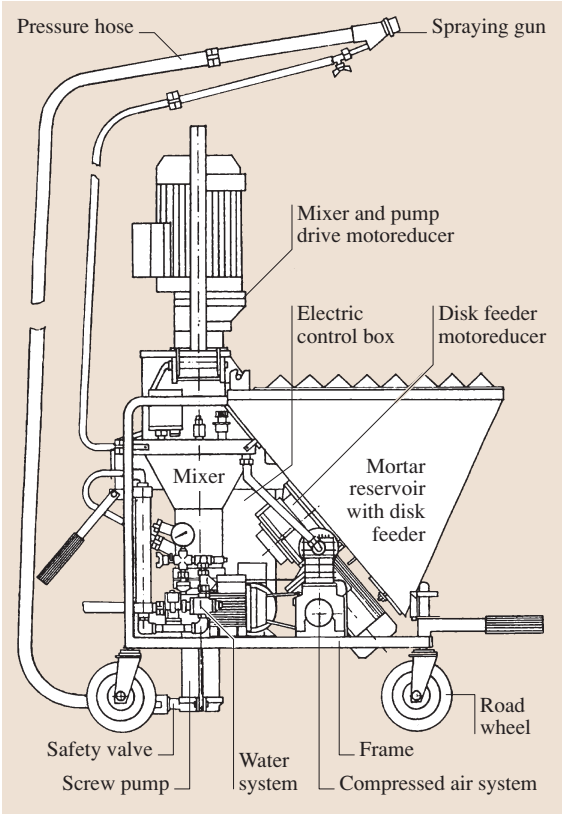

Fig. 14.118 Plastering unit for preparing and rendering mortars made from ready-made dry plaster mixes

The gypsum mortar flowing out of the spraying gun is torn apart by an axially introduced jet of compressed air and ejected from the nozzle at an accelerated speed. This ensures better adhesion of the rendered layer to the base. The shape of the jet can be modeled by adjusting the depth of insertion the compressed air nozzle into the spraying gun and by attaching spray-gun tips with different outlet diameters. Hoses with an inside diameter of 25 mm (sometimes 19 and 32–36 mm) are usually used for feeding gypsum mortars.

Electric motors with a power of about 5 kW are used to drive plastering units for gypsum mortars. They make it possible to feed mortar for a distance of 20–40 m at a working pressure of up to 4.0 MPa.

Plastering units for plaster-like coats (mortars containing plastics) are compact devices weighing a few tens of kilograms. They mix, pump, and render thin plaster coating mortars, adhesives, paints with fillers, dense insulating fluids, gypsum mortars, and so on.

The structure of a plastering unit for plaster-like coats is shown in Fig. 14.120. The reservoir can be charged with dry mortar, adding water subsequently, or with a mortar–water mixture. In order to ensure easy access for the spraying gun (particularly in window

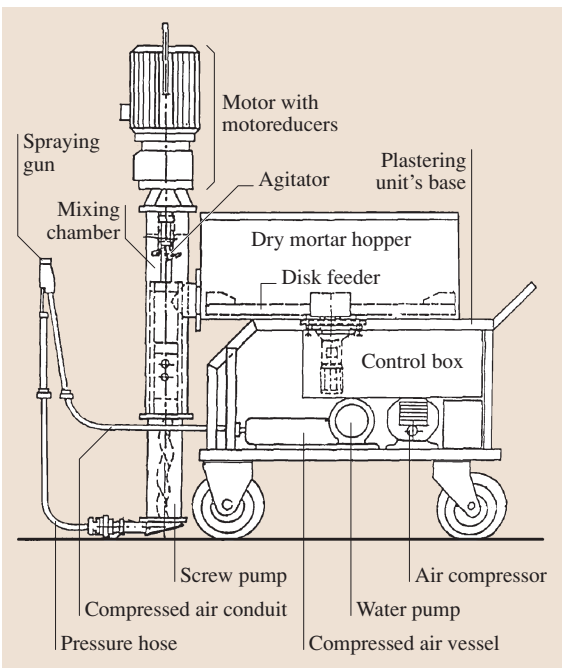

Fig. 14.119 Plastering unit for gypsum mortars

and door openings) screw pumps with a delivery of 0.3–0.7 m^3/h are used.

Hoses that are 25 mm (occasionally 19 mm) in diameter are used for feeding plaster mix. The simplest plastering units of this type can work in tandem with an external general-use air compressor. Plastering units are offered with an electric or diesel drive.

For operational safety reasons pressure conduits in all kinds of plastering units are protected by safety devices against an excessive increase in mortar or plaster mix pressure. Currently in most plastering units electromagnetic protection in the form of *pressure cut-offs* are used. Plastering units for conventional mortars, equipped with a piston pump, usually have double protection systems.

14.7.3 Equipment for Facing Work

Facing work consists of finishing surfaces by fixing decorative layers of different materials to them. The range of facing work is very wide. The most commonly used facing materials are: ceramic tiles, stoneware, and natural and artificial stone tiles.

The basic machine for facing work is a cutting-off machine. Such machines can be used not only for cutting the aforementioned materials, but also to cut concrete blocks, reinforced concrete, bricks, roof tiles, and so on [14.39].

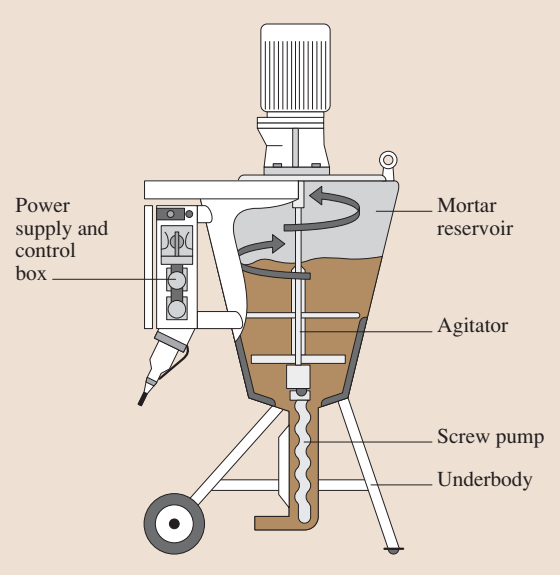

Fig. 14.120 Plastering unit for mortars containing plastics

Four types of cutting-off machines can be identified (Fig. 14.121):

- Type 1: A machine with a movable table having a fixed (permanently or by means of clamps) or swinging moveable cutting head (tiltable or not), which is located over the table
- Type 2: A machine with a fixed table having a horizontal moving cutting head and, if applicable, vertically adjustable and tiltable cutting head located over the table
- Type 3: A machine with a fixed table having a vertically moving cutting head
- Type 4: A machine with a fixed or movable and/or inclinable table having a fixed cutting head, intended for use only with continuous-rim tools having a maximum diameter of 250 mm (the motor being located under the table)

Cutting-off machines are used for cutting along straight lines, in planes inclined at various angles. The working tool is usually a solid or segmental disk with a diamond glued to it along its circumference, forming a ring. The disk is cooled with water. For less precise cutting (e.g., of bricks) disks with a diamond and metal can be used. The cutting disk is usually driven directly by a motor or sometimes via a belt transmission.

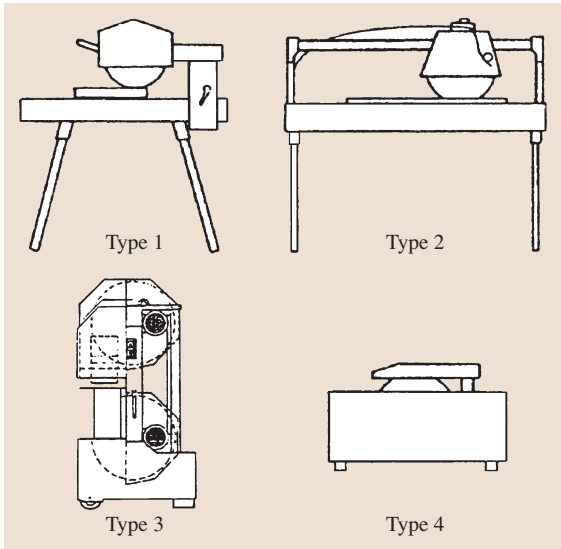

Fig. 14.121 Sketches of different types of cutting-off machines

The cutting disk is cooled and the plate of material being cut is wetted by immersing part of the disk in a tank with water, or by feeding water, flowing down gravitationally from a tank located over the disk or forced by a water pump, to the cutting disk. Wet cutting prolongs the life of the disk and eliminates dust emission.

The structure of a cutting-off machine is shown in Fig. 14.122.

The power of driving motors in cutting-off machines ranges from 200 W to 3 kW.

The group of machines used for facing work also includes a mixer for preparing adhesives and mortars. A mixer for preparing 40 l of mortar by mixing dry components with water is shown in Fig. 14.123. In order to fill bin one should tilt, by means of the handle, the mixing unit into the upper position and lock it with bolt. The handle is used to relocate the mixer.

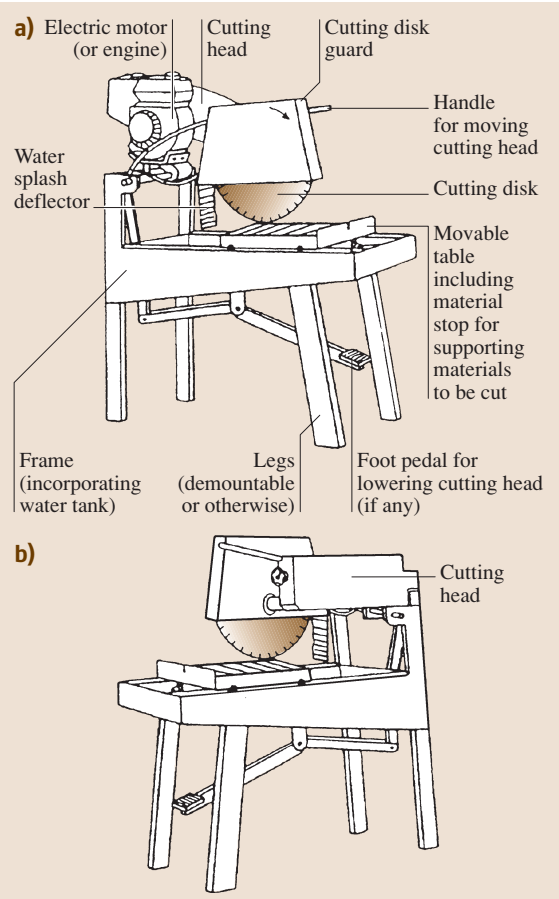

Fig. 14.122a,b Examples of cutting-off machines: **(a)** cutting-off machine with internal combustion engine; **(b)** cutting-off machine with electric motor;

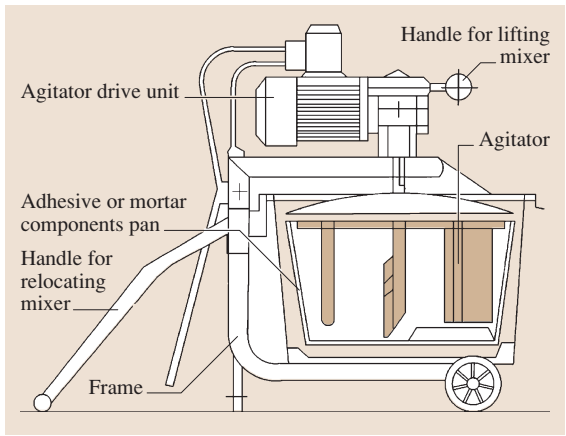

Fig. 14.123 Mixers for adhesives and mortars used in facing work

14.7.4 Floor Work

Floors are elements of buildings consisting of several layers and made almost entirely on the construction site.

Depending on the floor materials, different machines and equipment are used. The machines most frequently used for floor work are:

- Pneumatic feeders for dense mortars (feeder of fresh concrete mix and mortar)
- Vibrating beams (described in Sect. 14.3)
- Floating machines for concrete (described in Sect. 14.3.8)
- Grinders for stone and mineral floors
- Sanding–polishing machines for wooden floors (parquets)

A pneumatic feeder for dense mortars is used for mixing the components of cement mortar and delivering the latter to the placement site. A scheme of such a feeder is shown in Fig. 14.124. The vessel filled with the appropriate amount of water can be charged with mortar dry components manually or by means of a charging bucket. Compressed air supplied to the vessel and dosing unit forces mortar out of the vessel, but in the dosing unit the stream of mortar is separated by compressed air. As a result, in the pressure hose it already has the form of a series of small portions separated by spaces filled with compressed air. This transport system ensures stable flow of mortar into the hose's tip placed on

a tripod. Depending on their size, machines operating on this principle have a mortar capacity of 2–6 m^3/h and can feed mortar to an elevation of 50 m.

Electric motors or self-ignition combustion engines with power of up to 30 kW are used for driving pneumatic feeders for dense mortars. The most common pressure hose diameters are 63 and 68 mm.

Grinders for stone and mineral materials are being increasingly less frequently for finishing work in construction because of a change in the materials used. Commonly used until recently, terrazzo – which required grinding – has been replaced by lining in the form of stone and ceramic tiles with a ready-made smooth surface not requiring any machining after laying.

Wood floor sanders and sander–polishers form a numerous group of machines and find application in the construction of new structures and in renovation. The following types of machines can be identified:

- Drum (single- and double-drum) sanders
- Disk sanders
- Oscillating sanders

Drum sanders are intended for rough and finishing sanding of wooden floors. Sanders with one and two working drums can be distinguished. In the latter case, one drum performs sanding while the other stretches the abrasive belt. Both drums have a horizontal axis of rotation. The sander's working element is an abrasive (sandpaper or abrasive cloth). The sanding drum's working width is up to 250 mm and is limited by the necessity for the drum to exert appropriate linear pressures (about 20 N/cm) on the surface. The design of a single-drum sander is shown in Fig. 14.125.

A drum sander may weigh as much as 90 kg and the power of the driving motor can reach 3.5 kW at a drum rotational speed of about 2300 rpm.

Electric motors are exclusively used to drive sanders because the latter are intended mainly for work indoors and the possibility of ignition of the wood dust collected in dust bags has to be eliminated.

The described drum sander cannot sand the floor under heaters. For this purpose *disk sanders* (Fig. 14.126) are used. The working tool in this machine is an abrasive disk mounted at an angle of about 3° relative to the base. Sandpaper is Velcro-fastened to the disk or clamped with a nut. Because of the disk's inclination, its working base–contact surface amounts to about a third of the disk's surface area.

Power is transmitted to the disk by a V-belt or a cogbelt. The driving motor's power does not exceed

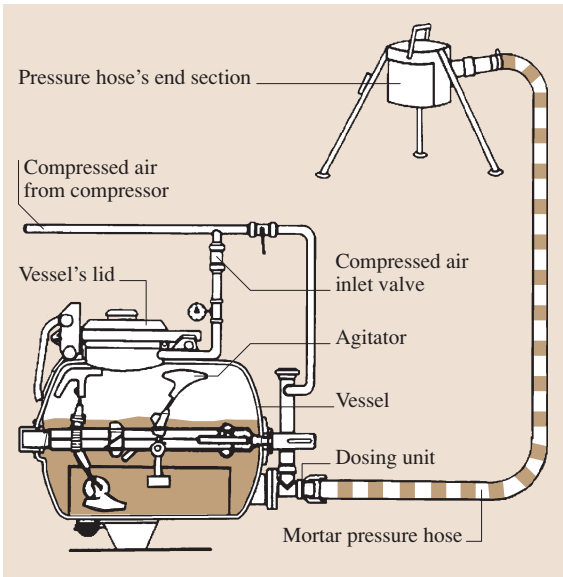

Fig. 14.124 Scheme of pneumatic feeder for dense mortars

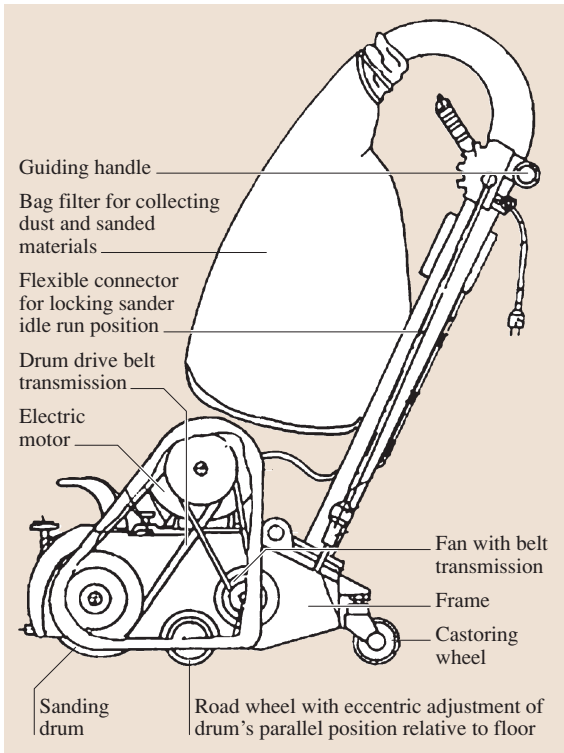

Fig. 14.125 Single-drum sander for parquet floors

2.0 kW at a rotational speed of about 4300 rpm. In currently manufactured disk sanders, disks about 180 mm in diameter are used.

In some sander designs, lights are fixed to the sander's body to illuminate the sanded surface at a small angle. This makes it easier for the operator to notice any surface irregularities and to obtain the required quality of sanded surface.

To sand corners of rooms and places not easily accessible to drum sanders and disk sanders *oscillating sanders and belt sanders* are used. These are typical mechanized devices with an electric drive.

Besides the above basic machines for floor work many small mechanical devices are used [14.40]. Their selection depends on the floor materials. This group includes:

- Industrial vacuum cleaners, thermal and mechanical cutters for polystyrene foam, sweepers, floor-washers, floor polish spreaders, and floor polishers
- For wooden parquet floors: hand-guided circular saws, circular saws with a table, and circular saw–fretsaw machines
- For laying plastic flooring: welding cord groove millers, circular tools, and welders

14.7.5 Equipment for Painting Work

Paint coatings are a very common way of finishing both building interiors and elevations. Paint coatings are applied to the surfaces of walls, ceilings, window and door openings, pipes, and heaters. Commonly used materials are emulsion, synthetic, and oil paints. The use of water (limewash and size color) paints is on the decline. In small rooms, paint work is as a rule done by hand. Painting units are used to apply paint coats in large rooms.

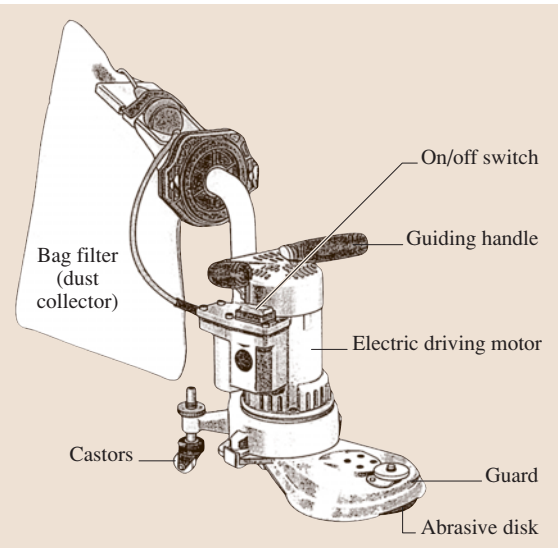

Fig. 14.126 Disk sander for parquet floors

Depending on the compressed air or paint pressure, painting units can be divided into three groups:

- Low-pressure (up to 0.55 MPa) painting units
- Medium-pressure (up to 2.5 MPa) painting units
- High-pressure (up to 25 MPa) painting units

Besides the above, electrostatic painting units are also distinguished.

Low-pressure painting units usually consist of a spraying gun, a paint reservoir, and an air compressor.

Spraying guns equipped with a paint reservoir are general-use devices. Paint reservoirs can be attached to a spraying gun from the top or bottom. There are also designs in which a jet of compressed air from a compressor is used to spray paint. The spraying parameters are set by means of valves, which control the paint and compressed air flows.

In medium-pressure painting units, similarly to in high-pressure painting units, paint is pumped without the action of air and so they are often called *airless*. Currently they are superseded by high-pressure painting units.

High-pressure painting units are used in construction for painting large surfaces and on roads to paint railings and roadway signs. The basic working unit is a piston pump which ensures a pressure as high as 25 MPa in the pressure hoses. The pumps and the paint forcing system's components are made of abrasion-resistent materials (tungsten carbide). High-pressure hoses, 12–16 mm in diameter, are usually employed. The hoses are protected against electric charge accumulation – typically by a conductor connected to earth.

Spraying gun nozzles ensure the rapid discharge of atomized paint in the form of a jet whose shape depends on the nozzle's shape (e.g., conical or flat triangular). The kind of nozzle and the spraying pressure are selected to suit the kind of work, e.g., the painting of large surfaces or the precision painting of stripes. The operation of modern high-pressure units is simplified as far as possible.

High-pressure painting units can be used for applying water-based paints, solvent paints, latex coats, acrylic coats, and so on. These machines are powered

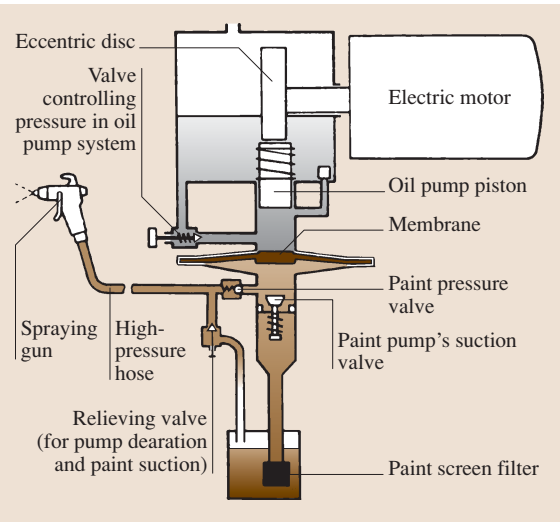

Fig. 14.127 Scheme illustrating the operation of a high-pressure (airless) painting unit

by electric motors, pneumatic engines or combustion engines, with a power as high as 4.1 kW.

A high-pressure painting unit is shown schematically in Fig. 14.127. The piston causes the pulsation of a membrane and the suction of paint from the reservoir through a filter and its forcing into the hose and spraying gun. A valve in the oil pump system is used to set the spraying pressure.

A typical high-pressure (airless) painting unit design is shown in Fig. 14.128. Paint is sucked in from a reservoir by the paint pump and forced (at a maximum pressure of 17.5 MPa) into the spraying gun with a nozzle 0.43 mm in diameter. The rate of painting is about 4 m^2/min.

It should be noted that in paint work, besides the application of paint coatings, preparation of surfaces and paints plays a vital role. Industrial vacuum cleaners, sliding grinders, and corner grinders are used for preparing the base [14.40].

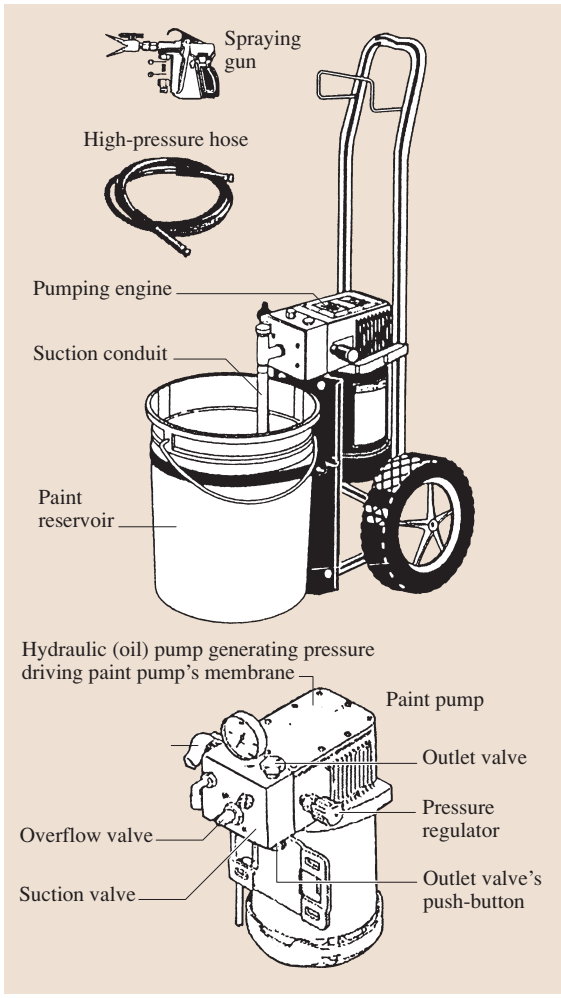

Fig. 14.128 High-pressure (airless) painting unit

Paints are mixed by means of hand-operated and mechanical mixers and strained using screens to remove impurities.

14.8 Automation and Robotics in Construction

Even today many people employed in construction associate the use of robots with the manufacturing industry, mainly the automotive industry, where they are typically employed to spray paint and spot weld the car body. However, considerable advances have been made in robotics applications in construction.

Robots are used not only because of their technical–economic advantages; they also result in improved work quality, increased output, reduced task realization time, reduced labor costs, and improved operational safety. The latter applies especially to work in conditions that are hazardous and detrimental to health, such as sewer

inspection, demolition work, underwater work, work in radioactive environments, earthwork on slopes, and work at heights. In many cases, it is for safety reasons that robots must be employed. A survey has shown that about 300 devices are currently available in the robot and automated equipment market.

The rapid development of robotics for construction applications in Japan began in earnest in the 1980s. Its direct cause was the shortage of labor in construction. Japan's business community turned to the government for permission to import workers from abroad. Because of the government's refusal, construction companies were forced to invest in research and development of robotics for automation in the execution of construction work. Another motivation was the difficulty with conventional performance of tasks that were deemed hazardous or arduous for human workers to perform. Waseda University's Systems Science Institute in Tokyo pioneered Japanese concepts of implementing industrial robotics on construction sites. Leading engineering construction firms such as Shimizu, Obayashi, Kajima, Taisei, Fujita, and others produced their own construction robot prototypes for various applications on construction job sites. These applications included single-purpose construction robotics as well as entire robotic systems for the performance of high-rise building construction.

In the USA the Robotics and Field Sensing Committee of the American Society of Civil Engineers engaged in coordinating research in automation and robotics for construction. The centers of active in this field included Carnegie Mellon University (Pittsburgh, PA), the University of Texas at Austin, Purdue University (West Lafayette, IN), the University of Southern California (Los Angeles), and North Carolina State University (Raleigh). Carnegie Mellon was a US pioneer in these developments, having started independent research and development of construction robotics in the early 1980s, shortly after the early developments of construction robotic concepts in Japan.

Also in the 1980s, construction automation and robotics concepts were researched in the former Soviet Union. These included systems and hardware developments at the Moscow Civil Engineering Institute and at the Central Laboratory for Construction and Heavy Manipulators [14.41–44]. Subsequent or parallel developments took place in France (*Centre Scientifique et Technique du Batiment*), Germany (the Fraunhofer Institute for Production Automation, Technical University of Karlsruhe, and the Technical University of Munich), the United Kingdom (Lancaster University, City University in London, and the former Bristol Polytechnic), and Spain (the Carlos III University in Leganés, Madrid).

As a result of the development of automation and robotics in construction in the last three decades this domain, integrating the achievements of robot technology, information technologies (IT), and design for construction (DfC), has acquired the status of a scientific discipline. Twenty years ago the International Association for Automation and Robotics in Construction (IAARC) was formed. This association organizes annual International Symposia on Automation and Robotics in Construction (ISARC). The 21st ISARC was held in Jeju (South Korea) in September 2004, and the 22nd ISARC took place in Ferrara, Italy in September 2005. Papers published in the symposium proceedings represent the latest achievements in this field.

In automated construction equipment two kinds of devices can be distinguished: teleoperation manipulators, referred to as construction manipulators, and construction robots. Construction manipulators are remote-controlled by the operator while construction robots are autonomous computer-controlled devices. The robot's software allows it to perform variable tasks within its application range.

In the development of automated equipment, four stages corresponding to the particular generations of this equipment can be distinguished [14.45].

The first generation, which can be called *automated construction devices*, was developed by outfitting existing construction equipment with electronic sensors and digital control. The principles underlying the development of the first-generation robots are still used in the automation of many types of construction machines. Expensive construction machines are equipped with sensors and computer control. The latter includes a data-processing unit and feedback control. Such adaptations are used in excavators, cranes, pile-driving equipment, transport to the horizontal transport of output, and in concrete mix transport and placement.

The second generation is associated with the application of manipulators to such construction works as laying reinforcement, building walls out of building blocks, floating concrete surfaces, and laying tiles. Manipulators are newly designed devices but still controlled by operators.

The third generation includes autonomous robots with no operator involved in their control. They need an operator only to prepare them for work and sporadically during work. They find application in many kinds

of construction work such as trenching, masonry work on construction sites, and in precast concrete plants for wall elements production, the assembly of steel structures, the transport of materials to the place where they are to be built in, the spraying of fireproofing insulation onto steel structures, and painting. Moreover, they are used for testing building structures and elements, e.g., sewers, the adhesion of tiles to tall buildings' elevations, and testing the quality of welded joints in steel structures.

Fourth-generation robots are designed for specific structures, taking into account the materials to be used. They are employed in automated building construction systems (ABCS). These robots are designed to be an integral part of a new construction methods which are adapted to the use of construction robots, known as design for robotic construction (DfRC).

All four generations of automated construction equipment are used in construction, and transition from one to another has been evolutionary. A major feature of this process is that the role of the operator is reduced, or completely replaced, by computer control.

Automated construction equipment used for particular kinds of construction work is described below.

14.8.1 Automation of Earthwork

Because of its significant share in the total building production, automation of earthworks deserves special attention [14.46]. However, some factors in earthwork make its robotization difficult, including:

- Variable forces of the ground-working tool interaction, due to the variability of the physical parameters of soil and material nonhomogeneity
- Variable height of the terrain
- Occurrence of buried objects such as electric cables, pipelines, etc.
- The possibility that machines working close to the edge of excavation edges may overturn
- The potential hazard to workers who find themselves within the machine's range of operation

For these reasons, remote-controlled machines and machines with a robot control system effecting the working tool motions controlled by computer-driven programs are usually employed in earthwork automation instead of true robots.

Such machines are used in work environments with radioactive and chemical contamination, in pile driving, underground work, tunneling, deep point-excavation, diaphragm excavation, and pneumatic caisson work.

The automation of earthmoving machines is proceeding in three directions:

- Use of remote control in machines
- Adaptation of machine control systems for automated execution of specific kinds of work
- Development of autonomous robots

The first direction (remote control of earthmoving machines) is the most common commercially available solution. On the basis of a three-dimensional image the operator controls the operation of machines and the loading of the excavated material. Remote control can be combined with a semirobotic control system when quality workmanship is required.

The second direction (adaptation of the machine's control system to make its fittings perform a specific task) includes, for example, the steering of the excavator bucket so that it moves along a predetermined trajectory [14.47–50], the control of the dozer blade to ensure that a smooth, leveled surface is obtained, and the control of drilling attachment mounted on an excavator diaphragm wall excavation.

The third direction is the development of autonomous third-generation robots for earthwork. The robot's design should be adapted to adverse service conditions and hazards.

Example Applications

The research and development work on the automation of earthmoving machinery is primarily concentrated on single-bucket excavators and then dozers and loaders. Many manufacturers offer machines operated by remote control. Extensive research aimed at developing robotic components and adapting the robots to practical service conditions is being conducted by various corporate laboratories throughout the world, including, e.g., the research and development units of the Caterpillar Corporation and Komatsu.

This research covers modeling of excavators as robotic manipulators [14.51], cognitive force control of excavators [14.52], soil mechanics with regard to ground-working tool interaction, kinematic and dynamic analysis of mechanisms, sensors enabling the determination of the position of mechanisms in a chosen location and in an absolute reference system, bucket trajectory optimization (leading to improved output and fuel economy) [14.47–50], and sensors detecting the presence of people within the machine's work range

and making it possible to determine the positions of the excavation's edge and the output removal vehicles.

An example of a remote-controlled machine is the pull shovel shown in Fig. 14.129. It is radio-controlled and has an operating range (distance from the control panel) of 1500 m. The working system's cylinders and travel drive are controlled by levers on the control console. Two video cameras, mounted outside the excavator, transmit a picture of the working area. A third camera inside the operator's cabin shows the indications of the gauges.

Fig. 14.129 Remote-controlled pull shovel

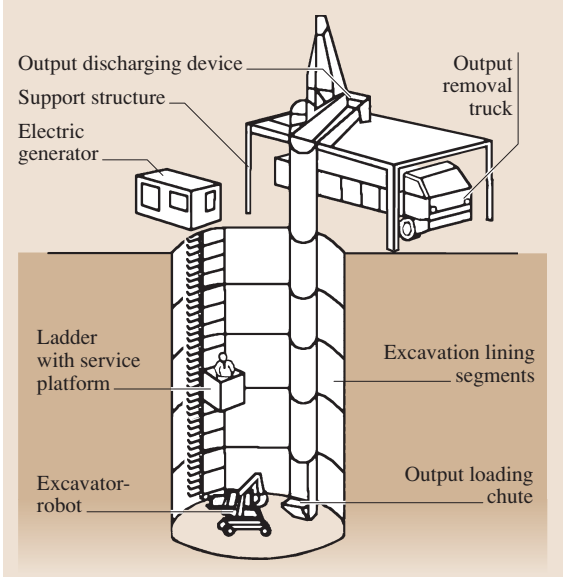

Fig. 14.130 Excavator with associated equipment for making deep point-excavations

Another example of a remote-controlled excavator is the excavator shown in Fig. 14.130 [14.53]. The machine is intended for making deep excavations, vertical transport of output, and loading it into transport means. A slewing body with excavating tools and containers or negative-pressure conduits for transporting output are mounted on the crawler chassis. The excavation's minimum diameter is 3 m.

The excavation rate and the output loading rate can be adjusted to the ground's properties. If soft rock is encountered, a milling drum can be mounted.

The excavator is used in mountainous terrain not easily accessible to pile-drivers to avoid the hazards (landslides, subsoil waters, toxic gases, and falling objects) to which the operator would otherwise be exposed.

Among point excavators there is a machine designed for work in hard rock [14.53]. Its rotary tool, mounted on a 0.7 m^3 undercarriage, is hydraulically driven. Boreholes 846 mm in diameter can be drilled.

Besides whole machines, computerized systems for controlling construction machines, allowing one to automate partially the operation of machines, are also available. Offered control systems can be installed on excavators, dozers, graders, and asphalt pavers. They incorporate tachometers, global position system (GPS) receivers or laser surveyor's levels. A simple example here is a control system for setting the position of the dozer's blade (Fig. 14.131) so that smooth, leveled soil surfaces can be obtained. A rotary laser on a tripod produces a horizontal reference plane. The control system with a signal receiver, mounted on the dozer, automat-

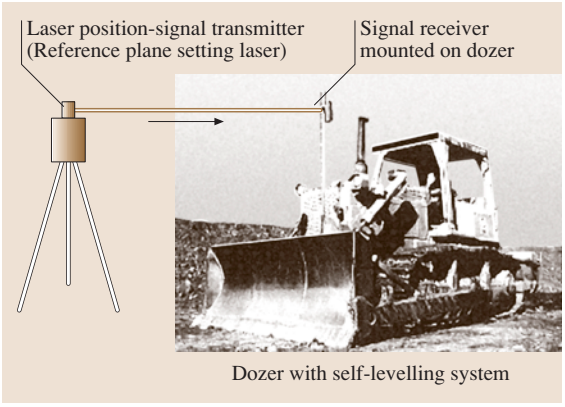

Fig. 14.131 Dozer with blade position controlling system for precision leveling of terrain

ically adjusts the elevation of the blade as the laser receiver follows the adopted reference plane.

A computerized control system for a grader works as follows. The task to be performed is stored in the memory of the machine's PC in accordance with a digital work execution scheme. The machine's actual location relative to the design data is determined by a tachometer or the GPS, which compares it with the design terrain elevation at a given point and on this basis sends signals to the machine's hydraulic system. For one such control systems, the accuracy of leveling is ±5–10 mm when a tachometer is employed and ±15–20 mm when a GPS system is used. Thanks to automatic control the number of passes of the machine, and so the work realization time and cost, can be reduced.

Besides control systems for single machines systems for the remote control of a set of earthmoving machines (Fig. 14.132) working in areas posing hazards to operators are also being developed [14.53]. Excavation and the loading and transport of the spoils are radio-controlled from a central control room located at a distance of 2–3 km from where the machinery is working. A vehicle with a radio relay station acts as an intermediary unit. The radio-controlled system incorporates the following subsystems:

- Transmission of stereoscopic images and graphics to a central control room.
- A bidirectional system for controlling vehicles and transmitting information about their position; the vehicles are located within a radius of 1 km from the radio relay station (Fig. 14.132).
- Audiovisual transmission providing information to the operators.
- Remote measurements using the GPS and an automatic tracking device (a three-dimensional laser positioning device).
- Monitoring the movement of the vehicles and the progress of the work and printing the results.
- Transmission of information about the excavation's cross-sectional dimensions and the positions and inclination of the vehicles.

Pneumatic Caisson Work

In pneumatic caisson work, because of the hazards (decompression sickness) to which the operators are exposed when moving from a pressurized space to atmospheric pressure, it is highly desirable to eliminate direct operation through automation [14.53]. Several methods of carrying out caisson earthwork have been developed in Japan [14.53]. One of these is a method of unmanned caisson work. The minimum diameter of a cylindrical caisson which can be used in this method is 8 m. If a rectangular caisson is employed, its minimum dimensions are 8.0×6.5 m. The preliminary work, which includes leveling of the ground to ensure even sinking of the caisson, is carried out using conventional earthmoving equipment. The system's common feature is remote control from ground level.

The equipment shown in Fig. 14.133 consists of a caisson scoop, a fast spoil-loading device, a caisson

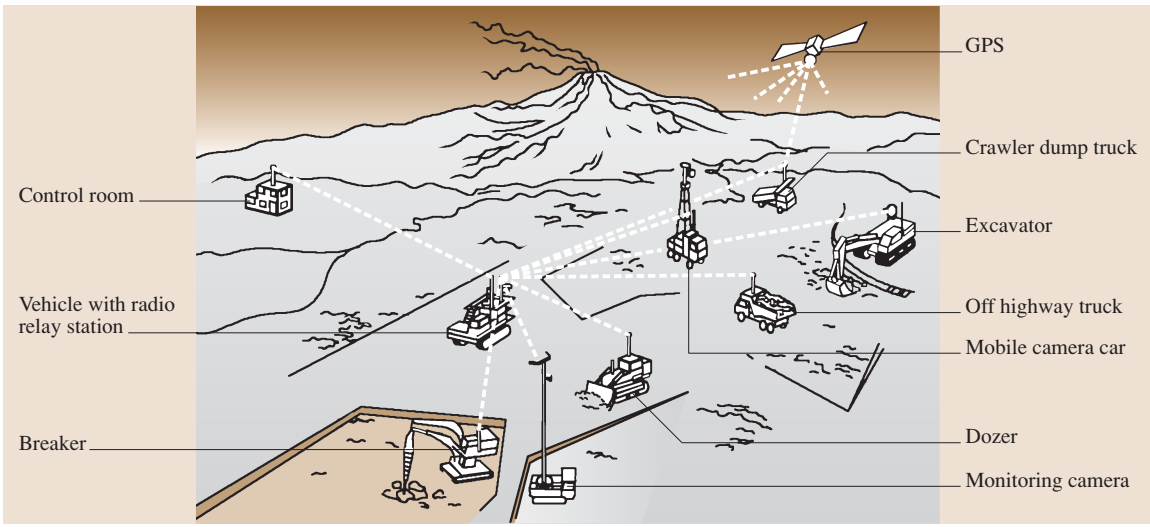

Fig. 14.132 System for remote control of earthmoving machinery

scoop control system, a measurement system, and a data transmission system.

The soil is excavated and transported by a specially designed caisson scoop that discharges its content onto a belt conveyor or the platform of a hoisting winch with a quick rotary-type spoil loader. Then the spoil is discharged into containers. The caisson scoop is radio-controlled and sensors installed on it monitor its operation.

Diaphragm Wall Construction

Diaphragm wall construction has been automated on construction sites in Japan. There are several commercially available systems for the erection of diaphragm walls. Automation covers excavation, the measurement of excavation execution accuracy, and quality control of the slurry stabilizing the excavation's walls and of the concreting process [14.53].

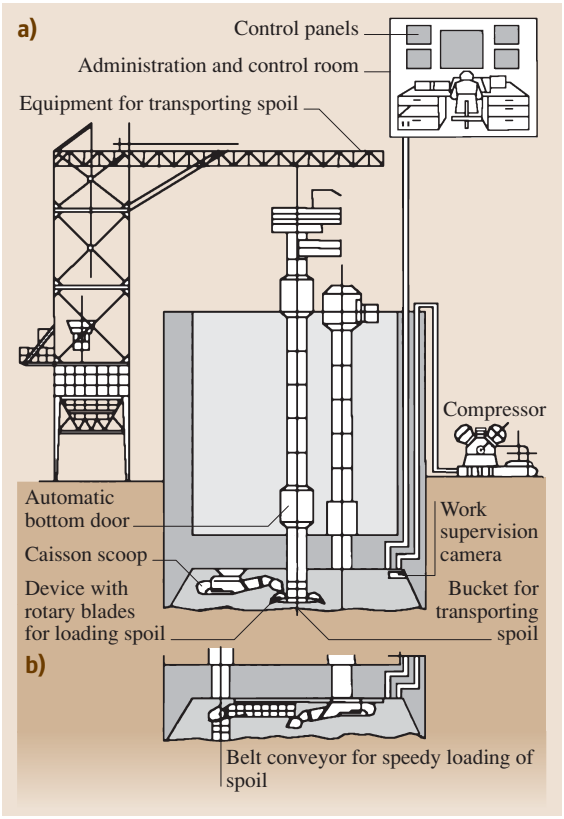

Fig. 14.133a,b Equipment used for unmanned caisson work: **(a)** equipment used in circular caissons **(b)** equipment used in rectangular caissons

An example of an automatic excavation system is the set of tools (Fig. 14.134) which was used for erecting a cavity wall of record dimensions (150 m deep and 2 m wide) in Izumiotsu near Osaka [14.53].

The system consists of a positioning system, an excavating system load control, and machine manual control by the operator on the basis of the information displayed on the monitor screen. The excavating unit, called an excavator, is suspended on a wheeled crane.

The measuring system consists of equipment located on two support structures and the excavators' instruments: adjustable guides, an inclinometer, a depth gauge, and a fuzzy controller to control excavation wall irregularity.

The position of the excavator is determined as a function of the horizontal shift of the two trace wires. The displacement of the trace wires is measured in an area of 100 mm^2 by a noncontact magnetic gauge with a junction measuring system.

The measuring system ensures accurate determination and correction of the excavator's position. For a 100 m deep excavation the excavating tool position accuracy is 30–50 mm.

Pile Driving

In the case of pile-driving machines, automation covers the control system ensuring the precise guidance of the working tool's end. A multijointed pile driver is shown in Fig. 14.135 [14.53].

The machine's main function is to drive in steel T-piles and sheet pile walls. In addition, various fittings, such as an earth drill or a vibratory hammer, can be attached to the multijointed work system's end. The machine is equipped with a computer-aided guidance system which guides the work system's end in the vertical plane as shown in Fig. 14.135. Before the new control system was introduced only a skilful operator simultaneously controlling the positions of the two arms had been able to make the work system's tip follow a linear trajectory. In the new system, which coordinates the movements of the two arms, control is effected by means of only one lever.

The computer-aided system of controlling the position of the work system's end ensures, by properly positioning the pile and maintaining its angle of inclination, that the pile is driven in accurately.

14.8.2 Automation of Concrete Work

Types of Concrete Works Covered by Automation

The automation of concrete works covers primarily the transport and distribution of concrete mix, and then the removal of the layer of corroded concrete from reinforced concrete structures, applying a new layer of concrete, the fabrication of reinforcement, the removal of irregularities in the surface of freshly set concrete, and the vertical shifting of formwork in the sliding erection process. Several applications of related techniques have been described [14.54]. The automation of concrete mix production in concrete batching and mixing plants is discussed in Sect. 14.3. Examples of the automation of the particular types of concrete construction tasks are provided below.

Transport of Concrete Mix

Most concrete mix transport automation solutions are found in the construction of dams [14.53]. The automation solution depends on the location and size of a dam. Figure 14.136 shows a diagram of an automatic concrete mix transport system used in the construction of a dam with a concreting work volume of 510 000 m^3.

The system covers the delivery of concrete mix from a concrete mixing plant to tipper trucks transporting it to the placing site. The fully automated system consists of the following devices: transfer car with a 4.5 m^3 capacity tank, two 4.5 m^3 capacity buckets, two cable winches with a hoisting capacity of 14.5 Mg, and two 9 m^3-capacity ground concrete hoppers. The transfer car draws concrete mix from the concrete mixing plant, transports it, and discharges it into one of the two buckets.

The operation of all the devices is controlled from a central control room. Information is displayed on a cathode ray tube (CRT) screen in the central control panel and, if necessary, the operator can intervene in the process. A basic requirement for the efficient functioning of the system is the precision positioning of the concrete buckets in the positions of concrete mix loading and unloading into hoppers. To ensure this, the bucket position is controlled in a spatial Cartesian coordinate system. The unloading of the buckets into hoppers is controlled wirelessly by means of systems with interlocking. The opening and closing of the hoppers gate valves is controlled by the truck drivers, who draw a specified quantity of concrete mix.

Besides computers and a program selector the other major components of the control system are gyroscopic sensors, optimeters, and coding units. Continuous speed control is employed in the cable winches' drives so that

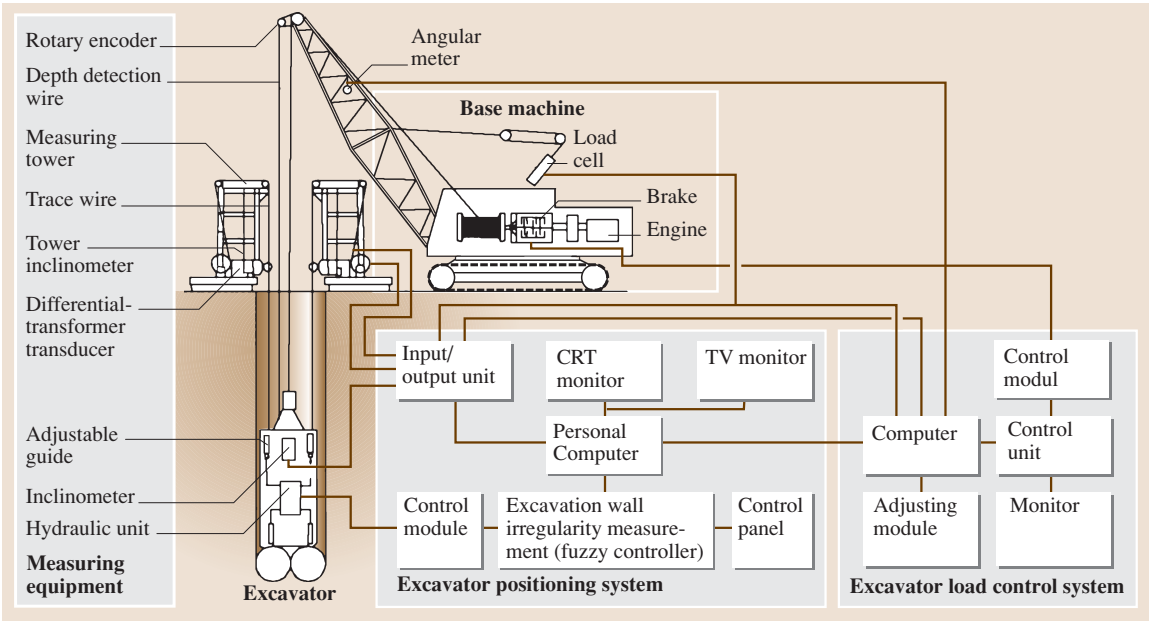

Fig. 14.134 Automatic diaphragm wall excavation system

the buckets can be quickly lifted and lowered, but positioned slowly.

Several concrete mix transport automated systems designed for the erection of dams are available on the Japanese construction equipment market.

Their common feature is the use of components such as transfer cars, cable winches, concrete buckets, hoppers, central control rooms, and radio-control systems. Instead of cable winches automated tower cranes can be used as the basic machines.

Distribution of Concrete Mix on Placing Site

Automation of concrete mix distribution is applied in the erection of large horizontal concrete structures such as floors and concrete bases. In this case, distributors fed by concrete pumps are usually employed [14.53]. Sometimes tower-mounted distributing booms are used, particularly in densely reinforced places where it is difficult to move distributors.

In order to be able to locate the delivery pipe's tip in the whole work area a typical distributor can perform the following work motions:

- Driving on a short (e.g., 3.2 m) portable rail-track
- Slewing of the whole delivery pipeline
- Mutual slewing of the particular pipeline segments
- Slewing of the flexible section of the delivery pipe

A concrete mix distributor with a capacity of 40 m^3/h (one of the smaller devices in this category) is shown in Fig. 14.137.

The distributor's delivery pipeline, which is 100 mm in diameter, consists of a steel pipe section and a hose, whose position can be changed in the vertical plane by means of the winch. The distributor can rotate at two points: at the junction with the travel section (on the track's axis) and at the junction with the rubber hose. In order to change its position the distributor is raised and turned by means of a jack lift and the rails are laid in a desired position. The distributor's whole delivery pipe can be rotated in the vertical plane in a range of ±35° and the hose in a range of ±108°. Moreover the elastic section can be raised up to 10° and lowered to 30°. The distributor is radio-controlled and one of the control modes is *partially automatic*, which eliminates the difficult simultaneous operation of two levers.

Among concrete mix distributors there is also a system for large concrete works with a four-jointed 20 m long delivery pipeline and an automatic concrete mix distribution system incorporating an automatically controlled tower crane [14.53].

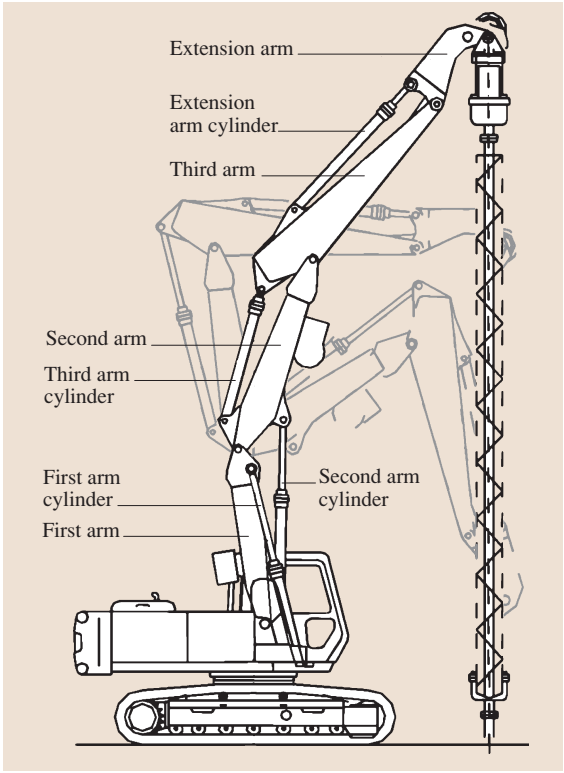

Fig. 14.135 Multijointed pile driver with automatic control of work system trajectory

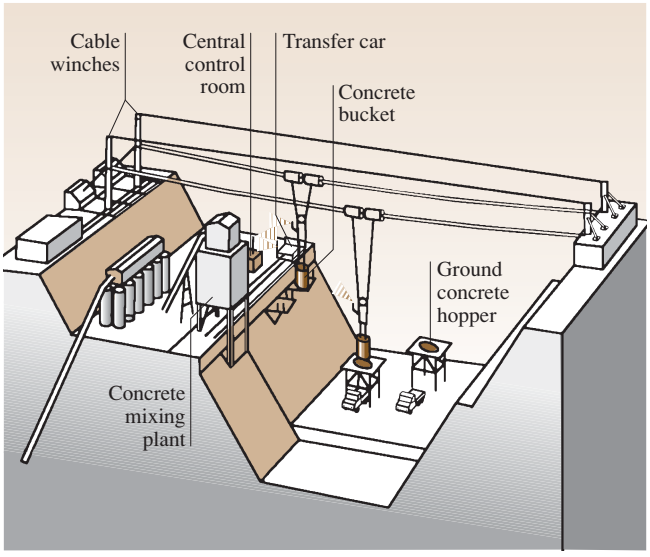

Fig. 14.136 Diagram of automatic system for transporting concrete mix on dam construction site

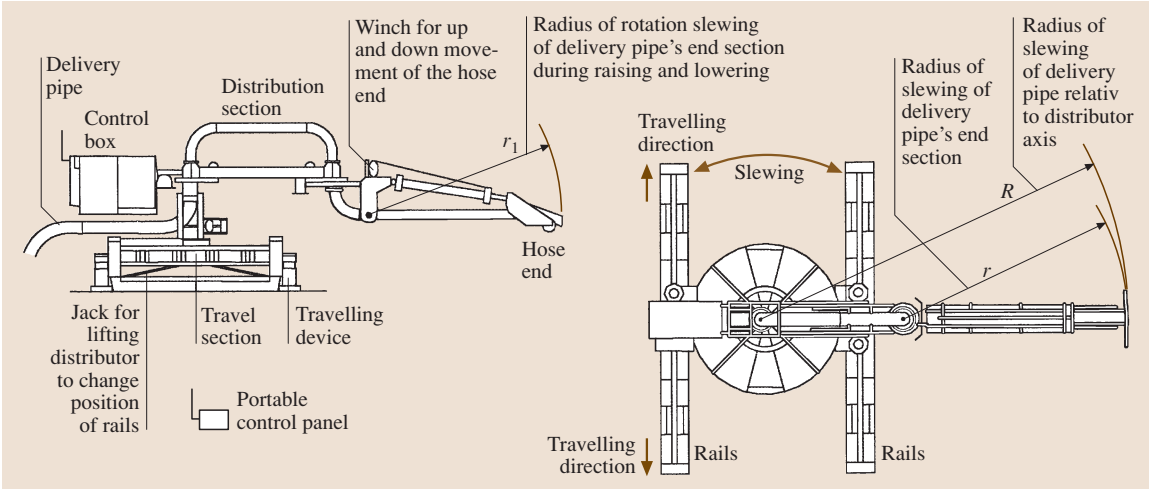

Fig. 14.137 Concrete mix distributor

For smaller structures, pumps with a distributing boom are employed [14.55]. Also here automation is introduced. One firm has developed *a computer controlled mobile concrete distributor* to distribute concrete mix on the placing site and better utilize the equipment.

Computer control makes it possible to position automatically the delivery pipe's elastic section from which concrete mix flows. In order to uniformly distribute concrete mix over the concreted floor one can select one of the three available modes of end section guidance. One of them is *follow-me*, shown in Fig. 14.138. The position of the pipe's elastic section is plotted in a coordinate system using a computer program. The operator sets the directions in which the elastic end is to move, directs the tip slightly in the desired direction (coordinates x, y), and toggles the switch up or down.

If the buyer wishes, the control system can incorporate the following modules:

- Fleet of vehicles management module (PD2000)
- Technical condition maintenance module (PARJS)
- Automatic stability control (ASC) module and automatic distributing boom control associated with concrete mix distribution

Concrete Spraying (Shotcreting)

The coating of reinforcement with a layer of concrete for anticorrosion protection purposes is used in new structures and for repairing old structures. The automation of this process is especially needed in the case of large surfaces, e.g., tunnels, pit shafts, and slopes in danger of sliding.

Research and development work aimed at automating shotcreting covers:

- Robots, incorporating devices for concrete mix proportioning, mixing, transport, and shotcreting; the robot shown in Fig. 14.139 [14.55] consists of a concrete mixing unit, a proportioning pump, and a remote-controlled robot arm. The robot arm is equipped with an automatically controlled oscillating nozzle which ensures accurate shotcrete application. Its action radius extends to 13 m, both

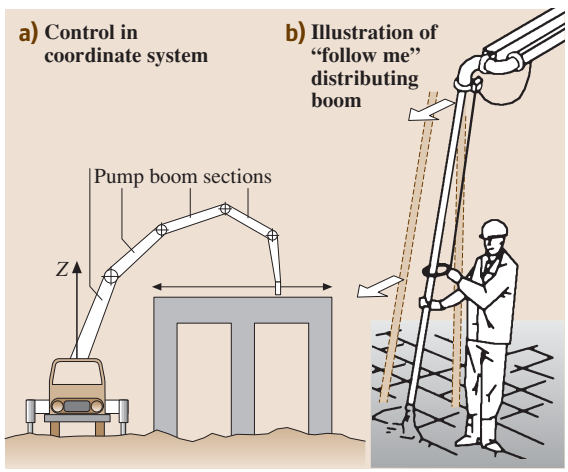

Fig. 14.138a,b Automatic control of delivery pipe's tip for concrete pump with *follow-me* distributing boom **(a)** control in coordinate system; **(b)** illustration of *follow-me* principle

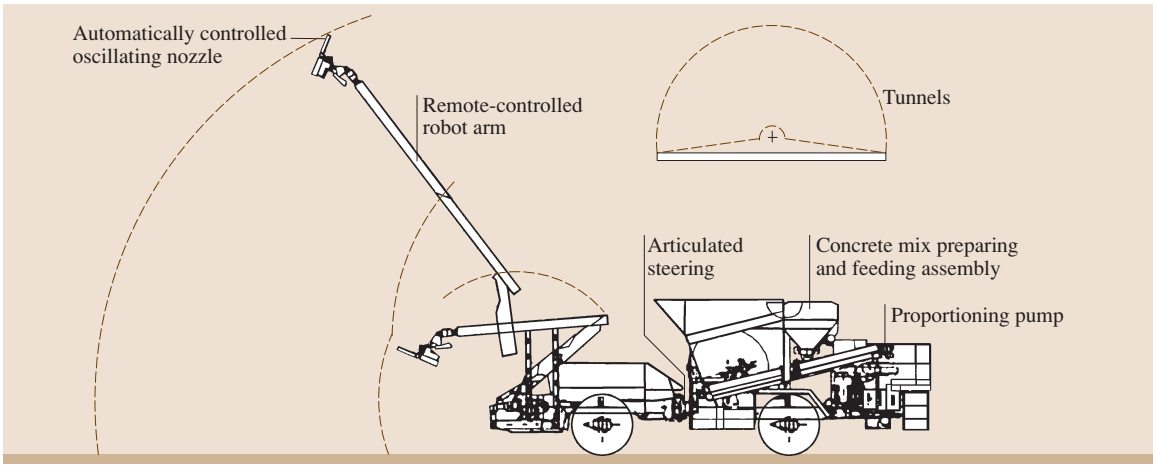

Fig. 14.139 Shotcreting robot

horizontally and vertically, and can easily be directed to cover all parts of the tunnel periphery. The concrete mixing unit consists of separate cement/aggregate bins with a total material volume of 5 m^3. The conveyance and mixing processes are effected by augers. All shotcreting is remote-controlled from a portable control panel, which enables the operator to choose the most effective position from which to work. The entire equipment is mounted on an articulated truck.

- A control system optimizes the amount of setting accelerant added to the concrete mix depending on the size of the concrete surface and the feed pump's delivery rate. The system can be used for any configuration consisting of a shotcreting device, a concrete feed pump, and accelerant feeder.
- Control equipment for secondary concrete lining placement. The equipment controls the quality of the shotcreted surfaces and automatically fills cavities at joints or cracks with concrete mix.

Removal of Surface Irregularities and Roughening of Freshly Set Concrete

The removal of surface irregularities and the roughening of freshly set concrete needs to be automated when erecting large concrete structures such as dams.

A robot for removing surface irregularities and roughening freshly set concrete is shown in Fig. 14.140 [14.53].

An automobile chassis with an attached assembly of four roughening brushes, a rolling sweeping brush, a threshold lift, and a waste bin is used as the suspension system.

The roughening brushes and the waste transport assembly can operate dry or with water supplied under pressure to the brushes and wastes removed by a vacuum pump [14.56].

Fabrication of Reinforcement

Reinforcement fabricating robots are used when erecting multistorey buildings with a reproducible system of storeys or on large construction sites such as nuclear power plants or underground reservoirs. A robot for the fabrication of reinforcement, mainly reinforcing bars, in both site steel yards and precast concrete plants is shown in Fig. 14.141. The objective is to reduce labor costs and ensure dimensional reproducibility of the fabricated elements. The robot automates simple, repetitive actions that steel fixers perform manually. Reinforcement with 4–6 m long longitudinal bars, 19–25 mm in diameter, can be fabricated. The robot consists of

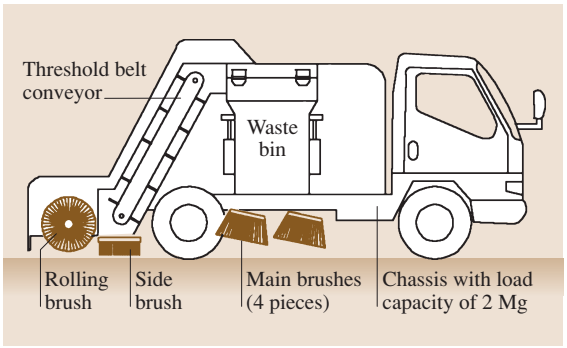

Fig. 14.140 Robot for removing surface irregularities and roughening freshly set concrete

the following assemblies: a base, an arm for feeding stirrups, an assembly for positioning stirrups, two (the upper and lower) automatic tying machines, a coil wire transfer car, arms supporting the (upper and lower) longitudinal bars, a power unit, and a control panel.

The main problem encountered when designing this robot was the precise longitudinal spacing of stirrups and securing them from shifting. This was solved by introducing a cam mechanism in which stirrups are positioned in the grooves of a plate that is shifted by the cam.

Other applications of robots to reinforcement fabrication include the following:

- Automated reinforcement pre-assembly line [14.53] designed for large structures and heavy rebars
- Automatic rebar bender and rebar column fabrication unit [14.53] designed for bending longitudinal rebars at an angle of 10–20° in six places and making a reinforcing cage

Removal of Damaged Concrete Layer in Reinforced Concrete Structures

Removal of a damaged concrete layer is used in repairs of structures such as bridges, pillars, tunnel walls, and dams, which have been damaged by the action of salts, environmental pollution and corrosion, or physical impacts. Two methods for the mechanized removal of a layer of concrete from a structure – a hydraulic method and a mechanical method – are distinguished.

In equipment operating on the hydraulic principle a highly pressurized (90–120 MPa) water jet penetrates the damaged layer of concrete and removes it at a rate corresponding to the operation of a few power hammers.

The advantages of the hydraulic method include: the possibility of adjusting the thickness of the removed layer through the rate of travel of the spray nozzle, eliminated dusting, a fixed magnitude of the acting forces (i.e., *healthy* concrete is not removed), and that rust can be removed from the reinforcement to be coated with a layer of concrete.

A limitation on the use of hydraulic equipment is ambient temperature, which cannot be lower than 0 °C.

Robots for removing a damaged layer of concrete by means of a high-energy water jet are shown in Fig. 14.142 [14.55].

The robot in Fig. 14.142a is equipped with a tower assembly kit providing an operating height 6 m. The robot shown in Fig. 14.142b removes damaged concrete from horizontal surfaces such as bridges and floors, but after reconfiguration can also be used on vertical surfaces.

The robot is controlled by a computer according to one of seven programs. All the machine travel parameters are set remotely from a control panel connected to the machine by a 4 or 6 m long cable.

In another robot operating on the hydraulic principle [14.53] a spraying nozzle whose work advance can be programmed through the association of slewing and advances was adopted. Such designs enable use in channels of circular and rectangle cross sections.

Accessories to hydraulic robots used for removing a layer of corroded concrete include 300 MPa feeders, distilled water tanks, and abrasive containers, in which cutting out holes in concrete structures becomes possible.

The number of robots available for the mechanical removal of a layer of corroded concrete is not large.

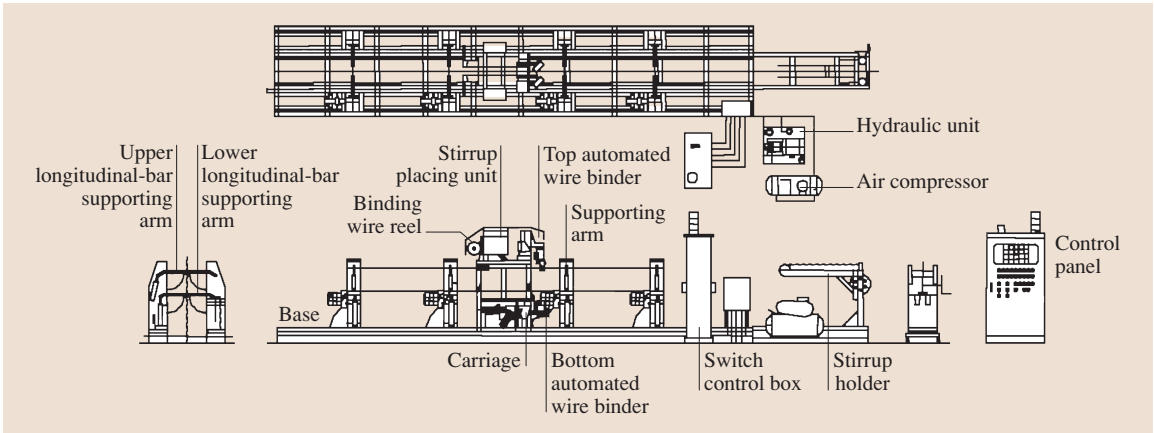

Fig. 14.141 Robot for fabricating rebars for reinforced concrete buildings

A *lining cutting robot* for work in tunnels resembling an ellipse sector in cross section is available [14.53]. The working tool is a rotary two-tool cutting head. The rotation of the head and the advance of the robot along the tunnel are controlled by a computer.

Forming of Concrete Structures for Sliding Forms

The automation of concrete structure forming mainly applies to sliding forms used in the construction of dams and structures such as chimneys, towers, silos, and bridge piers. A few methods of automating the erection of structures by sliding forms are described in [14.53].

14.8.3 Automation of Masonry Work

In European countries (Germany, the UK, and The Netherlands) research aimed at developing robots for masonry work has been conducted since 1991. This work has been focused on robots for erecting external and internal walls from aerated concrete and gypsum blocks.

A crane-manipulator (Fig. 14.143) for transporting and assembling 0.6×0.9×1.0 m aerated concrete blocks has been developed in The Netherlands.

The prototype robot shown in Fig. 14.144 was developed as part of the European Rocco project in 1995.

Research on the mechanization and automation of block-work wall erection focuses on the following equipment:

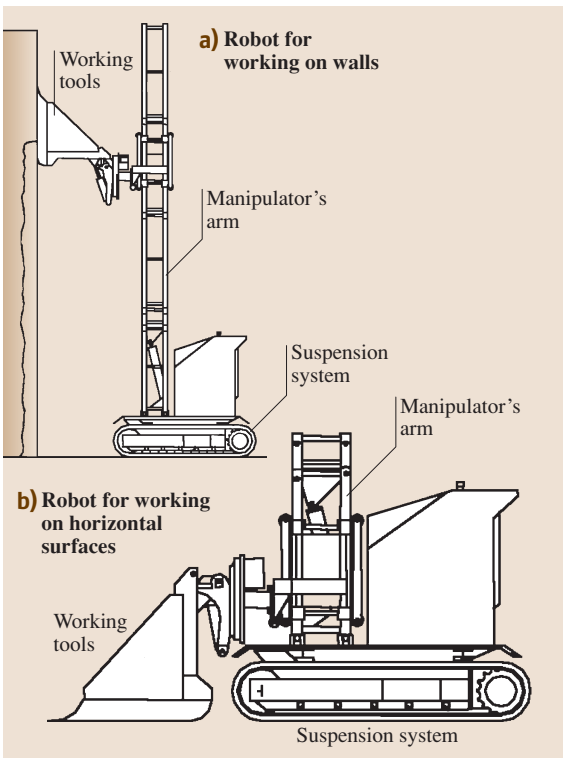

Fig. 14.142a,b Robots for removing damaged layer of concrete by means of a high-energy water jet: **(a)** robot for working on vertical walls, **(b)** robot for working on horizontal surfaces

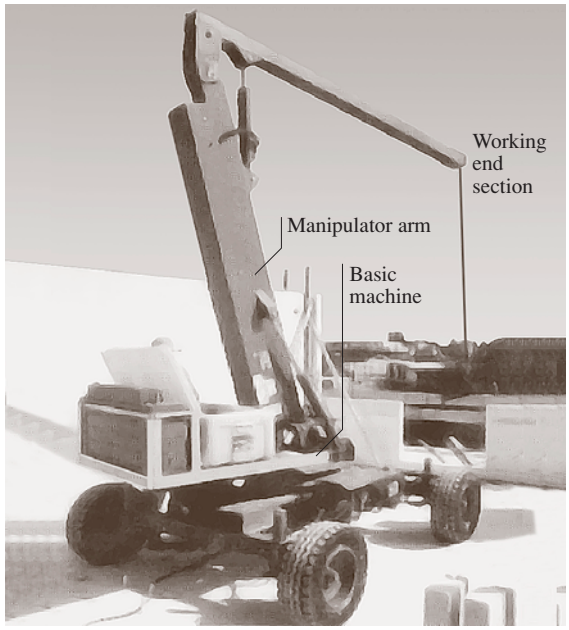

Fig. 14.143 Small-sized crane-manipulator for transporting and laying aerated concrete blocks

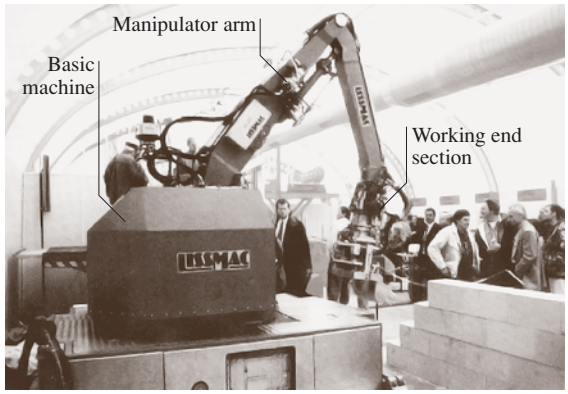

Fig. 14.144 Prototype robot for erecting walls of masonry, developed as part of the Rocco project

- Special bricklayer's platforms for adjusting the bricklayer's position to the height of the wall under construction
- Special winches or air-driven arms for compensating for the gravity of the blocks so that the latter can be manipulated weightlessly

Information on the numerous areas of research into robots for masonry work can be found in [14.45].

14.8.4 Automation of Cranes

The automation of cranes is connected with their specific use in a construction process. These are usually tower cranes (but also crawler hydraulic cranes) with an automatic control system, for transporting and distributing concrete mix and laying reinforcement.

A tower crane adapted for transporting and distributing concrete mix in housing construction is shown in Fig. 14.145.

The crane is a peculiar combination of the tower crane and the concrete pump's placing boom. The 32 m long four-sectioned boom can cover the entire work area. The final section of the boom concrete mix pipe is rigid (not flexible as in most cases) so that concrete can be placed accurately with no need to involve any workers.

Concrete mix is distributed from the level of the horizontally laid concrete mix pipe, whose position is remote-controlled. The elevation of the pipe above the concreted structure is constant and automatically maintained by means of computer control and a joystick. The position of the pipe's tip is specified in a Cartesian coordinate system on the basis of data (angles between the boom's particular sections received from sensors). In the case of joystick control, in order to maintain the boom horizontal, its position is automatically computed on the basis of the speed set by joystick and the current position of the boom. Joystick control allows one to move the first three boom sections in the vertical plane while the end section of the concrete mix delivery pipe remains horizontal. Depending on the application needs, the boom can be controlled automatically or manually.

Another example of the automation of cranes is an automated crane for transferring and arranging reinforcement (Fig. 14.146), intended for work on nuclear power plant sites. It can lay reinforcement at a rate of 0.05 m. No workers are needed to suspend the reinforcement bars, which can be arranged both horizontally and vertically by the system. The crane's specifications are:

- Maximum load: 1500 N
- Operating radius: 2.5–10 m
- Height of lift: 15 m

The crane is equipped with a special device for gripping rebars. The lifting and placing of the first rebar is manually controlled. This operation becomes automatic for subsequent rebars.

In [14.53] one can find more examples of the automation of crane control systems such as a crawler hydraulic crane for dam construction and a tower crane for the automatic distribution of concrete mix during the erection of a high-rise building.

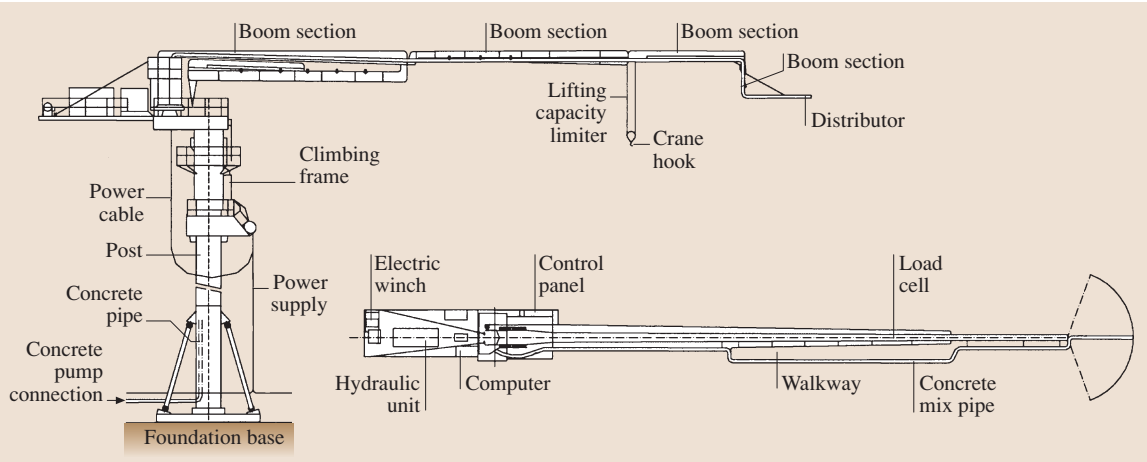

Fig. 14.145 Tower crane for placing concrete

14.8.5 Automation of Materials Handling and Elements Mounting by Mini-Cranes and Lightweight Manipulators

Mini-cranes and lightweight manipulators are used for materials handling, fitting building finishing elements, and transferring heavy construction equipment that cannot be moved manually. A radio-controlled mini-crane is shown in Fig. 14.147. The machine is intended for putting up aerated concrete block walls. This mini-crane with a three-sectioned telescopic boom has a lifting capacity of 500 N at an operating radius of 3 m. In its working mode the mini-crane is supported by four outriggers, whereas for relocation or transport it is mounted on a crawler chassis.

The crane can move up and down stairs and for transport can be fitted into a delivery truck. The crane's working dimensions are given in Fig. 14.147.

A lightweight manipulator designed for assembly work and transporting construction equipment inside buildings is shown in Fig. 14.148. Equipped with all kinds of attachments it can be used instead of interior work scaffoldings as a staging for ceiling work such as the fitting of lightweight beams, soffit, lightening, and heavy items. Its main advantage is that the position of the fitted element can be adjusted by means of the traversing and lifting gears operated from the handle attached to the manipulator's tip. Thanks to its small outer dimensions the manipulator can be moved through doorways and transported to different floors in the building's passenger lift. The manipulator has a lifting capacity of 150 daN and mass of 560 kg [14.53].

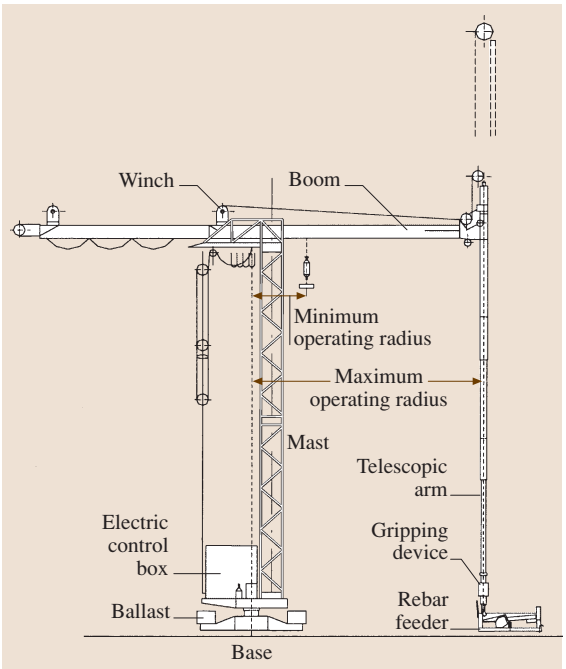

Fig. 14.146 Automated crane for transferring and arranging reinforcement

The offered mini-cranes and lightweight manipulators include:

- A mini-crane for fitting lightweight lining components, with a lifting capacity of 8000 N × 1.8 m, a lifting height of 5 m, a three-sectioned hydraulic boom, and a crawler undercarriage. It has an elec-

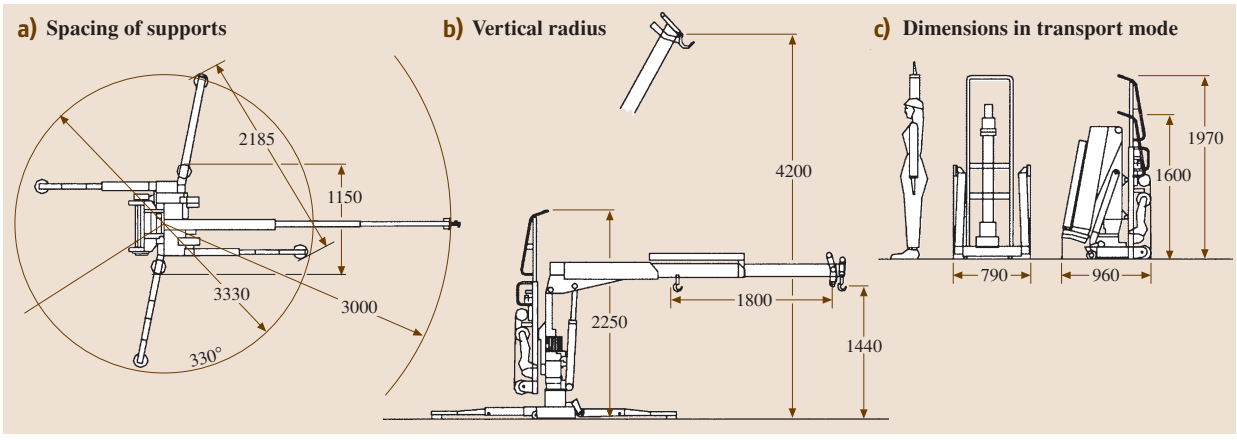

Fig. 14.147a–c Working dimensions of a mini-crane for erecting aerated concrete block walls: (a) spacing of supports; (b) vertical radius; (c) dimensions in transport mode

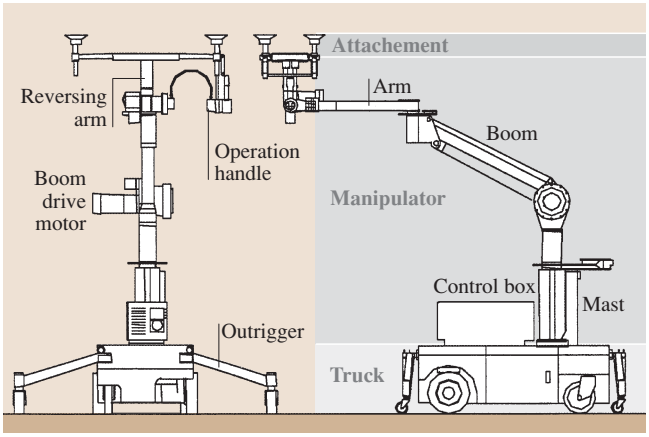

Fig. 14.148 Lightweight manipulator for finishing work

tric drive and a wired remote control. In order to make it possible for it to work in narrow rooms, the crane is equipped with a special mechanism, called the *dual-axis offset system*, which uses a combination of complex operations such as manoeuvring the winch while at the same time raising or lowering and extending or retracting the boom [14.53].

- A robot for transferring and positioning steel plates, weighing as much as 170 kg, used for reinforcing beams and columns in buildings located in seismic zones [14.53].
- A robot for fitting curtain walls made from panels, weighing as much as 250 kg, fitted between steel sections. The robot consists of a carriage with a wall panel gripping and transferring arm, positioning sensors, and a data-processing system which controls the fitting operation. The sensors on the arm determine the deviation between the appropriate position and the current one.

14.8.6 Automation of Construction Welding Work

Among construction welding work the welding of steel columns and beams is the focus of automation and robotization aimed at reducing welding work time and improving the working conditions of welders who, when hand welding on construction sites, are exposed to sparking, high temperature, and work at heights. The following devices for automating welding work on construction sites and prefabricating plants are available on the market:

- Robots for welding columns
- Robots for welding steel frames
- A device for automatic welding of girder braces

The robot shown in Fig. 14.149 is intended for welding columns together in steel construction. It executes horizontal multilayer welds. The whole column welding system consists of a robot with a wire terminal, rails attached to the column to allow the robot to travel, a control box, and a carriage for transporting the power source and a wire feeder.

The system also incorporates a welding control system. The shape of the weld between the columns is checked by laser sensors. The robot automatically selects the appropriate welding parameters from the system's database. By changing the shape of the guide rails and the control software the robot can be adapted to welding tubular columns.

Information about the steel frame welding robot and the device for automatic welding of girder braces can be found in [14.53].

14.8.7 Automation of Finishing Work

General Directions of Finishing Work Automation

A survey of the available literature indicates that automation and robotization are mainly applied to the following kinds of construction finishing work:

- Leveling, compacting, and smoothing concrete mix when making concrete bases

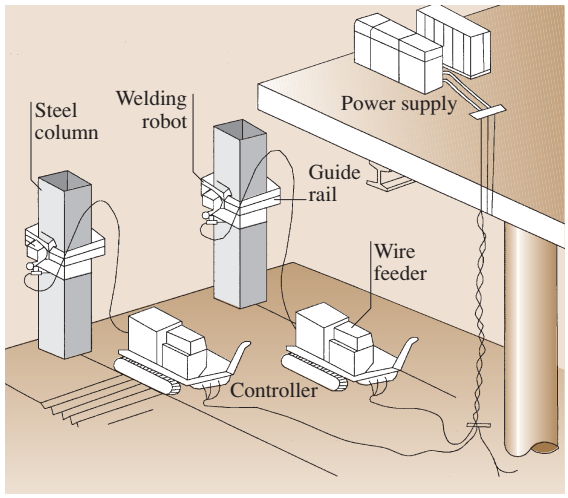

Fig. 14.149 Steel column welding robot

- Floating concrete bases and floors
- Painting
- Spraying fire-proofing materials on steel structures to protect them against damage by fire
- Laying tiles

Devices for automating the above finishing works are presented below.

Leveling, Compacting, and Smoothing Concrete Mix in Execution of Concrete Bases and Floors

Robots performing the function of a vibrating beam are used for precision leveling, compacting, and smoothing concrete mix when making concrete bases and floors.

The robot shown in Fig. 14.150 consists of the following units: a truss girder with a traveling mechanism, a working unit (composed of a leveling worm and a vibro-plate), saddles, and a control system. Leveling and smoothing are performed automatically by the working unit moving along the girder, i. e., perpendicularly to the movement of the robot. The maintenance of the base horizontal plane is controlled by a laser receiving set, an inclinometer, and a hydraulic cylinder, which automatically raises or lowers the working unit.

The robot is capable of leveling surfaces up to 15.5 m wide.

Another robot for screeding floors with a deviation from plane of ± 1 mm and a control system with two laser beam receiving sensors is described in [14.45].

Floating of Concrete Bases and Floors

The aim of floating is to impart smoothness to a concrete surface. Building floors on which fitted carpeting is to be laid must be floated.

Since the floating of concrete surfaces is often performed on construction sites, several types of robots controlled by radio or via an overhead conductor are offered [14.53]. Most of these are rotary floats with the working tools in the form of blades. In one exceptional model, six vibro-plates with a supersonic vibration frequency were adopted as the working tool. One of the models equipped with a traditional working tool in the form of rotating steel blades with an adjustable angle of inclination is shown in Fig. 14.151.

In the most common float models, the direction of the working travel is selected by appropriately inclining the floating disk, whereas the robot shown in Fig. 14.151 is equipped with a driving axle and an autonomous navigation system which allows it to determine its actual position and move along a programmed route (Fig. 14.152).

In order to program the robot it is enough to key in the dimensions a and b.

The robot is controlled via a wire. The travel control system consists of a microcomputer, gyrocompass, and a travel distance sensor. A touch sensor prevents the robot from bumping into obstacles. The robot's floating capacity is 500 m^2 per hour.

Painting

In painting work, robots are usually used to paint exterior walls. The next area where robots are employed is surface preparation for painting and surface preparation and painting combined.

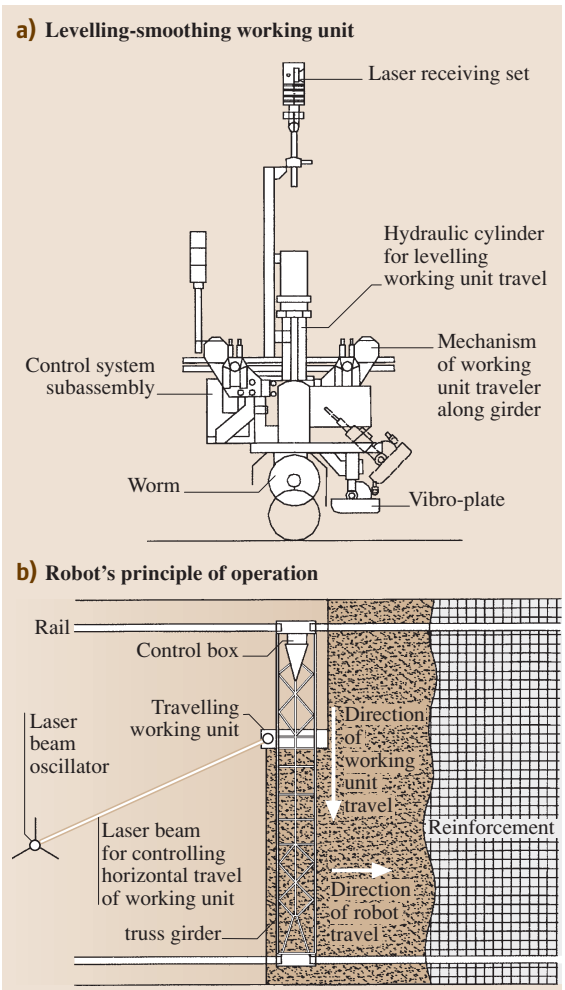

Fig. 14.150a,b Robot for finishing concrete bases and floors. **(a)** Leveling–smoothing working unit; **(b)** robot's principle of operation

One such robot for painting outer walls is shown in Fig. 14.153 [14.53].

The robot is mounted on a hanging scaffold and moves up or down and crosswise together with the scaffold.

Besides the scaffold and its drives and the robot itself, the system includes a control box, a control panel with buttons, monitoring equipment, and a paint-feeding unit.

The robot maintains a constant distance between the spraying nozzle and the building's wall. In order to apply paint uniformly, the nozzle's oscillatory motion is also controlled. To increase its painting capacity the robot is equipped with two spraying nozzles. The robot's average capacity is 200 m^2/h.

External-wall painting robots differ in their adaptation to construction site conditions (high-rise buildings with a complicated shape, or low buildings with simple design), and in their methods for reducing paint mist dispersion or eliminating unpainted areas. Paint can be applied by spraying nozzles or a roller. The preparation of a surface for painting consists of cleaning by means of a rotating cloth disk, with the dust being sucked off into a bag filter.

In the case of some robots, a surface is cleaned for painting by means of wire brushes or a shot-blast machine [14.53].

A robot for removing old paint prior to renovation painting removes paint using a jet of water flowing out under a pressure of 150 MPa. A pressure generator and a spraying nozzle are placed on a hanging scaffold attached to the wall by means of suction cups [14.53].

Spraying of Fire-Resisting Materials on Steel Structures

For fire protection the building's load-bearing structure must be coated with a layer of an insulating material – usually a 25 mm thick layer of rock wool. Because of the harmful effects of rock wool dust on the human body, workers manually spraying the semiliquid insulating mass must wear masks to protect them from inhaling harmful dust and wear special protective clothing.

Therefore it is vital to automate the insulating mass spraying operation and eliminate any direct participation of people in the application of the protective layer.

Two robots for coating structural beams with fireproofing mass are shown in Figs. 14.154 and 14.155.

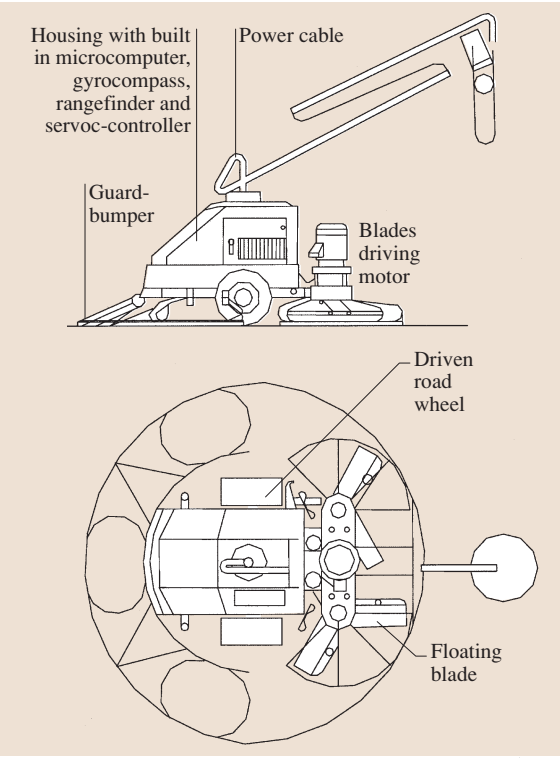

Fig. 14.151 Robot for floating concrete slabs

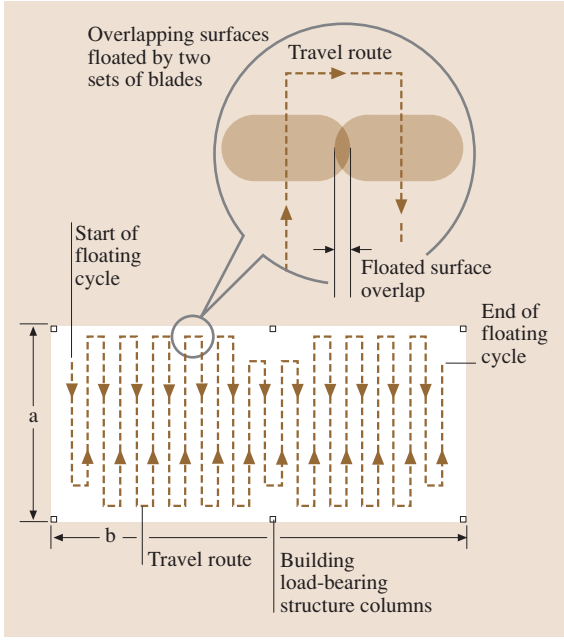

Fig. 14.152 Route of programmed robot travel in rooms with dimensions $a \times b$

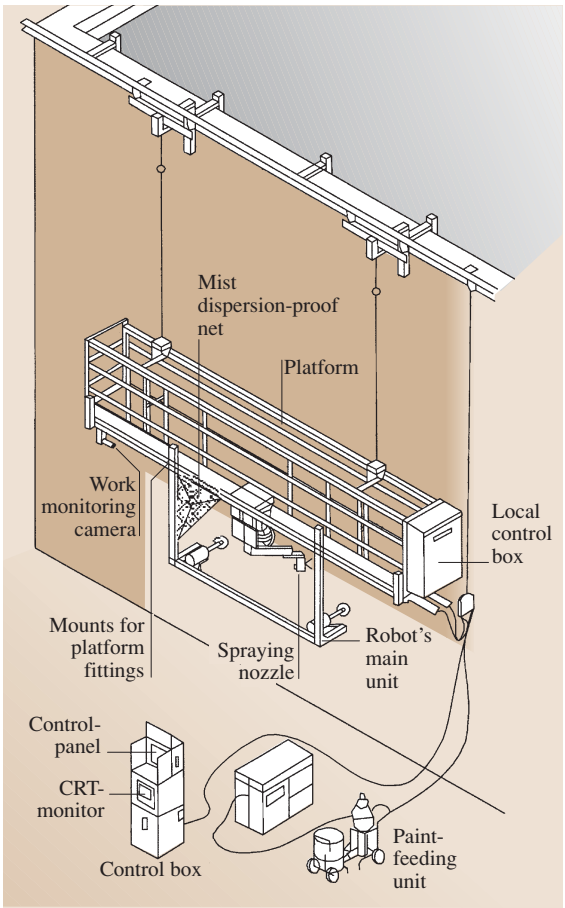

Fig. 14.153 Robot for painting exterior walls

The robot in Fig. 14.154 consists of two main fire-resistant mass preparation units (Fig. 14.154a) and the fire-resistance mass spraying robot proper (Fig. 14.154b). Once the beam's elevation and length are keyed in the robot starts moving, sensing its position by means of an ultrasonic sensor and spraying fireproofing mass on the section's bottom and sides. The spraying nozzle can be raised to a height of 2.8–4.4 m by means of a screw elevator. Special software makes the entering of robot operation data simple and easy.

The robot shown in Fig. 14.155 is intended for work in narrow rooms that are inaccessible to equipment operators. It consists of a carriage, an articulated arm with a spraying nozzle, and a control unit. The carriage has two sets of wheels: one for moving the robot longitudinally and the other for moving it transversely relative to the beam being sprayed with fireproofing mass. The articulated arm can rotate in both the horizontal and vertical plane and it can be moved to a distance of up 1500 m along the carriage's platform. Computer control enables the automatic combination of working motions for guiding the spraying tip.

Besides the described robots for spraying fireproofing mass onto structural beams one should also mention robots based on a typical industrial robot. An articulated arm with a spraying tip makes it possible to spray fireproofing mass on both horizontal and vertical surfaces [14.56].

Laying Wall Tiles

Laying tiles to form wall linings is an operation that is difficult to automate, mainly because of the requirement

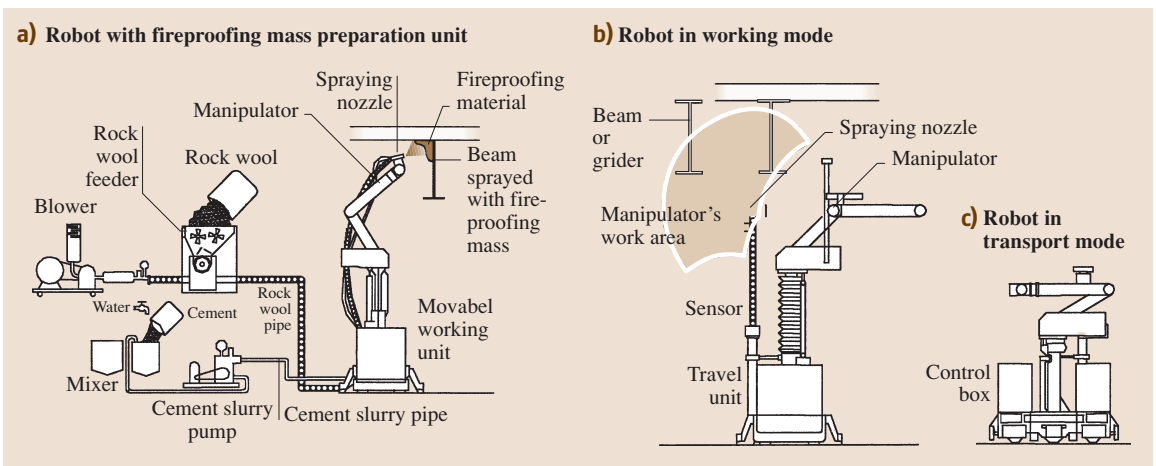

Fig. 14.154a–c Robot for spraying fireproofing material: (a) robot with fireproofing material preparation unit; (b) robot in working mode, (c) robot in transport mode

to spread adhesive or cement, which requires high positioning precision. Nevertheless, because of the large share of lining work in finishing work, attempts are being made to automate this field. Progress has been achieved by employing a rubber belt conveyor with suckers so that several tiles can be laid simultaneously. Tile-laying robots are mainly used for covering with large surfaces of exterior walls with tiles. A tile-laying robot moves on rails fixed to scaffolding. A robot for laying tiles on the building's facade, developed jointly by several Japanese companies, is shown in Fig. 14.156.

The robot is intended for laying 227×60 mm (8–15 mm thick) tiles on traditional mortar. Its daily capacity is 14 m^2. For comparison, a craftsman is able to lay 7 m^2 in this time.

More information about the robot can be found in [14.53].

14.8.8 Automated Building Construction Systems for High- and Medium-Rise Buildings

Automated building construction systems (ABCS) for high- and medium-rise buildings were developed in Japan as a measure to alleviate the labor shortage in the construction industry. Fourth-generation robots, designed according to the principle of design for robotic construction (DfRC) integrating robot design, building erection, and the materials, are employed for the realization of buildings in such systems.

Prefabrication of structural elements and adherence to the schedule of materials delivery to the construction site are of vital importance.

The benefits from using ABCS include: labor saving, improvement in work safety, and a reduction in construction time, stemming from the minimization of labor and protection against inclement weather (the working platforms are provided with roofing).

The following features of ABCS can be distinguished:

- *The automated transport of building structural components*, i. e., columns, beams, flooring slabs, and exterior walls from a storage place to the construction site (where they are built)
- *The use of prefabricated components* so that forming and working on the construction site are eliminated
- *Just-in-time delivery* of the required components
- *Automatic positioning and fixing of components*: the prefabricated components of columns and structural beams, floor panels, outer walls, and modular piping are automatically positioned in the appropriate

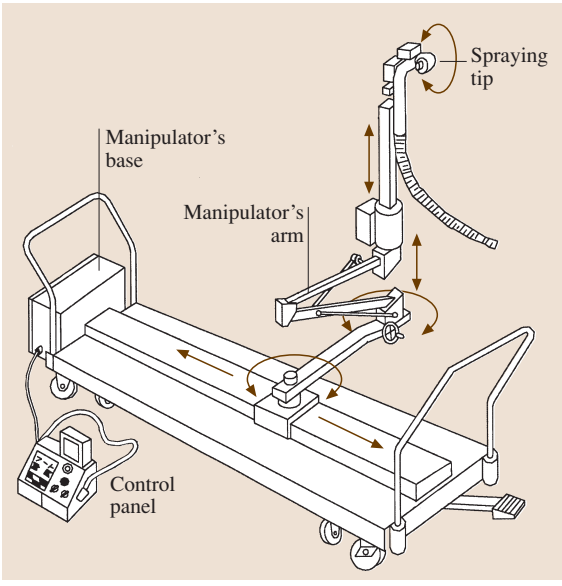

Fig. 14.155 Robot for spraying fireproofing rock wool mass in small rooms

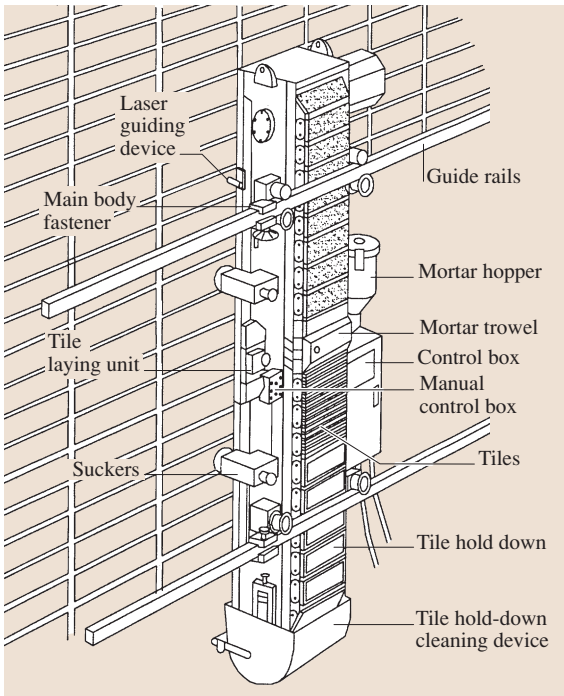

Fig. 14.156 Robot for laying tiles on building elevation

places, welding robots weld the structural components together, and the exterior walls are fixed by quick-connect fittings
- *Raising (by means of hydraulic lifts) of the support structure* with the suspended overhead cranes (the working platform) for the construction of the next storey
- *A building design that takes into account work automation*, sot that all building components and their joints lend themselves to automated transport and assembly

The existing ABCS can be divided into the following three groups:

- Those employing a special support structure (situated above the building structure under construction) for suspending overhead cranes and hoisting winches [14.57]
- Those using the roof structure or the top floor as the working platform for fixing transport-assembly equipment
- Those consisting of the construction of successive storeys on the zeroth level and the raising of the constructed part of the building

In all the above construction systems it takes 5–8 days to build one storey.

ABCS are used for erecting mainly steel-frame buildings, but also prefabricated reinforced concrete buildings [14.58].

Only a few of the many ABCS have stood the test of time and proved economically and technologically viable.

Selected ABCS are described below.

ABCS Employing Special Support Structure for Suspending Overhead Cranes and Winches

A construction system based on a special support structure for suspending overhead cranes and traveling winches during the erection of a steel-frame building is shown in Fig. 14.157.

The basic equipment for work realization in this system includes the support structure with a suspended

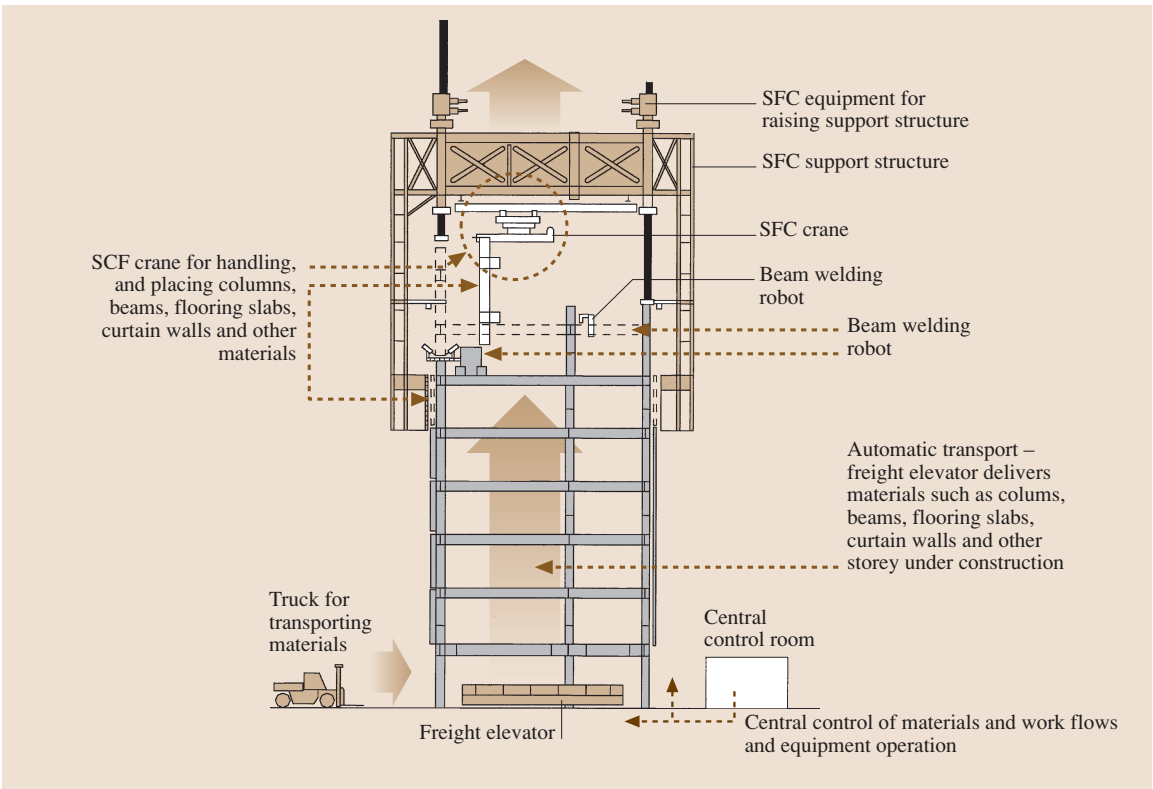

Fig. 14.157 Schematic of ABCS for erecting steel-frame buildings. SCF – the support structure with a set of equipment located on the top storey is called a super construction factory (SCF)

overhead crane and robots for welding the building's columns and structural beams. The support structure's weight is carried by the building under construction. The crane's operation is automated and coordinated with an elevator delivering materials in the appropriate sequence. Welding robots are attached to a floor or beams by one-touch fasteners. All operations are controlled from a central control room.

An ABCS for constructing buildings from prefabricated reinforced concrete slabs, referred to as *Big Canopy*, is shown in Fig. 14.158. This system has been developed by the Obayashi Corporation of Japan.

The special support structure, called a canopy, is supported on four corner posts.

Three assembly cranes and winches, each with a hoisting capacity of 7.5 Mg, are suspended from the canopy. Structural members are transferred to the storey under construction by a traveling crane, a fast building elevator, and a combination of overhead cranes and winches in order to provide access to the entire assembly area. The canopy is raised every two storeys.

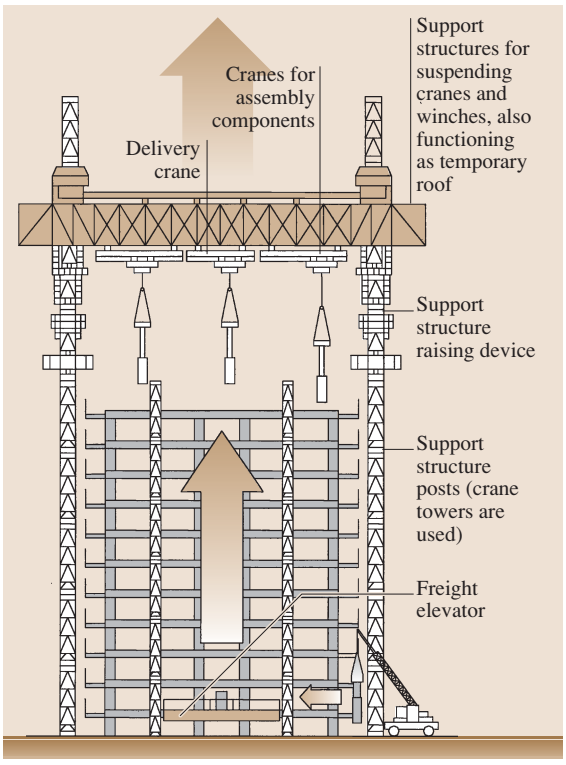

Fig. 14.158 Schematic illustrating the erection of a reinforced concrete building using the Big Canopy system from Obayashi Corporation

Finishing materials are transferred to the places where they are to be built-in during the erection of the load-bearing walls. The main part of the canopy is dismantled once the building reaches its full height, while its perimeter frames are jacked down and dismantled on the ground.

The automatic control covers the delivery of building components from the stacking yard, their transfer within the building, and their assembly. The components are identified by plates bearing a bar code which includes the position in the building and basic specifications.

ABCS Using the Roof or Top-Floor Structure as a Working Platform

Construction systems using the roof or top-storey structure as the working platform constitute the most numerous group of ABCS. A schematic of one such system which uses the top floor as the platform for the assembly of the steel load-bearing frame and reinforced concrete flooring slabs is shown in Fig. 14.159. The system is called the Shimizu manufacturing system by advanced robotics technology (SMART) [14.53, 59].

Construction starts with the assembly of a roof (hat-truss) and a special support structure for suspending overhead cranes and traveling winches The two structures are assembled on the ground and then jacked up using a system consisting of four tubular pillars equipped with lifting gears. A single lifting gear consists of two rings (the top one and the bottom one) and three hydraulic cylinders between them, each with a lifting capacity of 120 Mg and a working pressure of 12 MPa.

Once the roof is raised, the first storey is built. When it is completed, the roof with the support structure is jacked up one storey. Then the lifting system is also shifted up and supported on the load-bearing beams of the previously erected storey. As the individual storeys are constructed, structural building components (reinforced-concrete flooring slabs, interior and exterior walls, and utility systems) are fitted. Even though one storey weighs about 1200 Mg, it takes only 1.5 h to jack up the roof with the support structure and shift up the lifting gear.

In order to provide protection against bad weather the roof and the periphery of the storey under construction are lined with screens.

SMART embraces the automatic handling and assembly of building components, welding by robots, the raising of the roof and the structure for suspending overhead cranes and winches, protection against

adverse weather conditions, and a computer building construction control system. Because of its integration of the automation of the particular kinds of construction work with control systems, SMART is considered to be a state-of-the-art system.

Besides the described systems, several other systems based, among others, on the idea of constructing consecutive storeys on the zeroth level and successively lifting up the constructed parts of the building have been developed. Besides Shimizu and Obayashi, a number of other Japanese engineering construction firms have developed their own proprietary systems with similar functionality, e.g., Taisei, Kajima, Takenaka, Fujita, and others. Buildings up to 15 storeys high are erected with the use of these systems.

14.8.9 Automation and Robotics in Road Work, Tunneling, Demolition Work, Assessing the Technical Condition of Buildings, and Service-Maintenance Activities

This section provides a general overview of systems developed in this area and the reader is referred to the additional technical literature on the subject for further details.

Automation of Road Work

Automation and robotization of road construction and maintenance presents unique sets of challenges and opportunities, as described in [14.60]. Roadwork includes earthwork, concrete work, and other works connected with road trench cutting, road-base making, and the placement of pavement. In this section, only the machinery connected with the automation of pavement work is presented. It seems that automation in this field has focused on laying of asphalt mixture and road profiling.

Robots with all the pavement work operations automated are available in industry [14.53, 55]. The operations include transfer of asphalt mixture from delivery vehicles, feeding and spreading of asphalt, steering of the machine along a fixed route, paving rate control, and the start–stop control of all the operations. The asphalt paver operator does not need to pay attention to the loading of fresh asphalt mixture or driving the machine along a fixed route; their main task is to watch the screed to ensure that a high-quality pavement is obtained.

The asphalt paver's computer control system controls the following parameters:

- The thickness of the placed layer of asphalt mixture – the current paving thickness is displayed on the cab's monitor.
- The road profile – the operator can automatically change the paving thickness at one end or the other end of the screed.
- The uniform feeding of fresh asphalt mixture to the screed.

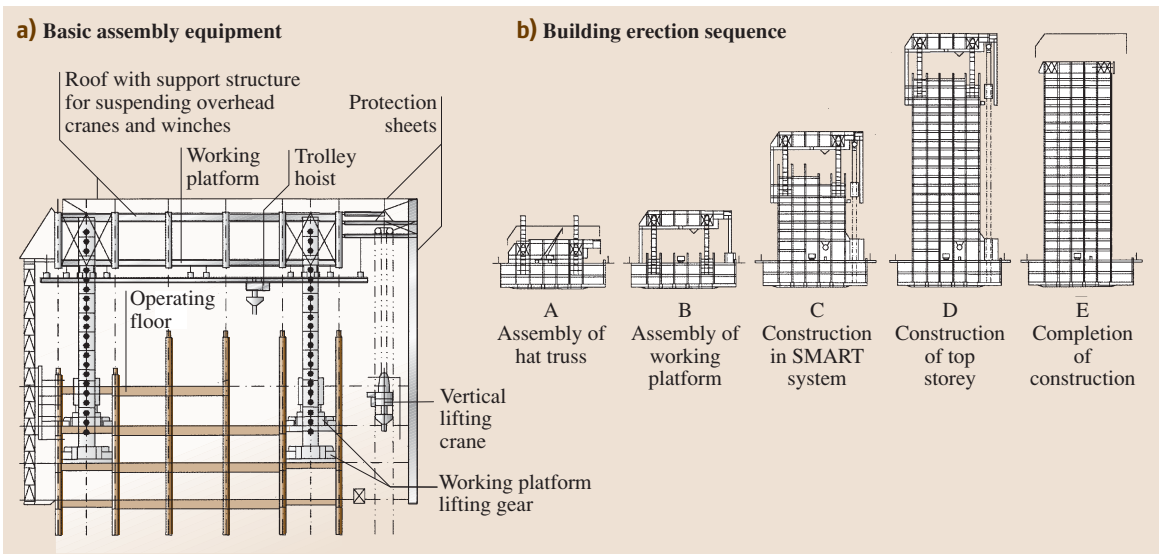

Fig. 14.159a,b SMART system for erecting steel-frame buildings: **(a)** basic assembly equipment; **(b)** building erection sequence

- The amount of crown.
- The uniform distribution of temperature on the screed.

Another machine is a hot in-place recycling machine intended for laying reclaimed asphalt pavements (RAP), which:

- Mills the pavement undergoing renovation, heated up by a preceding machine
- Prepares new asphalt mixture, which includes: reclaimed asphalt, fresh asphalt mixture delivered from an asphalt mixing plant, and chemical additives
- Lays a new layer of asphalt mixture

The hot in-place recycling machine consists of two separate, self-propelled units loosely connected by a conveyor. The set's front unit is composed of a feeder of fresh asphalt mixture delivered from an asphalt plant, a milling subunit, and a subunit for spraying additives. The rear unit consists of a reclaimed-asphalt pavement feeding and weighing subunit, a fresh-asphalt mixture batching unit, a mixer, and a subunit for laying new pavement. The two units move independently towards the destination, but operate in tandem.

The machine's automation covers: distance maintenance, the harmonization of the two units' driving speeds, the preparation of asphalt mixture, and feeding the mixture to the screed and laying it.

An example of a high level of automation is a road milling machine equipped with an automatic cutter control system (ACCS). With ACCS the machine can work in two modes:

- Contour-following mode, in which a constant cutting depth relative to the road surface is maintained
- Longitudinal and transverse contouring mode, in which the cutting depth is progressively adjusted to the required lateral differential

The cutting depth can be accurately adjusted to compensate for longitudinal and transverse unevenness in the pavement.

The cutting depth data for the road section to be milled are entered into the onboard computer, which automatically controls the position of the working tool in the selected operating mode.

Automation of Tunneling Work

The automation of tunneling is essential because of the hazard to people and the difficult working conditions, which are similar to those in underground mining.

The main aim of automation is to eliminate the presence of workers in the danger zone where they could be exposed to headwall landslides and inrushes of underground water in a confined space. Tunnel construction owes its rapid development to automation. The construction of municipal transport tunnels in urban areas, mini-tunnels for utilities (particularly for sewage pipes), and mountain tunnels for intercity transport is a major factor in the economic development of cities and regions. The general trends in the automation of tunneling work are presented below. Extensive information on tunneling machines and equipment can be found in [14.53].

The automation of shield tunneling covers the following operations:

- The automatic transport and assembly of prefabricated tunnel lining units, for which several systems of automatic lining transport and assembly have been developed for the different kinds of lining joints used
- The control of shield advance along a programmed route
- The complex automation of: tunneling, tunnel heading stability and shield advance control, output transport, lining assembly, and filling the space behind the lining with cement
- Shotcreting the lining's top layer reinforcement.
- Fabrication of reinforcement for the monolithic tunnel lining layer.
- Screeding of the top layer of the tunnel's invert.
- Transport and assembly of prefabricated concrete slabs for the tunnel's railway subgrade.
- Diagnosis of tunneling shield defects.

Most automation solutions are found in the areas of automatic transport and assembly of tunnel lining components and control of shield advance along a fixed route.

The automation in the construction of mountain tunnels covers the following aspects:

- Tunnel boring – when the start button is pushed the boring machine bores the ground in the tunnel's face, maintaining the tunnel's design cross section and following the fixed route with a high degree of accuracy. The available machine designs are capable of boring tunnels in hard and semi-hard rock without using explosives.

- The construction of a pre-lining (the pre-lining support method – PLS) to protect the tunnel face and adjacent structures against ground settlement; the pre-lining is made by excavating the soil around the tunnel face circumference and filling the slit with concrete; the PLS machine is equipped with a set of five augers or a chain cutter.
- The construction of another monolithic tunnel lining, using the vibration method to compact concrete mix.
- Tunnel face determination and marking prior to tunneling.
- Shotcreting of the lining's surface layer
- Determination of the position of explosive charges in the tunnel face
- Measurement and investigation of the fractured region and the strata in the ground ahead of the tunnel face
- Ventilation of the tunnel during its construction

A discussion of tunneling work automation should include the automation of mini-tunnelling. Mini-tunnelling is used in the construction of municipal sewerage and water-supply systems, gas grids, and so on without open excavations and the associated traffic problems. The technique consists of sinking two shafts (working chambers) at the start and end of the pipeline's route, boring a mini-tunnel by means of a tunneling shield, removing the excavated material, and forcing through pipes to form the mini-tunnel's lining (Fig. 14.160). The spoils can be removed mechanically (on conveyors) or hydraulically, being transported in suspension (partially recoverable). Equipment for boring mini-tunnels 250–4000 mm in diameter, running straight or curvilinearly, is commercially available. Mini-tunnels longer than 1000 m require intermediate working chambers. This technique can be used even in rocky soils.

Automation of Demolition Work and in Repairs of Building Structures

The aim of the automation of demolition work and in repairs of building structures is to increase productivity, reduce costs, and improve the working conditions of the laborers by improving their safety and reducing their physical effort. The devices presented below are used for crushing bricks, stones, and concrete, repairing cement kilns and metallurgical furnaces, and removing the surface layer of concrete in structures undergoing renovation. Several robots have been developed for these purposes. Depending on the size of the reduction tools, they can be divided into two groups:

- Robots equipped with mechanical tools, e.g., a hydraulic hammer
- Robots equipped with hydraulic tools using a high-pressure water jet

The two groups of machines have different ranges of application. Robots equipped with a hydraulic hammer and other fittings are designed for crushing building materials and for repairs, whereas those using a wa-

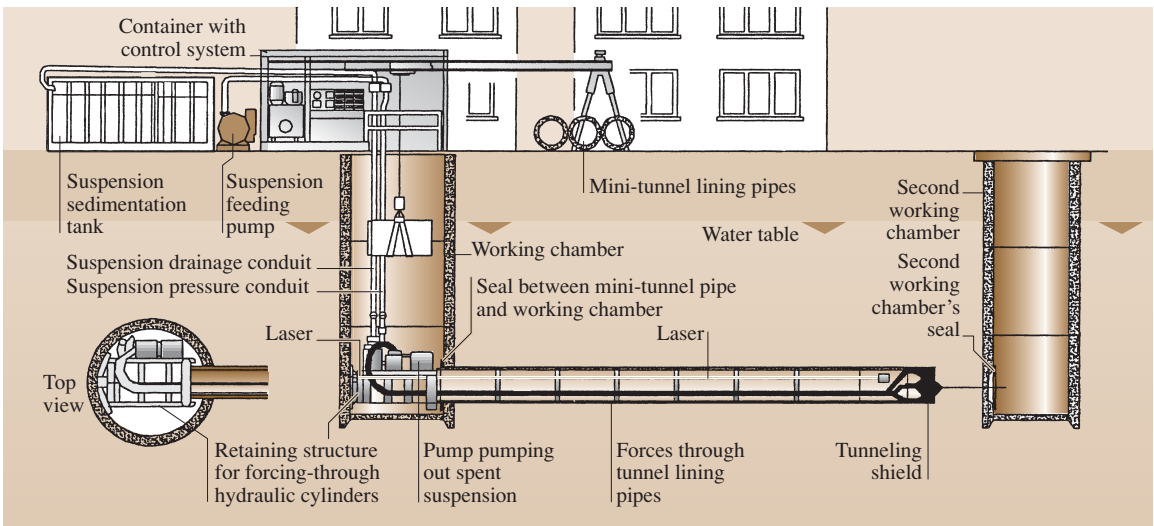

Fig. 14.160 Illustration of a mini-tunneling technique:

ter jet are intended for removing a damaged layer of concrete.

In the group of robots equipped with a hydraulic hammer one can distinguish, depending on the installed power and the tool's reach, small, medium, and large machines. Machines for small jobs are equipped with a 4 kW electric motor, medium machines have 11–15 kW motors, and large machines are powered by 22–30 kW motors. Their horizontal operating radius is, respectively, 2.4 m, 4.4 m, and 6.5 m.

These robots can be mounted on wheeled or track chassis. The robot shown in Fig. 14.161 is equipped with a 30 kW motor and electrohydraulic drives. Its three-sectioned boom allows one to accurately position the working tool within the operating radius. Apart from the hammer, the machine can be equipped with other working fittings: concrete shears, breakers, and pulverizers. The robot is remote-controlled from a portable control panel.

Instead of the electric motor, a diesel engine or a diesel–electric drive can be used as the prime mover. The boom's fittings include: a hydraulic breaker, crushing jaws, a loader or excavator bucket, and a gripping device. Detailed information about demolition robots can be found in [14.55].

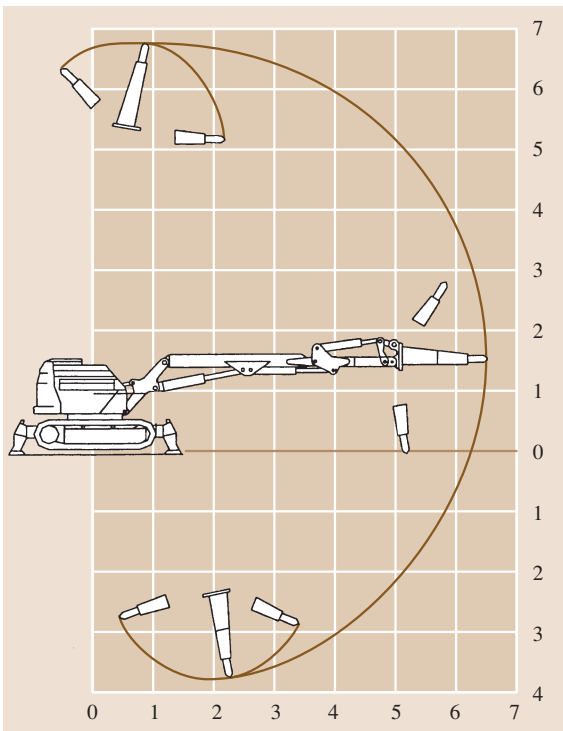

Fig. 14.161 Operating radius of robot with 30 kW motor for demolition work and material size reduction

Robots for Assessing the Technical Condition of Building Structures

Robots for checking the technical condition of building structures, referred to as inspection robots, are used for inspecting the following elements:

- Exterior wall facings
- Utility piping
- Concrete structures such as water dams and bridges
- Underwater structures

The most numerous in this group are tiled elevation inspection robots. Depending on their function, they check the adhesion of tiles to the base or check for layer corrosion. As time passes, adhesion decreases and, since the tiles may start falling off the wall, it becomes necessary to inspect the tiled walls at regular intervals.

A schematic of a robot for checking the adhesion of tiles to the building's elevation is shown in Fig. 14.162. The robot is drawn up on by a chain secured to the roof edge.

The check is conducted by continuously tapping the lining with ten small balls arranged in a row and analyzing the sounds generated. The diagnosis results, including the tapping locations, are transmitted to a computer on the ground, saved on a diskette, and represented graphically. The robot can also be used to assess the adhesion of plasters. It can operate at a rate of 700 m^2/day [14.53].

Besides tapping tiles with balls, other techniques are used to check the adhesion of tiles to the elevation, e.g., vibrating the wall and measuring the vibration characteristic. These vibration measurements are subjected to an analysis that differentiates between the frequency distributions of unstuck and adhering tiles.

Another inspection robot diagnoses layer corrosion of lining tiles. It moves on walls and is equipped with a tapping unit, a directional microphone, and an analyzer. Exfoliation is assessed on the basis of acoustic wave attenuation characteristics.

An automatic piping corrosion inspection system is intended for diagnosing the technical condition of cold and hot water systems. The inspection system can be used to check damage to 50–150 mm-diameter pipes. It measures wall thickness in a range of 1.5–9 mm by means of ultrasonic probes. A probe scanner mounted on a pipe automatically travels along the pipe, maintaining appropriate contact with it. A data processing and control unit controls the traveling and scanning move-

ments of the scanner and processes the data from an ultrasonic thickness meter [14.53].

Owing to the small diameter (150 mm) of its body and its four thrusters, a robot for the visual inspection of underwater structures can work in narrow passages, and even in pipes. A camera mounted on the slewing gear provides a wide view. The robot can work to a maximum depth of 30 m [14.53].

Depending on the user's needs, a robot for checking the technical condition of concrete structures such as bridges can be equipped with various fittings for:

- Nondestructive testing of structures
- Servicing and maintaining high-rise buildings
- Cleaning and renovating building elevations

The robot serves as a carrier for equipment and can climb vertical surfaces made of various materials. A special mechanism (with patented kinematics) with extremities in the form of vacuum suction cups [14.55] enables the robot to move on such surfaces.

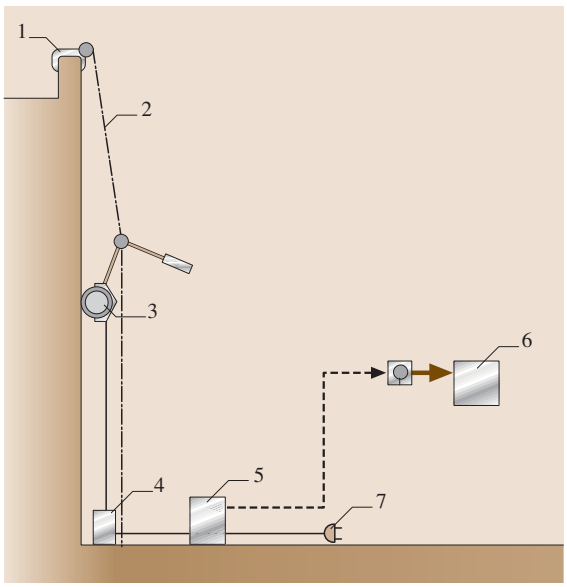

Fig. 14.162 Schematic of robot for checking adhesion of tiles to building's elevation (*1* securing robot to roof edge; *2* chain; *3* robot (hoisting gear motor and carrier of: tile adhesion diagnosing balls, analyzing circuit, and driving and communication control circuits); *4* power supply unit (performs various robot positioning functions); *5* winch controlling computer (position recording and communication control circuits); *6* output units (computer, *X*–*Y* plotter); *7* 100 V AC power supply plug)

Cleaning and Renovation of Building Elevations

Cleaning and surface-finishing tasks in buildings present a cost-effective opportunity for the application of robotics [14.61]. Several robots and automated devices for the cleaning and renovation of building elevations are available on the equipment market. Depending on the kind of elevation material (facing boards made from mineral materials, glass, etc.) appropriate renovation methods are used.

Elevations made from mineral facing boards are cleaned by blasting with an abrasive, by brushing or spraying with high-pressure water. Both the abrasive and the water are collected for reuse [14.53, 55]. Glass elevations are washed with hot water and detergents by robots equipped with sets of cylindrical and wheel brushes [14.55].

Room Air Cleanliness Monitoring

Room air cleanliness monitoring robots measure the following:

- The amount of dust in the air; in one measuring position the device collects three samples at different heights and determines the occurrence of dust divided into different diameter fractions [14.55]
- The room's environment characteristics (air flow, air pollution, temperature, and humidity) [14.55]

Cleaning of Construction Equipment

Construction equipment cleaning devices includes the following [14.62]:

- An automatic system for cleaning aluminum scaffolding boards
- An automatic washing station for cleaning the undercarriages of construction machines

The system for cleaning aluminum scaffolding boards removes concrete and dirt particles adhering to the board by means of high-pressure (40 MPa) water jets (Fig. 14.163) and ultrasonic vibration.

After washing with six high-pressure water jets the board is subjected to ultrasonic vibration. Fourteen vibrators are installed at the bottom of a large tank in which the board is immersed. In order to increase washing efficiency degassed water is used.

In the automatic washing station for cleaning the undercarriages of construction machines, washing is carried out in three stages: low-pressure water washing, high-pressure water washing, and low-pressure and

high-pressure water washing combined. The main components of the washing station are: water spraying and purifying equipment and a washed-out mud removal installation. Machine-specific automatic cleaning programs are used. All the pumps, the water purification circulation, and the removal of washed-out mud are controlled as a whole [14.53]. Force control of the robotic manipulator plays an important role in achieving successful automation of the cleaning tasks [14.63].

Surveying for Construction

Modern surveying techniques for construction are based on the global positioning system (GPS), which uses artificial satellites. The GPS has been upgraded so that it can be used in construction. The new surveying techniques are labor-saving and highly effective and do not require visual contact between the surveying stations. GPS surveying can be conducted across barriers, such as mountains or buildings, which make visual contact impossible. Moreover, surveying can be conducted in adverse weather conditions, such as fog or rain, 24 h a day, and with high accuracy.

The available surveying systems for GPS-based terrain projection use fixed datum points in combination with a mobile surveying station mounted on a truck or in the form of a remote-controlled crawler robot. Datum coordinates are transmitted to a point whose position is known [14.53, 56].

These surveying systems find application in the building of dams, roads, airports, housing estates, and so on.

Robot Implementation Issues in Construction

Construction is the single largest contributor to the national economies of most developed nations. However, the level of automation and robotization in this industry falls significantly behind that in manufacturing and many service-oriented industries [14.64]. Much of the predictions made in 1980s regarding the widespread use of robotics in construction by the beginning of the 21st century have not yet materialized. However, the core technologies and the prototypical applications of robots in a wide variety of construction tasks have been successful, as outlined in this section. Much research and development remains in order to reach the full application potential of robotics in this highly fragmented and diverse industry [14.65, 66]. New areas for future research in this domain focus on systems engineering work to redesign and re-engineer construction tasks and work sites to meet the capabilities of construction equipment. The theoretical foundations for this research were developed in the late 1980s and during the 1990s [14.67–70], but widespread support and investment from the construction industry in most countries, with the notable exception of Japan, is still mostly lacking. It is expected that the advent of applications of advanced sensor technologies and sensor networks, as well as integrated construction management systems utilizing enterprise resource planning (ERP) technologies and web-based project portals, for construction site instrumentation will contribute to significant growth of integrated, rather than single-use, fleets of robotics for application in this industry [14.69, 70].

15. Enterprise Organization and Operation

Francesco Costanzo, Yuichi Kanda, Toshiaki Kimura, Hermann Kühnle, Bruno Lisanti, Jagjit Singh Srai, Klaus-Dieter Thoben, Bernd Wilhelm, Patrick M. Williams

Organizations (derived from the Greek word *organon*, meaning *tool*) are instruments for enterprise objectives fulfilment. These objectives are to perform and produce products and services. Engineering and industrial production emphasize human-initiated, controlled, and deliberately executed combinations and transformations of resources by energy and information for the supply of market goods and products. Therefore organizations in engineering and manufacturing include the planned and purposeful action of human beings. In order to meet such objectives, formal groups of people with shared goals concerning transformation execution and output performance are configured.

Any arrangements of resources devoted to objective fulfilment constitute operations functions, or for short, operations. Technical devices can be provided to execute operations for transformation steps.

The amounts of labor involved can be coped with faster and with better quality by planned division into packages assigned to individuals for well-coordinated (repetitive) execution. For the individuals involved, operations represent tasks to be fulfilled. Combinations and syntheses of tasks and responsibilities in total constitute organization structures or parts of organizations.

In this section, the focus of our attention is on noncontractual and contractual types of collaborations among independent enterprises, pooling their core competencies to form so-called *enterprise networks*, aiming to achieve a common goal. The enterprise networks considered are composed of two or more partners collaborating under a variety of bilateral relationships [15.1].

15.1 Overview

Planning in enterprises is the definition of enterprise objectives and the anticipation of activities that are necessary to meet these objectives. In manufacturing companies, engineering focuses on transformations of materials into products and market goods by deliberate use of resources. Resource planning means the coordination of human experts, materials, technology, operations, and orders to be executed with the ultimate goal of tuning their operation. Plans (the result of planning), i. e., how all the objectives may be achieved by optimal setups and processes, may cover short-, mid-, and long-term planning horizons.

Logistics comprises all activities of planning, implementing, and controlling efficient, effective flows as well as storage of goods, services, and related information from their point of origin to their point of consumption. Seamlessly integrated logistics for the purpose of meeting customer requirements is the ultimate goal of logistics. Its achievement is generally restricted by the availability of resources, technologies, and capabilities. Recent cutting-edge research envisions logistic setups as part of a wider organizational context, as the organizational structures determine all activities and operations along the relevant value chains.

Organization and operations are studied by a number of disciplines. Relevant issues may concern technical, social, cultural, and economic areas. First scientific approaches originated in administrative, and later technical and economical, contexts as well as contributions made by organization theory. Later, efforts in sociology, psychology, political sciences, contingency theory, systems theories, and management sciences appeared.

Organizations (from the Greek *organon*, meaning tool) are instruments to achieve enterprise objectives. Enterprises and manufacturing companies emphasize organizational solutions for specific business areas, drawing results from all the disciplines and approaches mentioned above. For a given set of objectives there are most appropriate organizational setups for arranging groups of people. The clear distinction of these groups from their environments motivates the institutional meaning of the term *organization*, i. e., that they are all part of the same institutional organization. In this sense, organizations are institutions whose primary purpose is to accomplish established objectives. Rational organizational behavior is best achieved through defined rules and formal authority maintained by control and coordination.

For enterprises, the context of organizations and operations is a strategic field, as smooth, efficient operations are decisive for prosperous business development. Therefore these areas are the subject of substantial research progress and ongoing dynamic developments. Resource planning focuses on sequences of operations, which take up resources, time, space, and expertise in order to produce the intended outcome. Such sequences of operations – also called processes (from the Latin *processus*) – include all activities of analyzing, controlling, implementing, and improving, e.g., by harmonized sequences of operations (batch or flow mode) and arrangements of machines and equipment. A well-known result of elaborate process planning frequently referred to is the assembly line, based on detailed labor division and precise work flow design. All these basics of

the organization are outlined in the first section of this Chapter.

Moreover economic intentions result in objective systems favoring organizational setups for the repetition of tasks (the learning curve) by adequate design of task structures and job assignments. Individuals, facilities, and tasks are assigned in a manner consistent with the objectives, in order to obtain clear, unambiguous responsibilities, organization charts (organigrams), operations plans, and job descriptions are provided, representing the full description of a hierarchical organizational setup.

Less repetitive jobs, relying on fewer routines and therefore requiring more improvisation, require more flexible team organization principles, engaging self-organization and autonomous groups of skilled people. The teams as units may be orientated by (self-similar) subordinate objective systems that may be derived from the overall objectives.

Project organizations are very short-term structural setups for temporary enterprises, where task definitions, labor division, responsibilities, and objectives are supplied from scratch. Projects may be seen as independent organization types as well as embedded in other long-term organization structures.

Very widespread and widely applied descriptions of organizations envision companies' organizations or entire process chains as consisting of a set of linked skills and capabilities. All procedures and routines to support the efficient execution of process steps are considered to be a part of this process organization. Process organizations select and optimize alternative means to transform material or objects as well as technologies by using capabilities and competencies. Thus, evaluating, establishing, developing, shaping, and maintenance capabilities in order to ensure effective and competitive operations and processes generally represent key areas of enterprise organization. For efficient planning, checking, measuring, and correcting of the skills and competencies involved, indicators and benchmarks for best practice are particularly appropriate

Electronic data processing (EDP) has particularly triggered the development of organization and operations in enterprises. Software solutions as well as information and communication technology (ICT) implementations provide strong support for organizations as well as processes. Well-established logistics and procedures for planning and control have been made available as software packages for organization and operations management. The functions most frequently supported are accounting, enterprise resource planning (ERP), manufacturing execution (MES), and process control. Specific modeling languages and models of enterprises, organizations, and processes as well as software frameworks are used to provide formalizations and software codes. Organization and ICT may therefore generally be envisioned as complementary domains, profiting from each other's progress.

Driven by an ultimately competitive organization principle (lean production), industrial organization is actually subject to a paradigmatic shift. Fewer restrictions, faster development of markets, and the spread of technology have outdated familiar mass-production setups. Substantial efforts have been invested in overcoming the strictly functional principles of labor division in favor of dynamic organizational structures. Emphasis is placed on renewal of company culture, human-centered organization, and decentralized management. The common main feature is that human creativity and improvisation is given greater decision power. More flexible and efficient enterprise organization approaches have appeared, such as as agile manufacturing, holonic manufacturing, bionic manufacturing, and the fractal company.

Widening objectives and increasing demands for company know how, capabilities, and knowledge for engineering and manufacturing are the reasons for enterprises to loosen their organizational rules and open up their organization structures. New market opportunities, improved flexibility, quicker innovations, and better chances in local markets are the opportunities. Interorganizational structures in the form of virtual organizations, extended enterprises, or collaborative network organizations are the appropriate setups.

Aided by revolutionary ICT developments, such as the World Wide Web and global communication standards, instruments for the support of distributed organization structures are continuously improving; as equipment becomes mobile and wearable at work, individuals in industrial organizations may even work simultaneously and distributed globally on the same tasks. Communication and collaboration are now considered crucial skills in such distributed enterprise organizations. The collaborative networked organization, characterized by communication skills and totally networked structures, is emerging as an organization model for the future, in which instruments that support the collection and update of enterprise knowledge are of growing interest.

For decades the classical approach of an enterprise was to invest in the required resources and thus to plan

and realize production process by using its own resources. This has changed dramatically. Today no single enterprise is able to provide all manufacturing resources and competencies necessary for the realization of ever-changing customer demands.

There are at least three areas in which industry anticipates change and for which it must be prepared: shrinking margins, flexibility, and technology. Networked collaboration between enterprises merits greater attention. Current studies on this issue focus on important features for successful long-term collaboration (e.g., trust) as well as the management of knowledge.

As business relationships between companies and their distributed sites' complementary skills and manufacturing abilities become much closer, logistics is also affected. These changes cause the emergence of interorganizational enterprise structures, which themselves cause growth in the complexity of intra- and interenterprise logistics. Enterprise networks as a dynamic interenterprise configuration of manufacturing resources and competencies have become a promising alternative to provide required manufacturing infrastructure. Such networks include a whole range of processes in a value chain, as they do not only include supply operations of planning, sourcing, manufacturing, and logistics, but also product development activities such as research and development (R&D), innovation, product design, engineering, and customer-related activities of marketing, sales, and service.

The flow of parts through a production network has usually been preplanned by a central control system. Such central control fails in the presence of highly fluctuating demand and/or unforeseen disturbances, as is regularly the situation today. To manage such dynamic networks with low work-in-progress and short throughput times, autonomous control approaches are appropriate.

The application of autonomous control in production networks leads to a coalescence of material flow and information flow and enables every unit to manage and control its flow process autonomously.

Moreover such a strong focus on customer orientation with increasing transportation volumes results in higher supply frequencies as well as *atomization* of cargo into units. Conflicts in the objectives of logistic processes call for adaptive logistic process setups, which directly derives from changes in the production organizations.

Logistics service providers need to connect their information systems: interaction rather than integration is the means to connect. The use of agent technology and adequate organizational structures might enable these challenges to be met. Heterarchies and self-controlling units supported by multi-agent systems, intelligent load carriers, wireless communication, and ubiquitous computing are seen as the main ingredients of future logistics systems. The research work generally required in logistics planning is the transfer of methods for decentralized and autonomous control strategies that have been developed for production systems. Here too, autonomous control means decentralized coordination of intelligent logistics objects. These intelligent objects make autonomous decisions based on local information. The dynamics of such systems relies on the elements' local decision-making, generating the global behavior with newly emerging characteristics.

Since all intelligent self-controlling objects are elements in a network, information and negotiation are the results of collaboration. Therefore in logistics the greatest challenges to boosting competitiveness are concerned with organizational issues, rather than technical concerns. The design of collaboration is a fuzzy topic at best; however, one can gain insight into network design by analyzing the type of collaboration the company needs and the capabilities the company has to offer.

Bearing in mind these facts, Sect. 15.10 on enterprise collaboration and logistics places an emphasis on network and cooperation issues. Supply chain management (SCM) approaches have been considered to be useful, particularly for traditional industry where intelligent enterprise network setups are still viewed with caution. However, cutting-edge industry processes have advanced towards knowledge-driven supply network philosophies, which rely on collaboration and high-end ICT applications.

Analyzing typological issues of enterprise networks will support:

- Systematic problem analysis and solution synthesis with respect to cooperating enterprises
- A more structured view of the vast amount of possible real-life cases of industrial cooperation by characterizing these cases in a systematic way
- The analysis of cases and relevant types of industrial cooperation with respect to typical problems related to decision-making, production planning, etc.

Moreover competitive logistics includes efficient, accurate transfer of customer demands to the upstream supply partners and full interoperability between all partners. In spite of all the efforts to implement and operate technical and organizational standards such as as vendor-managed inventory, factory-gate pricing or col-

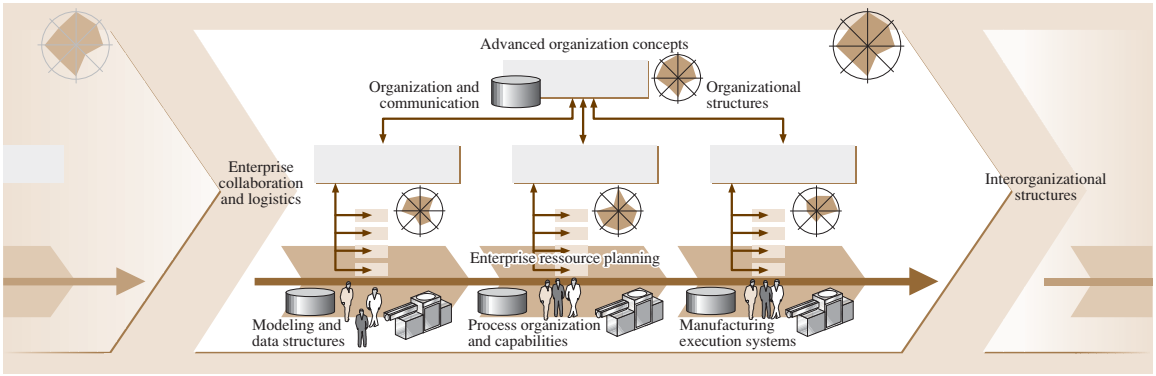

Fig. 15.1 Overview

laborative planning, forecasting, and replenishment, the key question for all partners remains: "Can I rely on my partners' information?"

In all trends underlying the dynamics of interfirm relationships, it is obvious that trust is a permanent and stable key element required to foster the implementation of any collaboration. Trust between parties involved in network activities therefore has to be considered as the key determining factor for achieving viable network outcomes. Trust, according to its various definitions, therefore plays a predominant role in the creation and development of networks. Finally, the Fig. 15.1 illustrates the main focus of the relevant topics discussed in this chapter.

15.2 Organizational Structures

15.2.1 Introduction

Enterprise organizations are large-scale social entities, where a certain level of standardization is favorable. The framework for this standardization, in which an organization defines how tasks are divided, how resources are deployed, and how departments are coordinated, is called the organizational setup. It includes:

- A set of formal tasks assigned to individuals and departments
- Formal reporting relationships, including lines of authority, decision responsibility, a number of hierarchical levels, and the span of managers' control
- Systems to ensure effective coordination of employees across units, e.g., departments

Organizations in industrial enterprises support the transformation of material and objects. Arrangements of resources devoted to these objectives constitute operations functions, or for short, operations. For the individuals involved, operations represent jobs. The job is generally the smallest entity within an organization, defining the finest degree of subdivision of tasks. Combinations and syntheses of tasks and jobs in total constitute organization structures, consisting of:

- Formal and legitimate rights of managers to make decisions, issue orders, and allocate resources to achieve organizationally desired outcomes (authorities)
- Duties to perform the tasks or activities that an employee has been assigned (responsibilities)
- People reporting and justifying task outcomes to those above them in the chain of command (accountabilities)

Manufacturing companies and industrial organizations differ from craftsmanship in terms of the complexity and larger numbers of the products they produce. Manufacturing therefore includes all human-initiated, controlled, and executed combinations of resources to provide market goods and products on larger scales. For the necessary operations and transformations, technical devices such as machines or transportation equipment are applied. Manufacturing organization and operations also includes planning, executing, and control functions for all units, performing

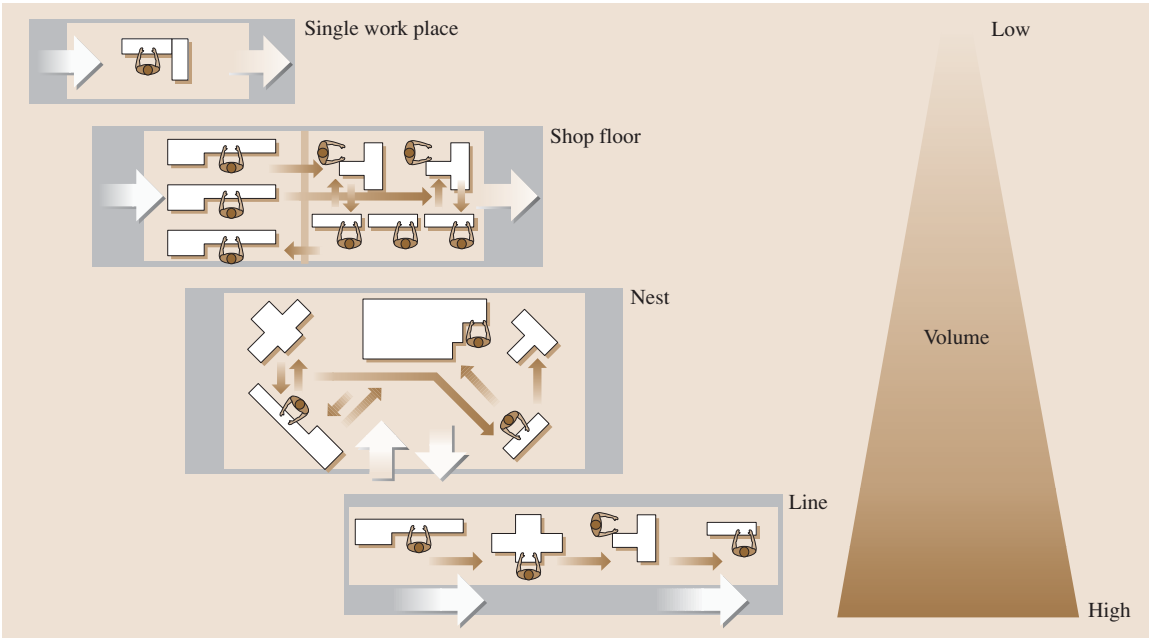

Fig. 15.2 Basic manufacturing principles

the supply, production, and maintenance of these products, goods, and services.

The basic idea of industrial organizations is to exploit the effects of multiple repetition of tasks (learning curve) resulting from labor division. This means the partition of task volumes between a number of workers, evoking the high level of specialization of individuals for a small number of tasks. Profound analysis and synthesis of all operations, functions, and tasks to be executed are the classical methods to determine the specialization requirements and the most favorable assignments of tasks to individuals, responsibilities, and technical equipment. As an information base, the definition of the sequences involved in each task, the design of the operations, etc. are established and used [15.2].

The task sequence plan prescribes all operations to be executed, e.g., assembly tasks, transportation tasks, and handling activities. The operations design specifies the operation steps to be done with more detailed descriptions (such as the machines to be used, the equipment and tools involved, machining and setup times, and qualifications needed) and order-specific information. The total information and data volumes are generally referred to as the bill of operations (BOO).

The German industry norm DIN 8580 [15.3, 4] defines and classifies important manufacturing operations.

Inputs for the definition and further specification of an operation are given by:

- Product
- Design setup
- Technology applied (technical process, time consumption)
- Volume to be produced
- Various additional parameters (material, geometry, mass, etc.)

Any sequences of operations are referred to as processes. The process definition includes all activities and instruments for analyzing, controlling, implementing, and improving industrial production under given objective settings.

Process procedures and routines of production are summarized by the term *process organization*.

Manufacturing principles describe the sum of all technological processes, designed for a volume of parts/objects, focusing on sequences of functions and geometrical arrangements (shop-floor layout) of the equipment involved (Fig. 15.2) [15.5].

Small series of a product are most frequently manufactured by applying the shop-floor principle, also referred to as the function principle, because it concentrates all machines and equipment executing identical or

Table 15.1 DIN terms and classifications for manufacturing operations

Manufacturing operation	Explanation	Examples
• Original forming (casting and molding)	• … is defined as the manufacturing of a solid body from unformed substance (metals are cast, plastics are molded)	• Extrusion, casting
• Further forming (mechanical forming)	• … is defined as a plastic change in the form of a solid body which does not change the mass or the cohesion of the body	• Bending, drawing, rolling, pressing
• Cutting	• … is manufacturing through changing the form of a solid body, thereby diminished its locally cohesion	• Turning, milling, grinding, sawing
• Joining	• … is defined as a process in which two or more bodies are linked, united, or assembled	• Welding, soldering, bonding, sticking
• Coating	• … is defined as a layer-adding process to spread a formless substance over a surface of a solid body, e.g.,for protection	• Painting, cladding
• Material property alteration	• … is the summary heading for various techniques to change material properties on the atomic level	• Tempering, hardening, quenching, nitriding

Table 15.2 Overview of the main functions of an enterprise

Procurement	Operations	Sales and distribution
Provides all goods and services necessary for the whole production process: – Raw materials – Supplies – Consumables	Comprises all kinds of operational goods and services, or is rather the realization of all intended measures for the fulfilment of operational tasks (immaterial as well as material goods). Goods and services contain immaterial and material goods	Appears at the end of the overall production process. The sale of products concludes the operational circle by initiating the reflow of cash resources
Integrating processes: provide the connections between the processing locations and fulfil the following main functions: – Transportation – Handling – Storage		
Securing processes: provide a smooth procedure for the main processes and fulfil the following main functions: – Quality assurance – Maintenance – Supply and disposal		

similar functions, e.g., milling, drilling, and coating, in the same location.

One characteristic of the flow principle is the arrangement of the equipment along the prevailing sequence of operations to be executed. The flow principle is initially derived from the product/object to be produced; therefore the term *product/object-oriented principle* is commonly used as well. Flow ideas date back to 1913, when Henry Ford introduced this principle to assemble cars, enormously increasing total effectiveness [15.6].

Production cells (production groups) concentrate all machinery and equipment covering sets of functions and technological operations necessary for the production of product or part families. Enriched by control, planning, and handling tasks, production nests have

Table 15.3 Overview of the enabling functions of an enterprise

Function	Description
Research and development	Methodical and systematic detection as well as determination and solution of causal impacts to enlarge technical knowledge
Procurement	Basically the following procurement objects are distinguished: – Operating resources – Raw materials and supplies – Staff
Production planning	Capacitated and quantitative planning of the entire production that should be realized in the upcoming period (resulting in a production programme)
Personnel planning	Providing the required employees to fulfill the following main functions: – Personnel requirements planning – Personnel procurement – Personal development – Personnel applications planning – Personnel discharge
Financial planning	Providing financial funds of any kind for the execution of operations functions
Scheduling	Supply of all the required documents for control and monitoring processes, which guarantee minimum expenditure for the manufacturing of products
Manufacturing	Production of geometrically defined solid objects by means of combining basic production factors
Assembly	Combination of individual units into modules or/and product
Marketing and sales	In addition to the name sales, other terms are applied in practice include distribution, selling, turnover, and marketing
After-sales service	Increases of customer loyalty by: – Efficient complaints management – Return of defect and surplus goods – General conditions for delivery and service (e.g., warranties)

good flexibility, high transparency, and short lead times. However, employees have to have high levels of qualifications and more skills; good levels of motivation and self-responsibility are expected.

At stationary work places a number of different functions and processes are performed on site, without having to moving the objects to be produced.

15.2.2 Enterprise: Main Functions

Generally the enterprise's organizational setup is visualized by using diagrams (organization charts) using principal functions descriptions such as procurement, operations and sales, and distribution, thereby integrating functions (e.g., transportation) and securing functions (e.g., quality assurance). These main functions represent aggregations of operations, therefore the terminology *main processes* is used as well [15.7]. The overall objective is to create value by planned input of resources. In this sense, the enterprises' main functions represent segments of value chains (compare Tables 15.2 and 15.3) [15.8].

Main functions and enabling functions are generally used for manufacturing companies. A frequently used organization chart by main functions is given in Fig. 15.3.

15.2.3 Organization and Tasks

Combinations and syntheses of tasks and responsibilities together constitute structures of organizations or parts of organizations [15.9]. For the individuals assigned, operations and functions represent tasks to be fulfilled. Task analysis decomposes comprehensive (en-

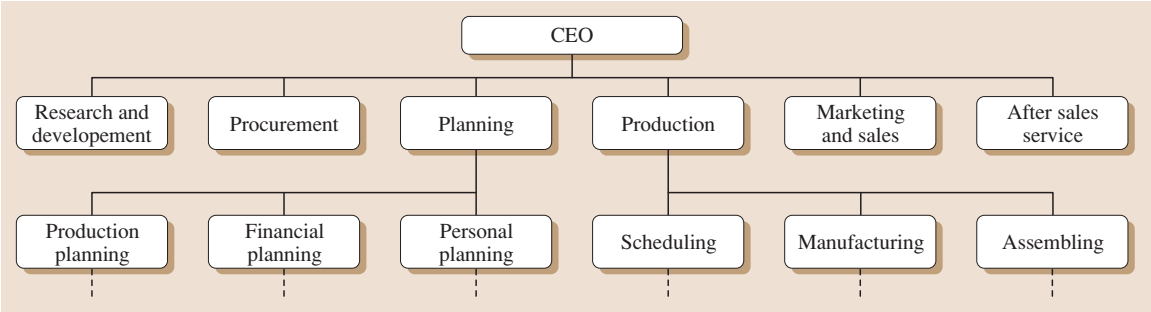

Fig. 15.3 Company main functions (overview)

terprise) tasks into subtasks and task elements. These task elements are to be assigned to task-executing units, e.g., persons, teams, and machines [15.6]. Using task synthesis, task elements are reconfigured.

Task Analysis

The overall tasks of an enterprise are decomposed by a multistage procedure into subtasks, to sub-subtasks, down to task elements, also known as elementary tasks, representing task volumes that cannot be broken down further.

The task decomposition principles may be based on the aspects of:

- Function/operation (purchase, sale, manufacturing, etc.)
- Object (products such as refrigerators and washing machines, or materials such as wood and aluminum)
- Phase (planning, implementation, control, maintenance, etc.)
- Rank (decision, operation, etc.)
- Purpose (administration, security, etc.)

Resulting task elements are linked to:

- Task-performing units within a company
- Predefined resource systems
- Available resources
- Time-dependent task volumes, execution, and fulfilment

Task Synthesis

In order to align entire processes, the analyzed subtasks and elementary tasks are clustered into sets to be assigned to units. The position (job) is the smallest unit within an organization. It includes resources and decision-making authority for resources required for the task's executions (Fig. 15.4).

Accurate job specification, demanding certain attributes and qualifications for people, can be seen as a permanent organizational challenge.

An organization involves continuous assignment of activities in the sense that labor, facility, and task elements have to be configured in such a way that the processes contributing to the overall enterprise task are supported.

A task is characterized by its

- Objectives, which should be achieved step by step
- The object to which the execution refers
- The time at which and time span during which the task is to be executed
- Responsibility (for when the task turns into an order)

In order to show clear, unambiguous responsibilities without interferences, additional instruments are provided, such as:

- An organization chart (organigram)
- Functional diagrams
- Job descriptions and documentation

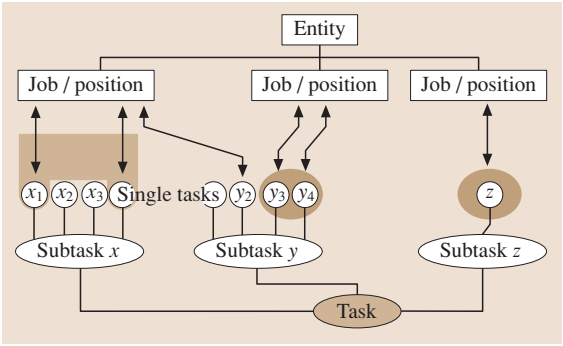

Fig. 15.4 Task analysis, task synthesis, and assignments to jobs

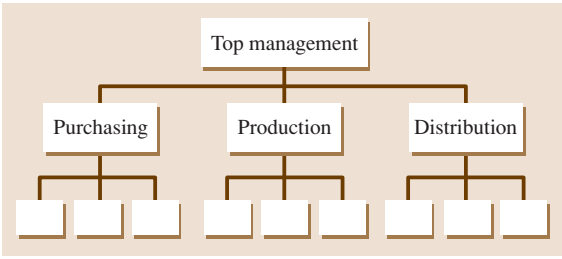

Fig. 15.5 Line organization

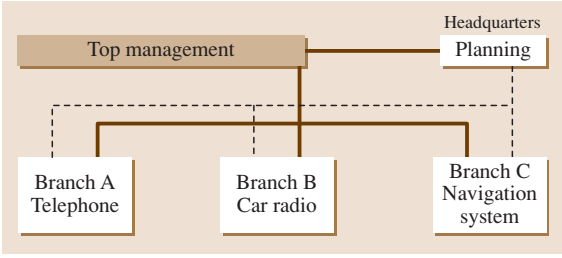

Fig. 15.6 Division organization of a consumer electronics enterprise

The collection of all these features represents a full description of an organizational setup.

15.2.4 Classical Forms of Organization

Line

Lines are derived from functions extracted from enterprises tasks, strictly hierarchically within one dimension. Orders are transmitted strictly top down, as are information and reports. Thus, an unambiguous one-dimensional information path between heads and subordinates characterizes this organization principle. Every person in the line has exactly one superior from whom they receive orders. The person is obliged to execute or pass on these orders and to report on orders' progress or status. The functional line, where the main functions of a company are structured according to the line principle, is a very common organizational setup in industry (Fig. 15.5).

Division

In this organizational form, the enterprise is decomposed into divisions, by products, product groups, services, manufacturing processes, customer groups, or regions. This object-related organizational setup allows object-oriented business units (as profit centers) to be set up within a company. Management and control is facilitated. Therefore the division structure is preferred by larger companies with diversity in production programmes (Fig. 15.6).

Matrix

The combination of the division and the line setup results in another important enterprise organizational principle: the matrix organization. Generally one hierarchy is *functional*, while another hierarchy is object-orientated, defining product responsibilities; neither of these dimensions is dominant. Matrix organizations are structures that are implemented for the manufacturing of a variety of complex technical products such as vehicles or electronic devices (Fig. 15.7).

Team

Teamwork is considered an organization structure without precise task assignment to individuals. Labor volumes resulting from rough task analysis are directly assigned to teams, where self-organizing teams take over additional tasks such as quality assurance and maintenance. By taking back the division of labor, individuals may execute more comprehensive and varying tasks. Collective responsibility for the intended

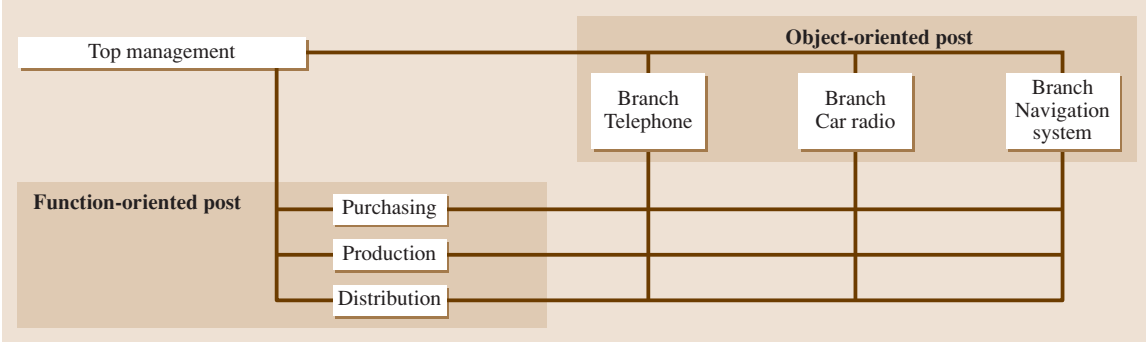

Fig. 15.7 Matrix organization of a consumer electronics enterprise

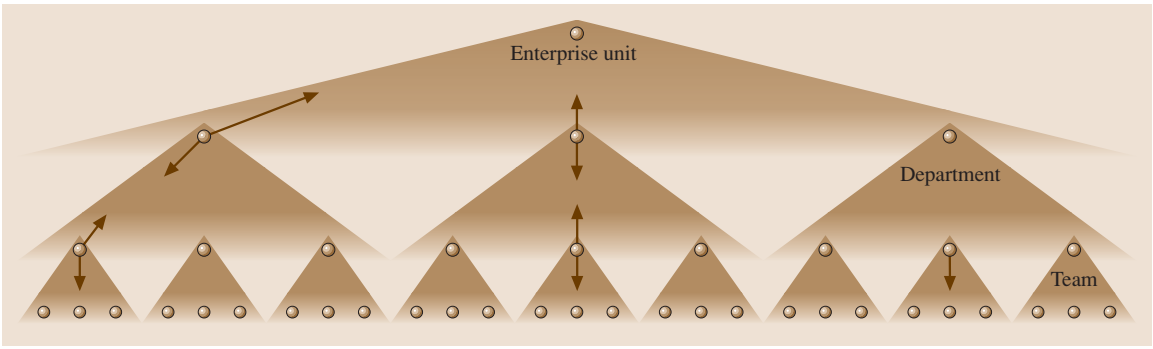

Fig. 15.8 Linked self-organizing teams [15.10]

outcome and the team members' qualifications may replace task planning and execution control. Over a longer period of time, teams implement norms and rules of behavior. Common objectives and close collaboration form the *team*. The team takes over the responsibility for the fulfillment of larger tasks (Fig. 15.8).

Teams can be classified according to their relationship to the main process areas as:

- Teams integrated in main processes
  - (Partially) autonomous teams
  - Production teams
  - Working groups
- Teams not integrated in main processes
  - Quality circles
  - Project teams

Teams and teamwork concepts offer advantages in situations where quick and flexible adaptations of structures are needed.

In cases where the enterprise tasks or task elements are subject to quick major changes, task analysis and task synthesis as well as assignments to individual responsibilities become impossible due to the lack of time and more detailed information. Teamwork or groupwork models have therefore been successfully applied in cases where speed and flexibility are required, and job enlargement (more tasks of the same type) and job enrichment (additional tasks) motivates employees [15.11].

Such process segments and the groups involved are able to reconfigure quickly (dissolve after an order, or take over a new task) and are frequently used for distinct products or for total responsibility for a project (Fig. 15.9).

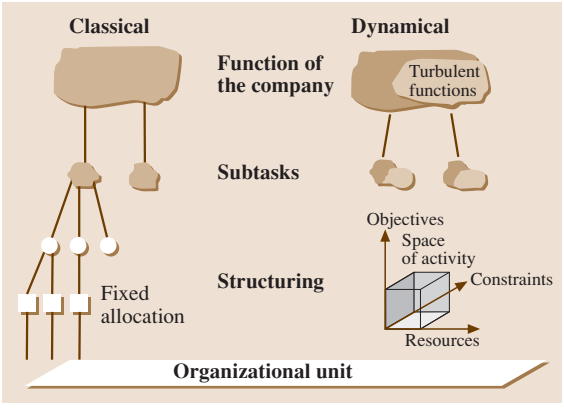

Fig. 15.9 From task assignment to process commitment

Segments and Fractals

High reconfigurability and flexibility require full commitment of all employees, which is supported by manufacturing segments. Manufacturing segments represent concentrations of machines and equipment for the complete execution of families of processes, i. e., similar processes for a set of products or product variants. Segments are an approach to combine the productivity of high volume with the flexibility of the shop floor. Segments are given a high level of autonomy (also known as *factories in the factory*), often run as cost or profit centers, in which wages are determined by output-related bonus systems [15.12].

Making even more intensive use of the advantages of self-organization, self-optimization, and dynamic team organization, the fractal organization principle decomposes the enterprise into objective-led small units. The fractal units negotiate objectives, benchmarks, and incentives, and decide on resources and working periods or operations within the assigned area. Processes are only detailed to ensure the definition of adequate unit (fractal) structures, which become totally responsible for process execution and outcomes. In combination

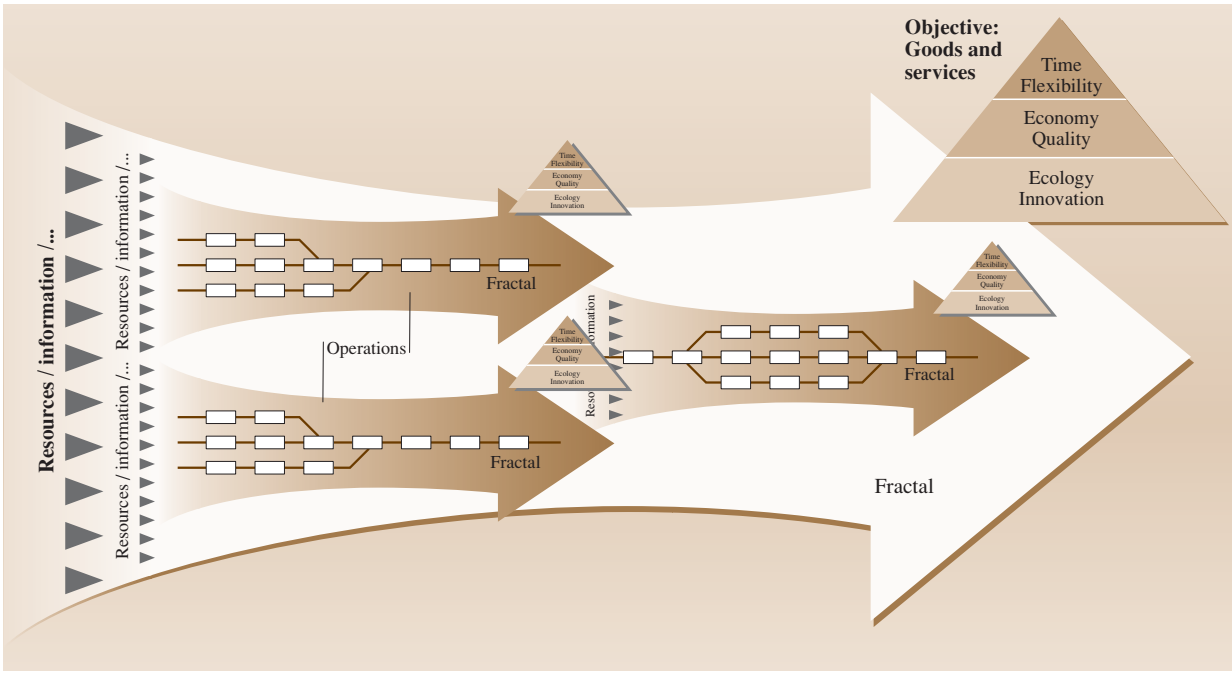

Fig. 15.10 Fractal self-similarity for objectives and processes

with incentives related to output and performance, such conditions may lead to high levels of motivation and continuous improvement [15.7]. An enterprise consisting of fractal units is referred to as a fractal company (Fig. 15.10 and Table 15.4) [15.13].

Project

Dynamic organizations are permanent organizational setups, focused on abilities to reconfigure and change over time. The setup and duration of a project organization however is limited and ends with the completion of the corresponding tasks or objects. A project is therefore a one-time task structure setup.

Project organizations are useful in various contexts. Examples are the development of a new technology, transforming organization setups, planning and execution of civil engineering objects, market introduction of new products or installations of data communication networks or software solutions in a company.

Project management includes all attributes of organizational leadership; its organization, methods, and instruments support the definition, execution, and success with respect to given objectives, including:

- Unambiguous assignments of tasks, competencies, and responsibilities
- Application of rationalizing systematic methodologies and decision support
- Ensuring information flows that support efficient and reliable decisions and controlling functions

Table 15.4 Features of fractals, the autonomous objective-led team units of an organization

Features of a fractal	Specification
Self-similarity	Fractals aim for enterprise objectives, broken down into units by negotiation
Self-organization	Operations and task assignments are done autonomously; fractals may restructure, regenerate, and dissolve
Self-optimization	The performance of all fractals is monitored for continous assessment and evaluation
Dynamics	Versatility enables coping with turbulent environment

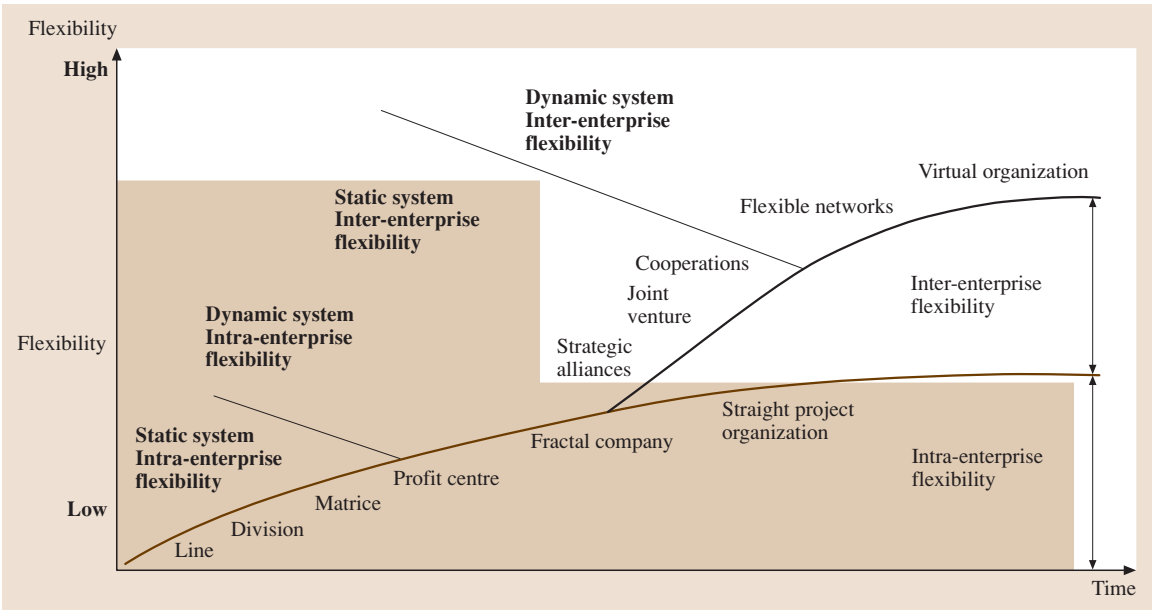

Fig. 15.11 Evolution of intra-enterprise flexibility (after [15.14])

- Building trust for collaboration within the project team
- Optimizing coordination of all units involved

Projects are defined and started in order to solve complex problems. Therefore a number of persons and units may be involved. In order to ensure that project objectives are met, projects have to be executed in a systematic way, emphasizing optimal coordination of all units involved in the corresponding phases [15.15]. A deliberate and well-prepared choice of the project leader/manager as well as the allocation of resources (front-end loading) is essential [15.16]. Project members should be assigned unambiguously to nonoverlapping tasks. Within an industrial organization there are basically three types of project implementation:

1. Genuine projects
2. Project coordinations
3. Project matrices

All of these types are characterized by a hierarchical setup. Figure 15.11 summarizes the above statements.

15.3 Process Organization, Capabilities, and Supply Networks

In general process organization defines and describes interactions between persons, equipment, and materials, executed tasks, and their fulfilment. In particular, it defines where (by which unit, by which working place) and when (in which sequence) which resources (persons, machines, etc.) transform the objects involved.

Trends point towards growing process orientation, increasing implementation of group and teamwork, and a focus on knowledge and organizational learning. Decentralized efficient units and teams reveal supplementary potential in industrial organizations and operations. Segments and product channels prove to be more powerful to cope with niche markets, in spite of possible conflicts concerning resources and management priorities.

Process organization engages flexible groups of people, including specialists across all relevant functions. Process chains describe the tuned (for a defined sequence) of process steps involving several functions. These functions are considered to be process chain elements, marked by sequence, utilized resources, op-

erations, and control. The combination of all of these function elements results in the total process, which is also referred to as the *value chain*.

Process capabilities are measures of the acceptability of variations of the process.

Usually variations in processes are interpreted as a statistical issue by engaging the characteristics of the normal probability distribution. Ambitious process capability objectives include *Six-Sigma* programs, implying 3.4 defect parts per million (ppm) and requiring elaborate instruments for process capability development.

15.3.1 The Capability Concept

Generally [15.17–19] capabilities are provided by a set of resources, networked together into a process (routine) for competitive advantage. The use of the term *capabilities*, describing firm competitiveness and business development, has a particularly rich history. The early literature on resources and capabilities has links with some of the seminal work on *rent creation* and the mechanisms to achieve this, the Ricardian perspective on *resource picking* and the Schumpeterian perspective of *capability building* [15.20]. The best usage of a firm's *bundle of resources* is discussed by *Penrose* in her original work, extending it to the area of firm services [15.21].

The resource-based view (RBV) perspective [15.17, 22] emerged in the 1980s, incorporating a broader definition of resources as a firm's *strengths and weaknesses*, and as any assets (tangible and intangible), that are semipermanently linked to the firm [15.22]. Others have suggested an all-encompassing definition of resources, such as "all assets, capabilities, organizational processes, firm attributes, information, knowledge etc." [15.23]. More recently, the resource-based view (RBV) has regained prominence under the basic premise that resources and capabilities provide the basic direction for a firm's strategy, and are the primary sources of profit [15.17, 24–27].

The term *capability* has been used interchangeably with a multitude of terms such as *strategic resources*, *organizational routines*, and *core competencies*, *meta competencies*, and these perhaps require some reflection as part of the historical context. Early RBV thinking suggested that the attributes of a firm's physical, human, and organizational capital that enable a firm to conceive and implement strategies that improve its efficiency and effectiveness are firm resources [15.22]. The separation of the capabilities element from the firm's *bundle of resources* [15.21] was captured in the seminal paper on core competencies by *Prahalad* and *Hamel* [15.28], suggesting that core competencies (essentially those capabilities that deliver competitive advantage) should provide:

- Potential access to a wide variety of markets
- A significant contribution to the perceived customer benefits of the end product
- A competence that is difficult for competitors to imitate

and that this is likely if the competence is a complex harmonization of individual technologies and production skills.

Barney [15.17] argues that the potential of *firm resources* to generate sustained competitive advantage is governed by four empirical indicators: value, rareness, imitability, and substitutability. Enterprise resources may be classified into:

- Physical capital resources (extended to include access to raw materials)
- Human capital resources: internal firm personnel, and also their relationships
- Organizational capital resources: reporting structures, planning, controlling and coordinating systems, and relationships within the firm and those with its environment

Two factors determine the value (*rent-earning potential*) deliverable from resources and capabilities [15.25]:

- Sustainability (in terms of durability, transparency, transferability, and replicability)
- Appropriability (the allocation of *rents where property rights are not fully defined*)

Various aspects of capabilities and resources in terms of value-creating potential have been developed, including: interfirm resource complementarities [15.29] (rather than similarities) that allow firms to learn new and valuable capabilities, combinative capabilities [15.30], and whether capabilities should be outcome focused, targeted at a particular desired end [15.31]. Alternative models identifying capability development approaches describe how competitive advantage may be created and sustained.

Teece et al. [15.32] recognized the need to extend the RBV into *the development and renewal of resources*

and by taking a *process* perspective involving the competencies of both internal and external resources. The focus however has been on the *integration* of external resources into the firm and the balancing of the resource mix as part of its development and renewal in a dynamically changing business environment.

Dyer and *Singh* [15.33] suggest that a firm's resources may span firm boundaries, and that these may be embedded in interfirm resources and capabilities. This *relational view* of interorganizational competitive advantage suggests an intermediate unit of analysis that sits between the *firm*-based perspectives in the extant and traditional RBV approach [15.17], and the *industry-structure*-based perspectives of *Porter* [15.26].

A parallel is drawn in the manufacturing networks arena [15.34], where there are specific capabilities of a network of manufacturing plants over and beyond those at the factory plant level. The evolutionary economics approach examines the implications of variation, selection, and retention. *Nelson* and *Winter*'s [15.35] framework is based on *routines* as the fundamental unit of analysis, and discusses their efficiency and effectiveness. Their definition of routines is indistinguishable from the RBV definition of capabilities.

Authors adopting the microeconomics approach have focused on measuring the attributes of firm resources and capabilities and correlating them with performance and, in the language of *Makadok* [15.36], form part of the *resource picking* school whilst others following the evolutionary approach form part of the *capability building* school of thought.

Capability concepts that have been developed in the 1990s [15.24] include:

- Superior rents derived from the ability to destroy and rebuild specialized inimitable resources or routines over time [15.37]
- Doubts cast on the stage theory of internationalization as new and small firms prosper (showing similarities to doubts about maturity-model stage-wise developments)
- Dynamic capabilities, i. e., specific processes that firms use to alter their resource base, as sources of competitive advantage [15.38]

The process-based perspective is given prominence by some authors [15.39], who argue that processes (and not resources) provide competitive advantage for the achievement of specific performance outcomes. This process perspective sits in between the RBV *barriers to imitation thinking* and the market forces approach (Table 15.5, based on [15.39]).

The concept of a capability lifecycle [15.40] has been introduced, incorporating the founding, development, and maturity of capabilities into several altered forms. This provides an interesting link to maturity models. Table 15.6 summarizes the key concepts, their evolution, and their implications for supply network operations.

15.3.2 Extending the Capability Concept to Processes and Supply Networks

The increasing reliance of firms on supply network partners for innovation, product replenishment, and service has complemented the traditional interfirm competition model with that of the competing supply networks model.

The evolution of the RBV therefore needs to take on board that the *organizational routines* span firm boundaries, and are not just about the interfaces within the firm, but that these network capabilities that provide competitive advantage may nevertheless follow the RBV tradition of being *rare, valuable, difficult to imitate, and not easily substitutable*.

Table 15.5 Resources, processes and performance outcomes

Operations				Markets
Resources ‘what they are’	⟷	**Processes** provide competitive advantage [15.21]	⟷	**Performance outcomes** ‘what they do’
BARRIERS TO IMITATION thinking Transform scarce resource to strategic resource (Wernerfelt 1984) Inside-out model approach (Hayes 1985, Ferdows and De Meyer 1990) Firm specific factors [15.19]				BARRIERS TO ENTRY thinking Competitive context (Anders 1984) Market influences (Hill 1984) Outside-in model approach (Miles and Snow 1984) Industry and market forces

Table 15.6 Perspectives on resources and capabilities – implications for supply network operations

Author/year	On resources	On capabilities (or routines)	Example of resources and capabilities	On competitive advantage/outcomes
Ricardo 1817	Some limited resources are inelastic	*Resource picking* (as an activity that takes place before resource acquisition)		Ricardian perspective on *resource picking* as a basis for competitive advantage
Schumpter 1950	Resource deployment and capability building	*Capability building* (an activity that takes place after resource acquisition)		Schumpterian perspective on *capability building* as a basis for competitive advantage
Penrose 1959	Tangible things (physical goods) and human resources … can be defined independent of their use (pg 24/25)	*Bundles of resources*	Resources are plant, equipment, land, FGs, WIP … and skilled and unskilled labor	Firms are *bundles of resources/services*
Nelson and Winter 1982/2002		*routines* are regular and predictable patterns of activity of the firm	Production routines, R&D, procedures, policies, … they are behavioral, inheritable, and persistant	Focuses on efficiency and effectivness of routines
Daft 1983	All assets, capabilities, organizational processes, firm attributes, information, knowledge etc. controlled by a firm that …		… enables the firm to conceive of and implement strategies that improve its efficiency and effectiveness	
Wernerfelt 1984	Any *strength or weakness* of a firm, … tangible and intangible assets which are tied semipermanently to the firm (Caves 1980)		Resources are machinery, brand names, in-house technology, efficient procedures, employment of skilled people, capital, trade contacts, etc.	Resource position barriers, attractive resources, supplementary (similar) resources, complementary resources, resource-product matrix synergies
Hayes and Wheelwright 1984	Structure/infra-structure?? (hardware/software – Slack 2005)	Structural and infrastructural capabilities of individual units (plants)	Structural elements are hardware/assets; infrastructural items are software/intangible assets	

Table 15.6 (cont.)

Author/year	On resources	On capabilities (or routines)	Example of resources and capabilities	On competitive advantage/outcomes
Prahalad and Hamel 1990	Key corporate resources include *Internal coordination and learning skills that cannot be acquired easily*	A competence that is difficult for competitors to imitate; … is likely if the competence is a complex harmonization of individual technologies and production skills	*core competences* are … coordination, learning, complex harmonization of individual technologies, and production skills	A *core competence* that is difficult for competitors to imitate
Barney 1991	Resources are the inputs, or basic units, that go into the *production* process	Capabilities (or potential competencies) of a firm are generated from a team of resources, networked together into a process (routine) for competitive advantage	Resources are assets, people skills, … capabilities are generated from a team of resources networked together into a process or routine for competitive advantage	Sustainable competitive advantage is possible if resources are valuable, rare, imperfectly imitable, and not substitutable; resource heterogeneity is a source of competitive advanatge
	Are *strengths* that firms can use to conceive of and implement their strategies	Physical capital (Williamson 1975), human capital (Becker 1964), organizational capital (Tomer 1987)		… strengths … that enable firms to conceive and implement their strategies
Grant 1991				*Rent-earning potential* from resources and capabilities governed by degree of sustainability and appropriability
Harrison et al. 1991/2001	Resource complementarity		Resource complementarity is not similarity	Resource complementarity allows firms to learn new and valuable capabilities
Barney 1992	Core competences focus on the technological and production expertise at specific points in the value chain	Capabilities are more broadly based, encompassing the entire value chain. They are visible to the customer.		Entire chain concept, visbility to the end customer

Table 15.6 (cont.)

Author/year	On resources	On capabilities (or routines)	Example of resources and capabilities	On competitive advantage/outcomes
Amit Schoenmaker 1993	*Component competence* terminology used to capture *resources*	Capabilities refer to a firm's capacity to deploy resources, usually in combination, using organizational processes, to effect a desired end	They are information-based, tangible or intangible processes that are firm specific and are developed over time through complex interactions among the firm's resources. They can abstractly be thought of as *intermediate goods* generated by the firm to prove	
Peteraf 1993				Supply inelasticity becomes a source of competitive advantage
Teece et al. 1997	Firm-specific assets that are difficult if not impossible to imitate	Dynamic capabilities as *the ability to integrate, build, and reconfigure internal and external competencies to address rapidly changing business environments*	Managerial processes and organizational (dynamic) capabilities	… the development and renewal of resources, and the integration and balancing of resources
	Assets are difficult to transfer … because of transaction costs, transfer costs, and that they may contain tacit knowledge			Internal and external resources, resource mix, internal managerial processes, resource development, and renewal
Shi and Gregory 1998		Networks of plants have additional capabilities that stem from their geographical dispersion, product and process structure/infrastructure		internal firm manufacturing network
Barney 1999	Superior deployment of internal resources is a necessary competitive requirement	Should be balanced by a broader perspective of assessing the relative capabilities of the firm and partners when formalizing the wider SC network		Realative capabilities of the firm and partners are an important factor

Table 15.6 (cont.)

Author/year	On resources	On capabilities (or routines)	Example of resources and capabilities	On competitive advantage/outcomes
Eisenhart and Martin 2000	Local abilities or competences that are fundamental to competitive advanatge	Dynamic capabilities, as specific processes that firms use to alter their resource base, as sources of competitive advantage	Resources are specialized equipment, geographic location, and human expertise.	Does not explicitly include spatial (geographic) dispersion
Winter 2003		An organizational capability is a high-level routine (or collection of routines) that, together with its implementing input flows, confers upon an organization's management a set of decision options for producing significant outputs of a particular type		
Lewis 2003	Strategic resources – as equivalent to capabilities – scarce, imperfect mobility, imperfect substitution/imitation (Wernerfelt 1984/1985)	Competence includes all resource and capability notions	Tangible (assets) versus intangible (Nanda 1996) resources	Processes (Penrose 1959, Nanda 1996) (and not resources) provide competitive advantage; resources ⇒ processes ⇒ performance outcomes (Martilla and James 1977)
Helfat and Peteraf 2003		Evolution of capabilities that encompass *operational* capabilities (collection of routines that directly contribute to production output or service) and *dynamic* capabilities (routines that build, integrate or reconfigure operational capabilities)	Parallels with PLCM. Use of terms widely used in maturity models … foundation stage, development stage, maturity stage, etc.	Introduces the concept of a *capability lifecycle*. Focus is on organizational and team capabilities (coordination) and not on the performance of individual tasks

Specifically, RBV theory promotes concepts that are, from a supply network perspective, incomplete as they are:

- Single-plant focused, i. e., their focus is on the structural/infrastructural capabilities of individual units [15.41] and they are not manufacturing network based
- Single-firm focused, i. e., not supply network oriented
- Internal assessments with few references to external network-dependent capabilities, i. e., they tend to focus on core (component) products, or internal managerial processes and organizational (dynamic) capabilities [15.32] and not multifirm (network) capabilities

The need for a more operational and network perspective of capabilities has been emphasized in the most recent literature:

Table 15.7 Supply network maturity models (adapted from *Srai* and *Gregory* [15.42])

Related cluster	Author	Maturity level 1	2	3	4	5	6

- The resource-based view (RBV) in which the superior deployment of internal resources as a necessary competitive requirement should be balanced by a broader perspective of assessing the relative capabilities of the firm and partners when formalizing the wider supply chain (SC) network [15.43].
- Networks of plants have additional capabilities that stem from their geographical dispersion, and product and process structure/infrastructure [15.34].

It may be argued that taking an external-to-firm supply network perspective challenges the basic premise of RBV of *internal resources*, perhaps adopting some elements of the external environment alluded to in Porter's competitive positioning work. However, by distinguishing between closely linked supply network partners and the organizational routines and processes between them, and thus removing *ownership* as an artificial barrier to what constitutes *available resources*, maintains the philosophical links between the RBV of the firm and the supply network capabilities of closely coupled partners.

Table 15.8 Supply network capabilities

Capability		Focus and key questions
Organizational capability	Focus	Traditional focus is at the firm level, team selection
(team focus)	Q.	Do we have the right organizational structure and people?
		Strive for optimum organizational structure.
Primary capability	Focus	Operates at the functional and cross-functional level
(outcome specific)		with a focus on process development and maturity
	Q.	Do we have the right processes?
		Strive for higher levels of operational process maturity.
Metacapability	Focus	Firm strategy, firm and supply network performance with the focus on primary-capability selection
(outcome specific)	Q.	Do we have the right capability sets (profile)? Strive for optimum business model. Is resource configuration a strategic variable?

15.3.3 Application Perspectives and Maturity Models

Maturity models have been used in a number of applications, in particular in the areas of business excellence models, software development, and process improvement, including in the areas of operations management, engineering, information technology (IT), and adjacent fields. They generally use qualitative assessments or *statements* to capture stages of capability *evolution*, but may also be supported by additional descriptive accounts and by quantitative measures. However, quantitative *performance measurement* across supply networks and across industry sectors is difficult [15.44], facing the combined challenges of consistency, context, and accurate key performance indicator (KPI) assessments. Consequently the various analytical tools struggle to discriminate the best from the rest.

In addition, alignment of operational capabilities with business goals is a key dimension that is not generally covered. The supply network capability map (SN capability map) capability map attempts to address these shortcomings by taking a holistic perspective of a broad set of capabilities. Five clusters of capability are identified covering supply network design, network connectivity, network performance, enabling process excellence, and new product development.

Table 15.7 summarizes, against each of the five supply network capability clusters, some of the related maturity models used in both the academic and practice literature. These maturity models vary greatly in their level of detail but have a common approach: the notion of stagewise evolution from a basic foundation level through to a leading-edge state of process excellence.

15.3.4 Operational Process-Based Capabilities

The extension of capabilities to beyond the firm, and to supply networks in particular, makes for a process-based analysis to capability development, as well as an outcome-based assessment at the strategic level. A central issue is the development of primary capabilities developed from established processes or routines. These processes are well recognized and are often difficult to implement, but are nevertheless standard routines. They have been embraced by a whole variety of organizations. Imitation, although difficult, is possible and generally practised. They include complex processes (such as Six Sigma, total productive maintenance (TPM), total quality management (TQM), and Kanban systems), processes that have been well documented. They are regarded as transferable processes or routines that in supply network terms exist within and between functions, and across firms.

Metacapabilities, on the other hand, or higher-order capabilities, involve selective resource picking, trade-off approaches to arrive at a particular set of primary capabilities (a particular capability profile). The selection process seeks to achieve a particular outcome or alignment to the business model, and thereby provides for a unique metalevel capability that is generally far less well understood. These metacapabilities are company (or supply network) specific, customer rel-

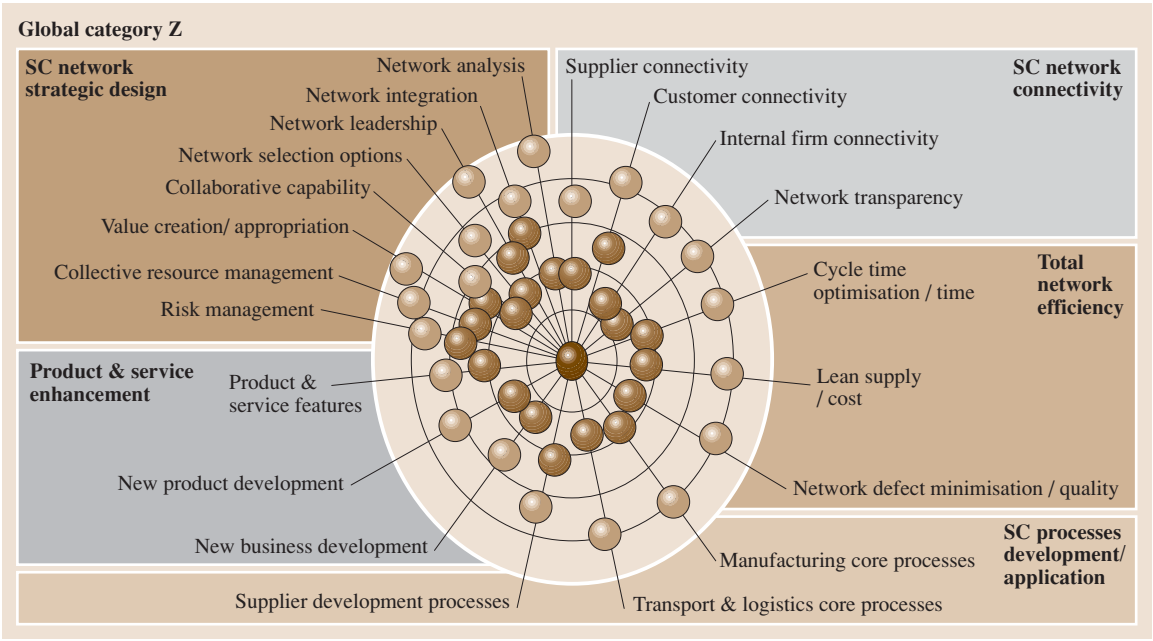

Fig. 15.12 Supply network capability map, actual versus business strategy (copyright [15.45])

evant, and business aligned. They have greater path dependency, team-dependent characteristics, and target-specific outcomes at the firm and network level. In theory, there are alternative methods for achieving similar outcomes by developing alternative combinations of primary capabilities.

Both primary and metacapabilities may be regarded as dynamic capabilities, as both evolve with time. The concept of dynamic capabilities working on operational capabilities [15.32] is not challenged in this view, and the concept of higher-order capabilities is indeed supported. However, rather than enhancing lower-level capabilities, the focus of higher-order capabilities is on overall coherency and fit with the business model, a process of selection and design for the *competitive advantage* or *outcome* that is being targeted.

In the case of primary capabilities, they mature through various stages of development, and their evolution (although difficult to achieve) is predictable. The stages of evolution in industry are captured by maturity models with well-developed processes for progressing through the various stages (compare Table 15.8).

With metacapabilities we introduce the *business model* or *outcome* approach, involving selective development of key primary capabilities to selected levels of process maturity. The overall capability profile becomes unique. Its development is less predictable and is much more difficult to imitate. Indeed the desire to imitate may be less, recognizing heterogeneity and path dependency factors, whilst the outcome will be a major focus of competitors.

15.3.5 The Supply Network Capability Map

The development of the SN capability map using the maturity model approach included the following design elements:

- The technique must maintain the business strategy/model relevance of the capability assessed.
- The definitions used should be broad and generic to have cross-sector validity.
- Increasing maturity is not necessarily valuable, as maturity is not an end in itself; rather an assessment is made of its alignment to business needs and the need to ensure a positive cost–benefit analysis.

In order to maintain a light-touch approach, five levels of maturity were used, each including description of key processes, level characteristics, systems deployed, performance standards targeted, and main activities, with only broad descriptions and limited detail on actual measurement and scoring (Fig. 15.12). The framework model, depicted as a radar chart, shows the primary supply network capability dimensions and their related

Cluster summary

Maturity level	1	2	3	4	5
Supply network strategic design	Accidental / initial	Repeatable	Defined	Managed	Mastered / optimised
Supply network connectivity	No coherent strategy	Piecemeal coordination	Systematic coordination	Network coordination	Cross enterprise alignment & collaboration
Total network efficiency	Baseline	Functional integration	Internal integration	External integration	Cross enterprise collaboration (industry leader)
SC processes developement / application	Baseline	(Reactive) problem solving	Systematic development programme	Network development	Cross enterprise collaboration
Product & service enhancement	Informal	Functional / formal	Project excellence	Portfolio excellence	Collaborative

Key: Achieved level | Current maturity level | Business SC target | Higher level of maturity

Fig. 15.13 Summary output: SN capability assessment

clusters. The five concentric circles represent the scale limits of one (inner) to five (outer).

A simpler summary table format is shown in Fig. 15.13. This has been found to be useful with regard to being more selective for areas in which to excel, moving beyond cost-based discussions with business colleagues, and the need to balance resources between maintaining continuous improvement activities and targeting new opportunities.

The model provides a holistic visualization of the network capabilities identified in the literature, and enables comparison with business strategy requirements and actual performance, allows consideration of trade-offs in supply network capabilities, and demonstrates the interplay of capability dimensions. The capability improvement task is itself strengthened using more process-based performance goals. The approach generates a capabilities profile and a gap analysis for a firm's supply network. The assessments are based on levels of process maturity, excellence models, and performance benchmarks. Opportunities and trade-offs can be assessed using processes that have both cross-sector relevance and practice history.

15.4 Modeling and Data Structures

15.4.1 Introduction

Efficient execution of operations and processes within industrial settings usually requires relevant information for all involved activities, providing instructions for how and when each activity, operation, or task must be executed for both organizational entities and the individuals involved.

In industrial production the relevant information will specify products (bill of materials, BOM) and processes (bill of operation, BOO). Based on these, production processes and the involved data processing are engineered and executed, often in an automated or semi-automated fashion.

Within the engineering as well as the execution of production processes electronic data processing (EDP) support is one of the key drivers for manufacturing and process organization developments. Engineering therefore increasingly focuses on formal design and analysis of enterprise organization structures and processes using a formalized representation of the information relevant within engineering and execution; for example, products may be embedded into an information flow from supply, through design, manufacturing, assembly, to distribution and sales. Methods of enterprise modeling support these complex tasks.

All main functions of an enterprise covering the application of relevant information, as men-

tioned above, may implement computer support through computer-aided design (CAD), computer-aided manufacturing (CAM), computer-aided process planning (CAPP), or production planning and control (PPC). Computer-integrated manufacturing (CIM) is the sum of the production systems information flows, managing all areas through central databases.

EDP has not only contributed to the support of organizations and processes, it has made technologies and information flows more *intelligent*, e.g., by integrating advances in information and communication technology (ICT) into the application/processing of relevant information. Examples are computer numerical control (CNC), net communication technologies such as field busses or industrial ethernet, advanced software design concepts such as object orientation and agent-oriented programming, and ontology-based contract protocols, to mention only some of the highlights of the last decade.

Interoperability requirements and the variety of ICT solutions, offered by increasingly modular setups of devices and software programs, highlight the importance of technical, ICT, and organizational standards, elaborated by national, European, and international institutions, engineering associations, and interest groups (e.g., the Institute of Electrical and Electronics Engineers (IEEE), VDI, ISO, and DIN).

To support the engineering and execution of operations and processes within industrial settings using EDP based on advances in ICT it is necessary to provide the relevant information in an electronically processable manner. Therefore, the relevant information has to be integrated into model-based structures.

These models separate the relevant information from the rest of the information available within industrial settings and structure it in a manner that abides by the requirements of EDP. They enables structured information collection, representation, and processing at all levels and for all purposes within industrial settings. Hence, models are an essential part of the successful application of EDP within industrial settings.

One important field of application of EDP-based information processing is the engineering and execution of organizational structures within industrial settings, i. e., the engineering and execution of business and business-like manufacturing processes.

In the following section we will discuss this field of interest with respect to information modeling-related terms, methods, tools, and models.

15.4.2 Definitions

The starting point of the consideration of modeling within the field of organizational structures within industrial settings is the term system *enterprise*. This can be described as a set of entities and a set of relations between these elements [15.46].

A *system* is defined as a *structured formation*, which is delimited or assumed to be delimited from the environment. It consists of a set of *elements* (parts) which affect each other due to fixed *relations*.

According to [15.47], there are various views to analyze systems thoroughly:

- The *functional view*, which understands system as an input/output system (I/O system) whereby the transformation of input data to output data describes the function of the system
- The *structural view*, which focuses on elements and relations between these elements
- The *hierarchical view*, which focuses on the fact that a system might be composed by a set of multiple subsystems and belong to a supersystem

According to [15.48] and [15.46] an enterprise can be understood as a system that is:

- Real (physical, observable – not theoretical)
- Open (relations to environment exist)
- Complex (large and continuously changing number of elements and relations)
- Probabilistic (prediction of future behavior has a certain probability)
- Artificial (created by humans)
- Dynamic (properties of elements and relations are variable over time)

A *model* of a system is a constructed, simply changeable, and easily understandable system that represents a hardly changeable, complex system regarding a certain problem or aspect. Therefore, only the corresponding relevant elements are mapped into the model. In general, models will only represent a subset of all the information that a system contains. Therefore, they are only projections of the original system to model systems that can be used to answer specific questions about the structure and behavior of the original system.

Various types of models can be distinguished. This distinction can be based on the set of questions that can be answered by a certain type of model as well as the viewpoint of the original system that they represent.

The first and highest-level distinction is related to qualitative or quantitative modeling. *Qualitative models* describe elements, relations, and properties *verbally*, i. e., they represent only dependencies among elements, relations, and properties without describing the level of dependency and the strength of the effects of these dependencies. In contrast to this, *quantitative models* express elements, relations, and properties by using *numbers*, i. e., they describe the strength of these dependencies among elements, relations, and properties.

Another high-level distinction between model types is the goal of model design, which distinguishes between models for description, explanation, and decision [15.49]:

- Descriptive models enable a black-box analysis of a system by providing a description of its overall behavior (data analysis).
- Explanative models enable an impact analysis of the relations between elements of a system.
- Decision models enable the evaluation of certain actions against the goals and constraints of a system.

Independent of the intended application domain of models or the set of questions to be answered by the model analysis the process of mapping the overall system information to the model system by selecting relevant information has to be well structured and to reflect the intended use of the model. This mapping process is called modeling.

Modeling is the creation of a model to describe the *structural design* of a system (*system synthesis*) and to generate methods (*algorithms*) for the evaluation of interesting system properties (*system analysis*).

The modeling process is generally iterative (i. e., a cyclic method with individual steps) consisting of:

- The definition of goals and system borders
- The definition of views for structuring of system
- The identification and modeling of elements and properties
- The identification and modeling of outer relations (relations to the environment)
- The identification and modeling of inner relations (between elements)
- The validation of system behavior
- The analysis of system behavior

Within the modeling process relevant information is collected based on the real system and modeling goals are defined, after which the modeling steps take place.

Once the model has been developed it has to be, on the one hand, evaluated and analyzed to validate or verify its correctness with respect to the intended viewpoint of the original system and, on the other hand, analyzed and interpreted to answer the addressed questions.

Based on this general modeling process, to set up *complex models* certain modeling methods have been introduced and have been proven to be useful. According to [15.50], a *modeling method* includes a modeling language (the syntax for model entities) as well as the rules for model design (the semantics of the model entities). A *modeling language* is characterized by a graphical notation and the description of the notation syntax. The rules for model design are described by the modeling steps, their fixed execution order and dependencies, and the results reached by the individual modeling steps (Fig. 15.14).

Every *modeling method* is based on a proper set of rules and expressions, i. e., model design rules and steps and modeling language constructs, for:

- Model design and model adaptation
- Recognition of reality and its design (the author's view)
- Decrease of risk and cost reduction (the user's view)

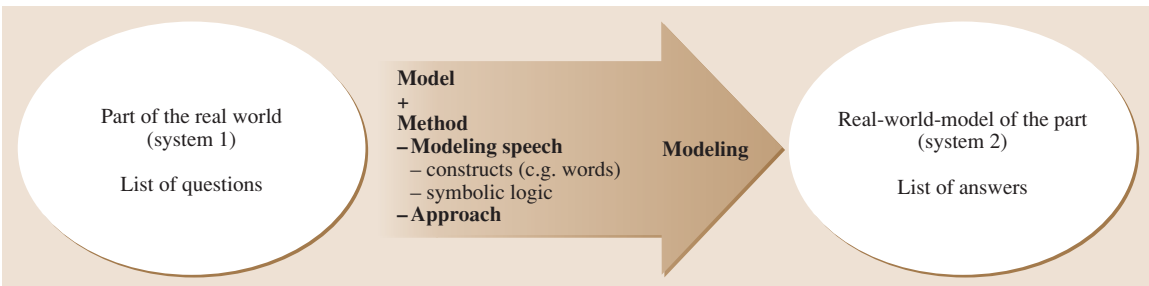

Fig. 15.14 Distinction between model, method, and modeling language

Modeling languages and modeling methods provide the basis for modeling technologies. While modeling languages define the syntax of models, modeling methods define their semantics.

To increase the applicability of modeling languages and modeling methods and reduce modeling risks and costs, reference models are used. A *reference model* provides the structures, properties, relation, and behavior of objects of an application domain in a general and usable form, supporting the creation of *specific models* by adaptation. Usually, reference models consist of various submodels or views, describing the modeled facts in varying levels of detail, and varying points of view on the original system [15.51].

Often-used viewpoints are the static structure of a system and the behavior of the execution of the system to be modeled.

The benefits achieved due to usage of reference models are:

- The recognition of weak points and the resulting improvements
- The documentation of existing workflows
- The standardization of terminology

A special type of a reference model is an architecture. An *architecture* defines the basic structure of a system resulting from a set of complementary and superimposing substructures and partially complementary viewpoints on the overall system. The architecture determines the structure of a system using two layers. On the one hand, the architecture establishes the model of the regarding system. Thus, it defines the object layer. On the other hand, the architecture defines rules that have to be considered during the development of the system [15.52].

Modeling architectures, as the most powerful but also most application-domain-oriented technology, form the top level of modeling technologies. They provide sets of models with fixed modeling syntax as well as model semantics related to the application domain. Thereby, they enable fast and efficient model system design and analysis by adapting inherent reference models to the original modeled system.

15.4.3 Guidelines of Modeling (GoM)

As mentioned above the modeling process requires a well-structured organization and well-defined inputs and outputs to reach the modeling objectives of providing a view of a system to answer dedicated sets of questions.

A framework to ensure the objectivity and correctness of modeling is provided by *guidelines of modeling* (GoM), the goal of which is to provide design recommendations for modeling to improve the quality of models beyond the matching of syntactic rules [15.51]. The guidelines of modeling (GoM) are given as follows:

- General principle of correctness:
  - Correct reflection of the mapped issue (semantically, the described structure/described behavior; syntactical, the consideration of notation rules)
- General principle of relevance:
  - Documentation of the relevant issues regarding the respective view
  - No mapping of irrelevant information
- General principle of efficiency:
  - Modeling activities shall be performed with a suitable cost–value ratio, e.g., through the use of reference models and support of reuse
- General principle of clearness:
  - Structure
  - Clarity
  - Readability (intuitive)
- General principle of comparability:
  - Comprehensive application of modeling rules
  - Goal: consolidation of independently created (sub)models
- General principle of systematic setup:
  - Well-defined interfaces to corresponding models (e.g., input data of the process model/reference to data model)

Applications of models are constrained by the method chosen for modeling. Models and methods cannot be combined arbitrarily. The following applications are available as modeling methods:

- Description of functional structures (aspects of operations in production systems)
- Mapping of functions and specification of organizations (system analysis)

15.4.4 Important Models and Methods

In this subsection examples of architectures, reference models, as well as modeling languages and methods relevant within to the field of organization modeling will be described. Thereby, the main characteristics of the different levels of model system design supported by them will be emphasized.

Modeling Architectures

Modeling architectures provide the possibility to model the original system by describing different points of view within different models, all of which are equipped with a predefined syntax and semantics of the model entities.

In the following the three architectures relevant for modeling of organizations and organization structures are described: the architecture of integrated information systems (ARIS), the generalized enterprise reference model architecture and methodology (GERAM), and the computer-integrated manufacturing open system architecture (CIMOSA).

ARIS. The architecture of integrated information systems (ARIS) is a modeling framework of methods for systematically developing enterprise application systems. ARIS is designed to reduce the complexity of enterprises.

This is done by separation into five specification views: the organization, the data, the control, the function, and the performance. This differentiation allows the application of specific methods for each view without having to consider the relationships to other defined views (Fig. 15.15).

Additionally, according to the general lifecycle concept, specification methods for information systems are used. The layers of specific concepts, data-processing concepts, and implementation describe an economical issue from the emergence of a problem to technical implementation. Through specification views and layers, ARIS defines an architecture in which selected proper (known) modeling methods are combined to a holistic method of business modeling [15.54].

GERAM. The generalized enterprise reference model architecture and methodology (GERAM) is understood as a *toolkit concept* for business process planning and design over the whole lifecycle of an organization. According to the IFIP-IFAC (International Federation for Information Processing, International Federation for Automatic Control) Task Force and ISO/DIS (Draft International Standard) 15704 [15.55,56] GERAM provides a pragmatic approach for a holistic framework to describe business processes due to different business development processes (e.g., founding, reorganization, fusion, re-engineering, setup of a virtual enterprise or supply-chain integration).

In this sense, all necessary elements are described; standards for tools and methods are set for useful accomplishment of integration and changing processes.

The basic reference model architecture provides an analysis and modeling framework based on the lifecycle concept that identifies three dimensions for defining the scope and content of enterprise modeling:

- Lifecycle dimension, providing a controlled modeling process of enterprise entities according to the lifecycle activities

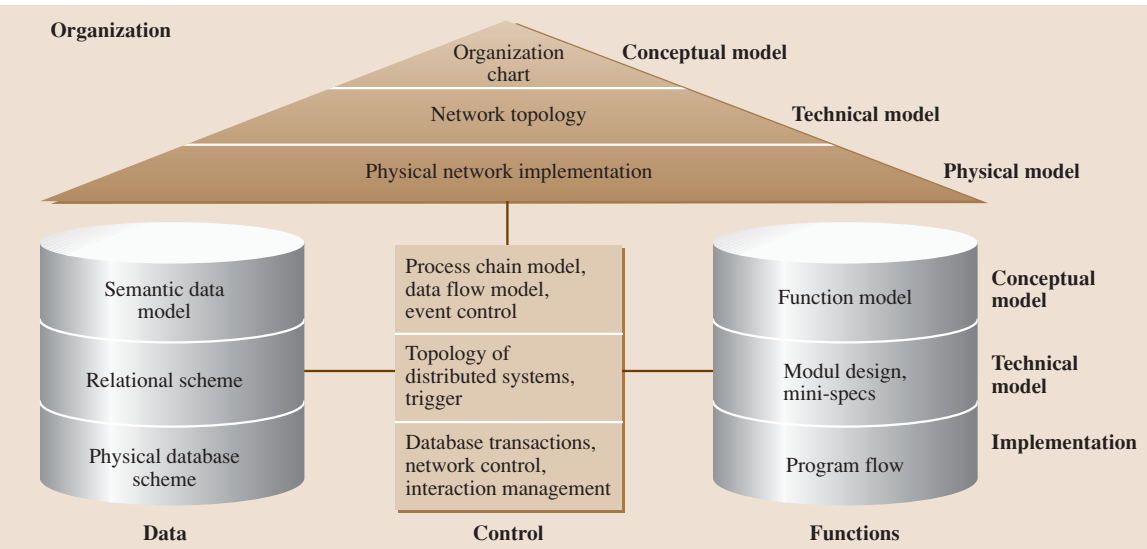

Fig. 15.15 View-concept of ARIS (after [15.53])

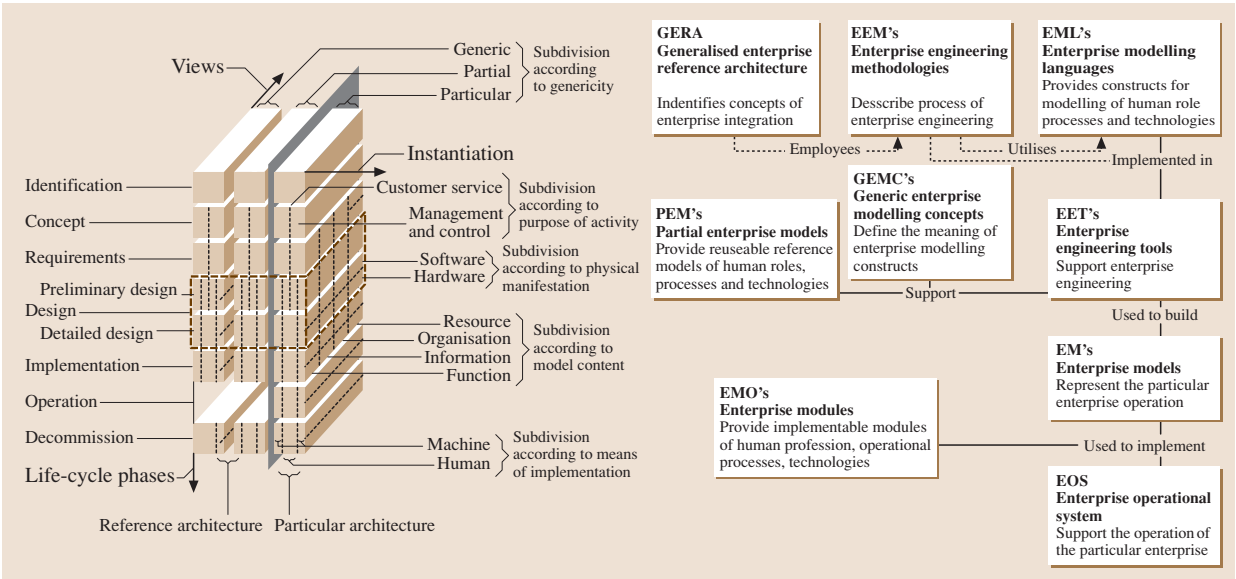

Fig. 15.16 GERA modelling framework and methodology components (after [15.55])

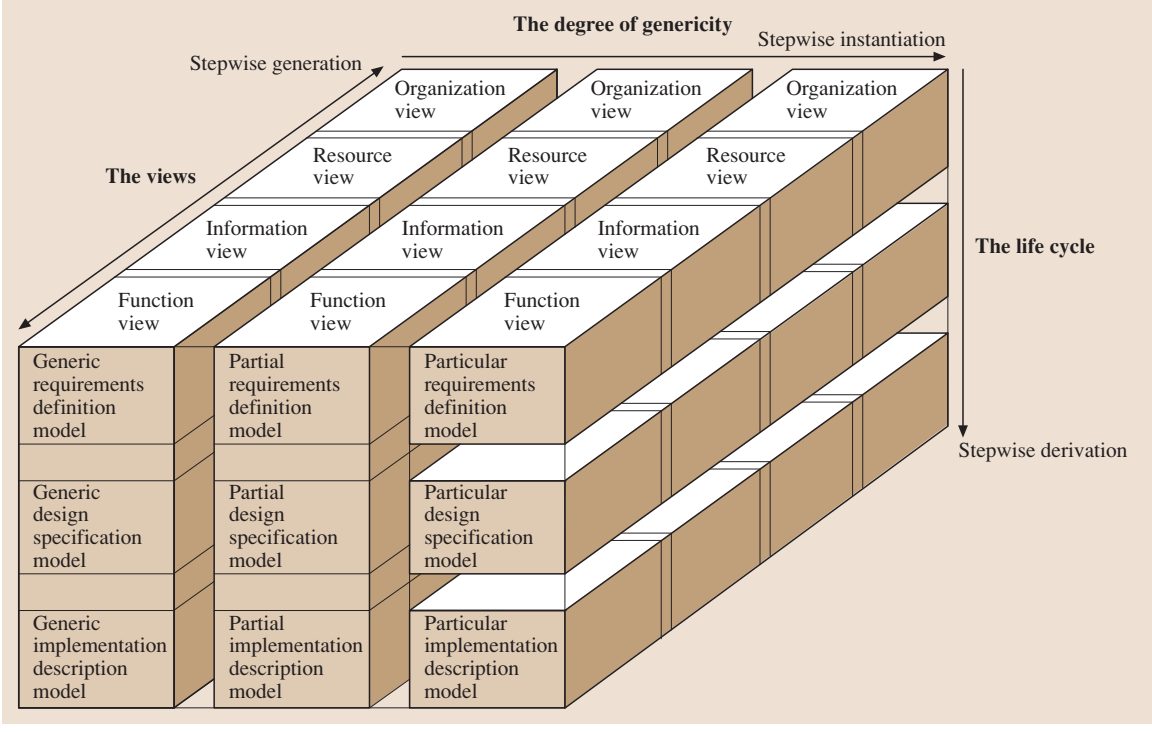

Fig. 15.17 CIMOSA architectural framework [15.57]

- Genericity dimension, providing a controlled particularization (instantiation) process from generic and partial to particular
- View dimension, providing controlled visualization of specific views of the enterprise entity

Figure 15.16 shows the three-dimensional structure identified above, which represents this modeling framework and the components of the methodology.

GERAM comprises several reference architectures for enterprise modeling as it integrates the content and aspects of GRAI integrated methodology (GIM), CIMOSA, and purdue enterprise reference architecture (PERA).

CIMOSA. The computer-integrated manufacturing open system architecture (CIMOSA) provides a process-oriented holistic procedure for enterprise integration for companies following the CIM philosophy. The variety of models and the necessary interaction between models as well as the transfer from planning to operative models require a model for modeling. To achieve this, the CIMOSA concept uses a three-dimensional frame to support the mapping of different aspects and views (Fig. 15.17).

The derivation dimension arranges the models in a sequence according to project phases: requirement definition, design specification, and implementation description. Instantiation arranges models according to increasing degree of abstraction or decreasing concretion. Starting from individual or particular models of business, it generalizes according to similar applications (e.g., industry sectors) to achieve partial models. The next step results in generic constructs and basic atoms. The opposite sequence is used for implementation. The generation dimension arranges complementary models which emerge from distinct technical disciplines (including their specific terminologies) and with different views on the factory.

The modeling is done in three phases: requirement definition, derivation of design specifications, and final implementation. Thereby, four views are introduced: function, information, resource and organization view [15.59].

CIMOSA modeling in an assembly plant analysis is illustrated in Fig. 15.18. This application includes the global modeling of processes for ordering parts and products as well as the material flow control in the manufacturing–assembly–warehouse environment. Modeling the different processes in the manufacturing domain allows the simulation of different business scenarios and the analysis and evaluation of the results in terms of throughput and turnaround time.

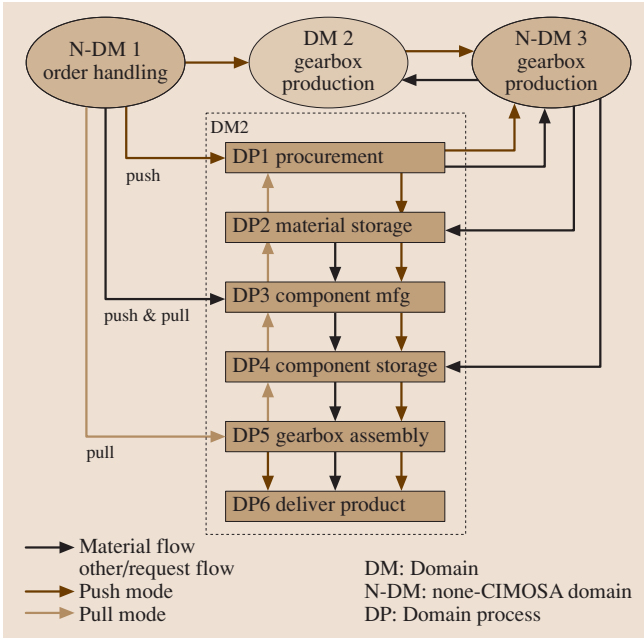

Fig. 15.18 CIMOSA model of an assembly plant analysis [15.58]

The Six-Layer Model. A specific CIMOSA derivate for description as well as implementation of organizations is used for fractal self-similar objective and structure break down. The cooperation between the fractals in a fractal company (Sect. 15.1) takes place on several levels, which can be seen and handled as a whole but which are separate from each other (Fig. 15.10) [15.60].

A company is defined as a social-technical system with a large number of subsystems enclosing process chains. To research and use these complex and nonlinear systems a model that allows a usable and complexity-reducing view and which otherwise avoided a particulate view on single aspects is required.

The model's basis is a horizontal integration of the company's functions. The results are different aspects (usable when isolated), without deleted the integration view of the whole company's processes [15.60]. Figure 15.19 provides an overview of the six-layer model.

There is no master plan to implement the basic principles of the fractal company by using the six-layer model. For successful implementation it is essential not to stay focused on a single aspect, but rather to use an integrated view of the subsystems. In this way it is possible to generate coherent solutions over all levels.

Reference Models

Reference models provide a view of a system based on a predefined syntax and semantics of the model elements.

In the following, three types of reference models relevant for modeling of organizations and manufacturing systems are described: operations modeling, event-driven process chains (EPC), and the entity relationship model (ERM).

Operations Modeling. A *process* consists of a number of continuous actions – operations, transports, and idle states – on an eventually manufactured part/object. If the latter consists of matter it is called material (in the broader sense).

It is usual to design a temporally limited (improvisation) or unlimited (organization) execution of actions if equal or similar actions are repeated. This defines (among other results) the path along which the objects will pass during the corresponding actions. The objects using this path form a *material flow*. The processes are characterized by the following properties:

- Contents: the type and size of objects or flow entities
- Strength: the number of objects per time unit
- Speed: the distance traveled per time unit
- Intervals: the constant or variable temporal distance between objects (for constant flow)
- Limitation: the path, channel, or pipeline, including reservoirs involved
- Direction: related to channel limitation
- Length: measured as a spatial distance or the number of process states
- Layout: the spatial configuration
- Consistency: duration of flow existence
- Significant points

Processes and operations may be represented in various notations, e.g., using operation sequence diagrams based on definitions provide by the Association of German Engineers (*Verein Deutscher Ingenieure*, VDI) or the American Society of Mechanical Engineers (ASME).

Following symbols mark the different actions (compare Fig. 15.20) [15.52].

Operations:

- ◯ Work: Object gets closer to desired final state.
- □ Check: Measurement and comparison with reference, recognition of differences.

Movements:

- ⇒ Transport: Self-contained action of location changing.
- ◯ Handle: and put, place, load and unload, move, accompaniment (auxiliary time) in conjunction with operation, transport, or storage.

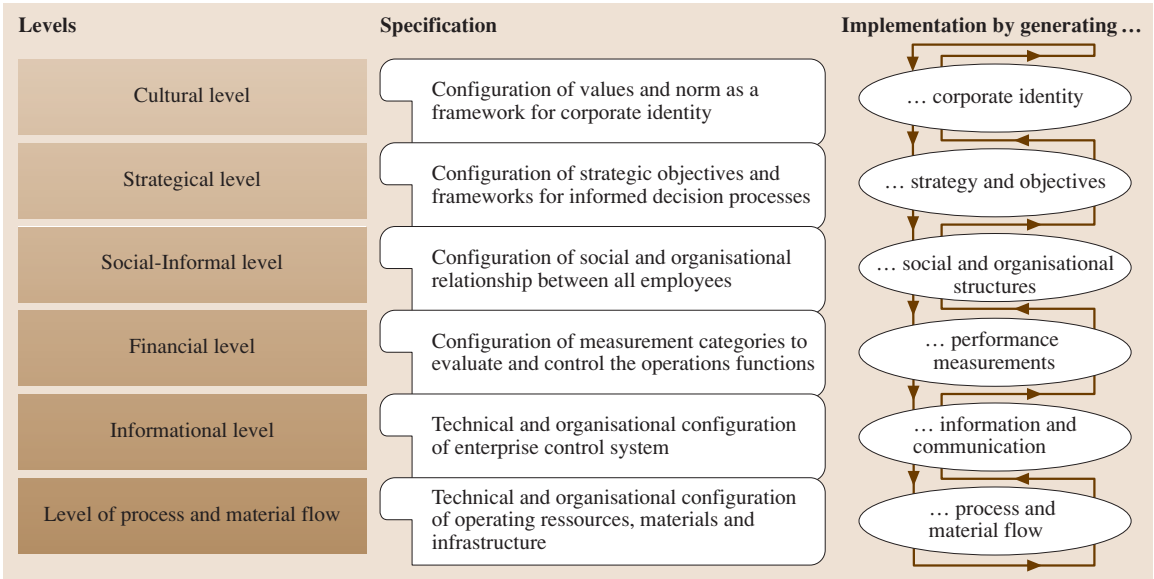

Fig. 15.19 The enterprise six-layer model (after [15.61])

Idle states:

- ▽ Storage: Intentional interrupt of material flow.
- D Delay (wait): Unintentional interruption of material flow: malfunction, stagnation, jamming, waiting at construction, or destruction of transport units.

To simulate discrete event processes, the following types of model elements can be distinguished [15.62] (compare also Fig. 15.21):

- Server (all time-consuming system elements, characterized by capacity, interarrival time, and throughput time)
- Model border points (sources, income of movable elements from the environment; sinks, emission of movable elements to the environment; characterized by the interemission time)
- Control points (unification or splitting of material flows, characterized by function and interemission time)
- Connectors (connection elements, characterized by direction)

Flows and processes can be sketched. In order to explore and forecast process design decisions richer simulation models are applied.

Before a simulation can be started, the structure and logic of the system (operation control) has to be modeled (i. e., presented with basic elements).

The example outlined in Fig. 15.22 is a mechanical process of two types of shafts in a pulsed production system. Two types of shafts are provided, with their own amounts and average arrival times. They are combined in a common pulsed material flow for milling and lathing. The material flow is split regarding the

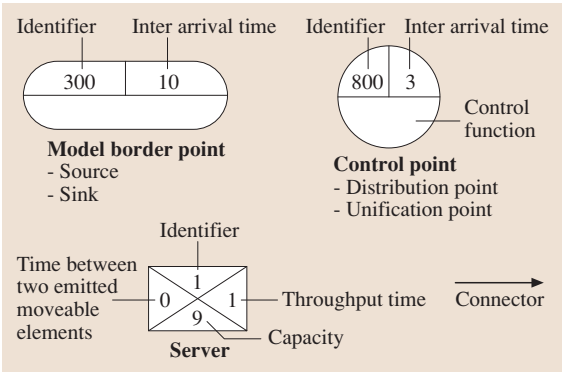

Fig. 15.21 Basic modelling elements for a simulator

shaft types because each type of shaft has its own finishing process. After finishing, the material flows are combined and pulsed again for final washing and sales.

The process will be simulated by a discrete/event-oriented simulation system. As well as the structure, data for system control may also be provided.

EPC. The event-driven process chains (EPC) is a general method for business process modeling. The essential constructs are: function, event, connector, and (sub)process chains (Fig. 15.23).

Besides the presentation of the control flow, the analysis of data flow is the subject of interest. This can be done via the input/output assignment of the information objects in a data flow model. An extension of the event-controlled process chains with the aspect of organizational responsibilities can be performed through the association of organization units to functions. Due

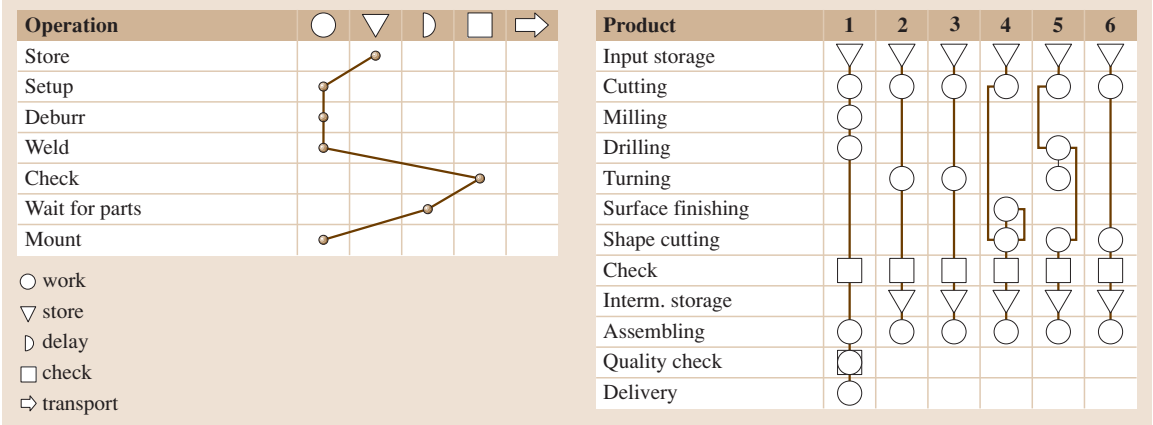

Fig. 15.20 Terminology and symbols for operations modeling

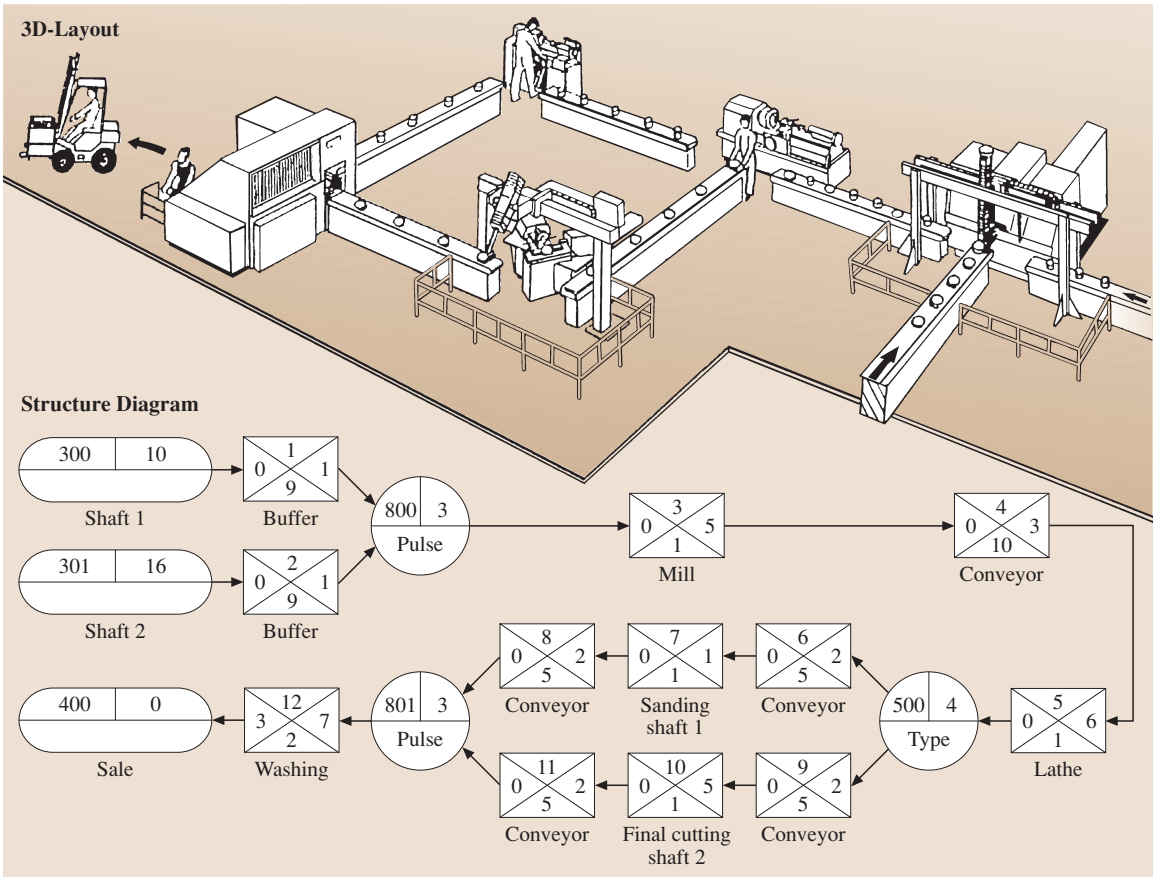

Fig. 15.22 Layout and structure diagram of a shaft manufacturing (after [15.62])

to the lack of an explicit presentation of process instances, the simulation of modeled business processes is difficult [15.53]. EPCs are explicitly designed for the modeling of business processes. Therefore they have individual elements of presentation of all related aspects. Thus, business models presented with EPCs are very demonstrative (Fig. 15.24).

Precise standards for business modeling with EPC are available.

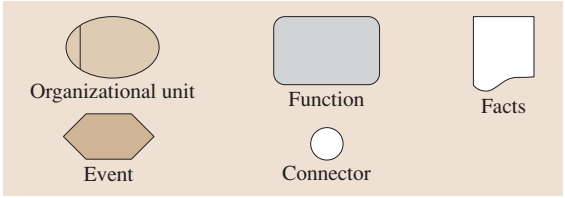

Fig. 15.23 Constructs of event driven process chains

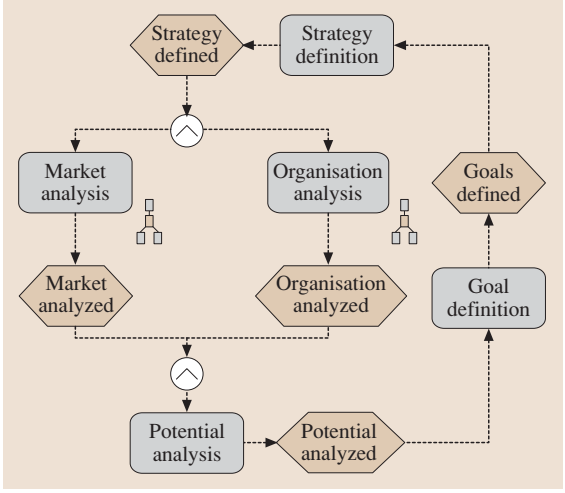

Fig. 15.24 Strategy finding process in EPC

ERM. The most widespread concept method for semantic data models is the entity relationship model (ERM) by *Chen* [15.63], which presents the relations between data units (entities) graphically. The entity relationship model is based on a classification of the real world into entities and relations. Thus, using an ERM, information flows can be modeled, setting events and processes (functions) in relation to each other. States become visible due to the inclusion of information technology resources into the model. Partly, organization units can be defined.

The main information in an ERM is provided by the presentation of relations and their occurrence between the objects. All forms of relations (1:1, 1:*n*, or *n*:*m*) can be presented. To keep practical applications simple, it is useful to insert artificial objects and to convert real relations into artificial, idealized system elements for the simplification of relationships. Multiple 1:1 or 1:*n* relations are usually easier to handle than one *n*:*m* relation.

Entities are objects or issues that can be immediately identified; relations are associations between entities. For example the project work can be a relation between two entities of type person and project (Fig. 15.20).

Data input is done using instances of entities, i. e., a certain characteristic of entities or relations is specified by a set of attribute value couples; for example, if *name* is an attribute of the entity *employee*, *Peter* is a value of this attribute in an instance of the entity. In an extended approach, information can be assigned to relations using attributes. The entities of a model are classified into different entity sets. The information about entity instances of an entity set are gathered in tables called an entity relation. Every row of the table is called an entity tuple. In entity relationship diagrams every entity is presented by a box; every relation is presented by a rhomb. The role of entities in the relation is static (Fig. 15.25). The method of ERM is used to illustrate complex contexts and if a reduction of complexity is intended. The ERM produces uniqueness.

a)

Attribute	Employee-nr.	Name		Age
Domain	Employee-nr.	Given name	Surname	Years
	1522	Peter	Meier	30
	1590	Fritz	Schultz	53
Entity-tuple	2007	Petra	Schwartz	22

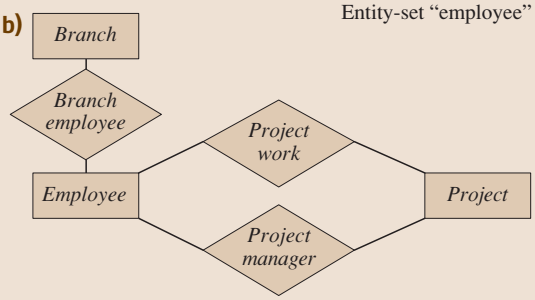

Fig. 15.25a,b Example of an entity set end an entity-relationship-diagram

Modelling Techniques

Modelling techniques provide either a syntax of the model entities or a semantics defining the modelling process.

With UML and SYSML two syntax defining models and with RUP a semantic based modelling process relevant within organizations modelling are considered.

UML. The unified modelling language is a language for specification, visualization, construction, and documentation of models for software systems and business models (in its specific sense) as well as systems (in its general sense). It is based on the unification and improvement of object-modelling technique (OMT, *Rumbaugh*), object-orientes software engineering (OOSE, *Jacobson*), and the method of *Booch* [15.64].

UML is a modelling language and notation but intentionally not a method. UML can be the base for various methods because it provides a defined set of modelling constructs with unique notation and syntax.

The current version 2.0 of UML defines a wide range of diagrams for modelling. They can be distinguished as structure models and behaviour models. The most important are (see also Fig. 15.20):

- The use case diagram applied to show users, use cases, and their relations and to describe the outer system behaviour in its recognition by a user.
- The class diagram shows classes with its encapsulated properties and data (attributes), its encapsulated behave-our (operation/functions), the relations between classes, and the structural dependencies among classes.
- The activity diagram shows activities, object states, states, state transitions, and events and, thereby, describes object behaviour using their activities, which are performed during execution.

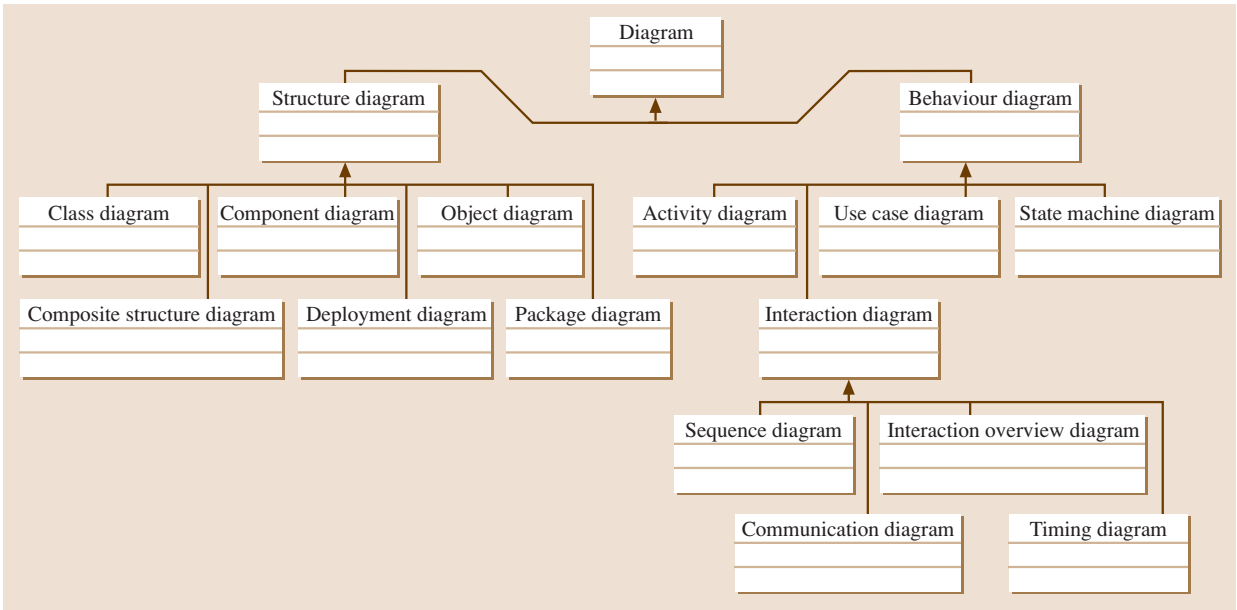

Fig. 15.26 UML diagrams

- The collaboration diagram shows objects and their relations including their exchanged messages and, thereby, describes the acting model objects for a certain delimited context.
- The sequence diagram shows objects and their relations including their exchanged messages and, thereby, describes the chronological sequence of interactions between a set of objects.
- The state diagram shows states, state transitions, and events of objects and, thereby, describes the distinct states of an object as well as the functions which cause the state transitions of this object.
- The timing diagram shows states, state transitions, and events of objects in its temporal dependencies and, thereby, describes the temporal behaviour of objects.
- The component diagram describes system components consisting of different model objects and their relations.

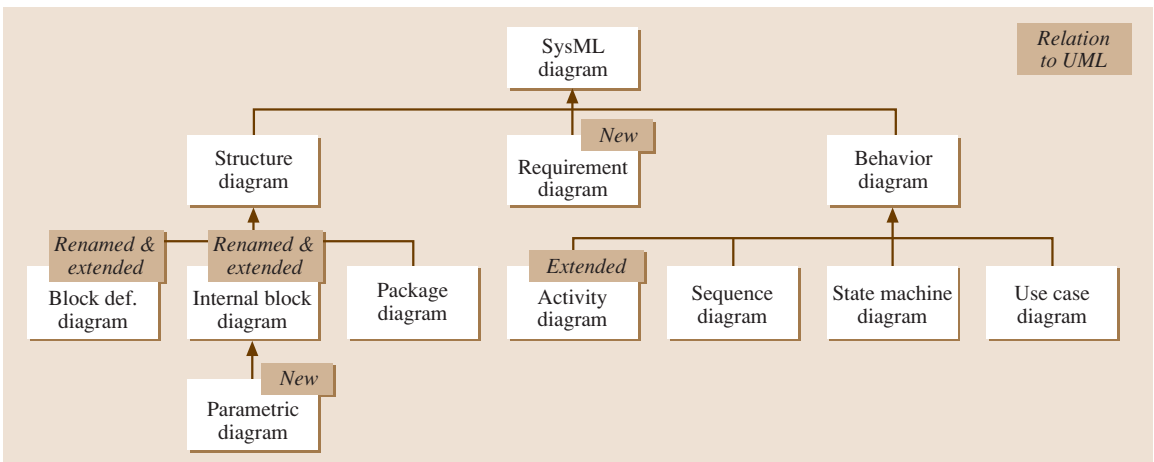

Fig. 15.27 SysML diagrams

- The deployment diagram shows components, nodes (devices/resources), and their relations and describes, which system components run on which devices.

UML enables the modelling of various systems from various points of view dependent on the intentions of the modeller. It is not related to a certain field of application.

SysML. The systems modelling language (SysML), is a modelling language targeted for the systems engineering domain. It is a visual modelling language supporting the specification, analysis, design, verification and validation of a broad range of systems and systems-of-systems.

SysML has been initially developed as an open source specification project. Now SysML has been adopted by OMG as international standard [15.66].

The foundation of SysML is a subset of UML which has been extended by systems engineering relevant modelling capabilities as depicted in Fig. 15.27.

The diagrams which are applied unchanged from UML are package diagram, sequence diagram, state machine diagram and use case diagram.

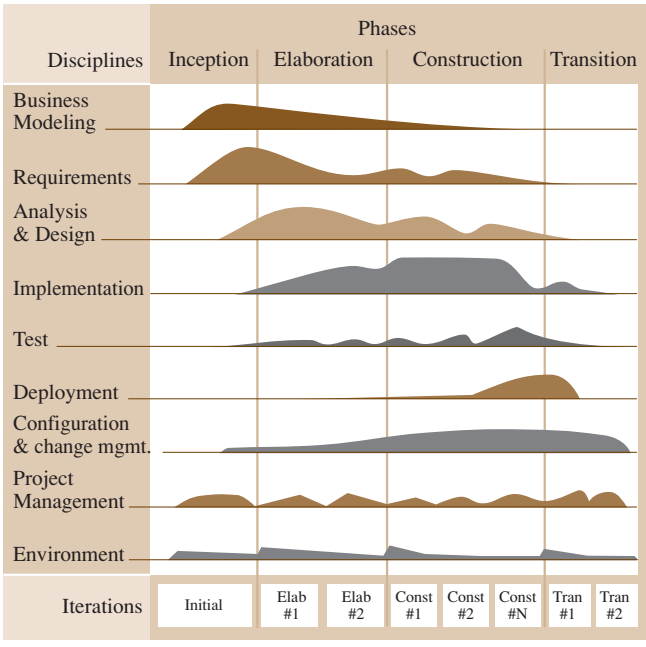

Fig. 15.28 Phases of the rational unified process in relation to hte activities made within them [15.65]

The renamed and extended diagrams are the block definition diagrams and the activity diagram.

Block diagrams are based on UML class and UML composite structure diagrams. They are based on the term of blocks which are the basic structural elements in SysML. Blocks describe the structure of elements or systems based on multiple compartments providing the block characteristics like properties, operations, constrains, allocations to the block, and requirements the block satisfies. The block definition diagram (bdd) describes the relation among blocks while the internal block diagram (ibd) describes the internal structure of a block.

SysML extensions to activities are the support for continuous flow modeling and its alignment of with enhanced functional flow block diagram (EFFBD).

Within both types of diagrams, block as well as activity diagrams, a (with respect to UML) new modeling concept is integrated representing communication among entities (blocks or activities). SysML specifies interactions points on blocks and parts called Ports. SysML has two port types, standard ports and flow port.

Facing the needs of systems engineering within SysML system requirements can be modelled and provided within the requirement diagram. Thereby, system analysis and evaluation can also cover requirement problem solution as well as description and evaluation of alternatives.

The second extension is the parametric diagram usable for the specification of the dependency of parameters within different entities of a system.

Similar to UML SysML is not related to a specific application domain. It provides a modelling syntax applicable within various fields.

RUP. The rational unified process (RUP) is initially an iterative software development process [15.67]. It is not a single fixed process, but an adaptable process framework. It can be tailored to the development of organizations and software design projects by selecting elements of the process that are appropriate.

The unified process was designed from the start to include both a generic, public domain process (known as the unified process), and a more detailed specification known as the rational unified process which could be marketed as a commercial product.

The RUP is based on a lifecycle consideration of a system design and implementation process within a spiral model. It has been created by assembling the content elements into semi-ordered sequences. Hence,

the RUP lifecycle is available as a work breakdown structure, which has to be customized to address the specific needs of a project. The RUP lifecycle assumes that a project has four phases (Fig. 15.28):

- Inception phase: In this phase the business case which includes business context, success factors, and financial forecast is established and complemented by basic business use case models, project plans, initial risk assessments, cost assessments, stakeholder considerations, project descriptions, and requirement descriptions.
- Elaboration phase: in this phase the problem domain analysis is made and the basic architecture of the intended system is developed. This is done by developing use-case models in which the use-cases and the actors have been identified, identifying significant use cases, and revising business cases and risks.
- Construction phase: In this phase, the main components and features of the intended system architecture and behaviour are designed. This phase is the main design phase developing the concrete system implementation.
- Transition phase: In the transition phase, the product will be moved from the development organization to the end user, i. e. the product will be delivered. In the case of an organization or a complex system the organization/system will be established.

The RUP provides a methodology for organization/system design fixing semantics of the results of different design phases. Intentionally it is not connected to special models and modelling techniques. Nevertheless, very often UML and SysML (depending of the intended domain of the result) are applied within RUP execution.

15.5 Enterprise Resource Planning (ERP)

Enterprise resource planning defines the task of enterprises to optimise plans for the most efficient input of all available resources. As these activities are generally computer supported, the term of ERP is actually used to describe software or software implementations to operate and optimize a number business processes in companies [15.68].

Enterprise resource planning systems attempt to integrate all data and processes of an enterprise organization into a unified software system. Formerly used terms have been also production planning and control (PPC), materials requirement planning (MRP) and manufacturing resources planning (MRP II) [15.69].

Revolving plans are generated for the production programs as well as for the allocation and expected demand of resources like production capacities or inventory. Forecasts and customer orders (primary demands) are broken down to the finished goods', aggregates' and parts' levels (secondary requirements) using a set of well established procedures (net requirements calculation, lot sizing calculation). Moreover ERP also includes a number of administrative functions, as accounting or billing.

In order to give an overview on ERP functions, the key procedures that are implemented shall be detailed in formal terms that clearly differentiate the resources regarded.

15.5.1 Resources and Processes

As all software systems, also enterprise resource planning systems are based on models of the business processes regarded. The easiest way to built up these models is to use the given information base in the company. As all companies use bills of material (BOMs) and work sheets or bills of operations (BOOs) the information concerning:

- Machine (cut, drill, mill, deform etc.)
- Move (transport, insert, eject etc.)
- Unite (assemble, weld etc.)
- Separate (saw, split, etc.)

may be read out and used for planning and process modelling.

Figure 15.29 shows a manufacturing flow model on the basis of BOM and BOO information. In ERP, a number of worksheets and bills of material are interlinked in order to obtain routing, process, and flow models as the data input for enterprise resource planning and control [15.70, 71].

In order to define the full manufacturing processes all resources are assigned to functions and operations that are necessary. In the ERP context, resources are workforces, skills, objects, and equipment. ERP uses

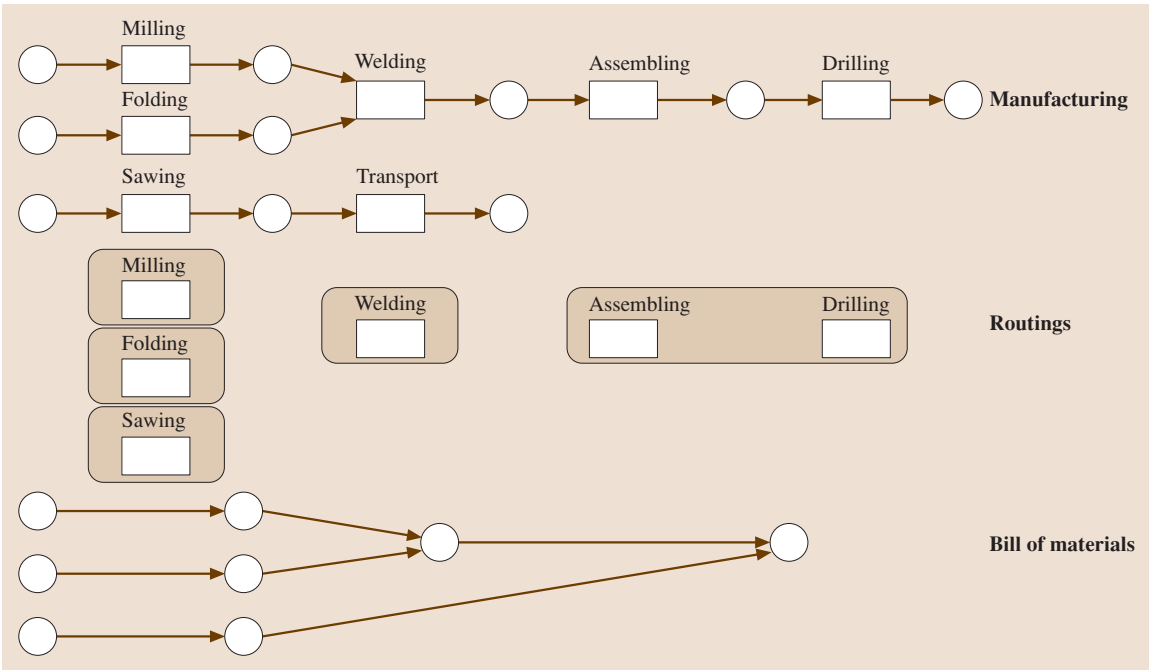

Fig. 15.29 List of date and models used by ERP

a basic set of resources R to model the manufacturing processes, where R may be split into subsets

$R = R_1, R_2, R_3, R_4$ meaning:

R_1–materials, parts, and final products (objects),

R_2–machines, lines, (and equipment),

R_3–workforce (human resources),

R_4–auxiliary equipment, tools, and measuring technology.

For every unit of these resources, inventories and availabilities may be forecast, planned, and observed over the time horizon.

15.5.2 Functionalities of ERP Systems

Enterprise resource planning (ERP) software solutions [15.72] are designed for systematic disposition and planning of all enterprise resources in production, distribution, logistics, finance, and personal. Different kinds of ERP systems offer varying degrees of functionality and the properties depend on the areas focused on, for instance, manufacturing business or service business [15.73]. Their primary objective is the optimization of business processes in product development, materials logistics, production, maintenance, quality assurance and service, sales, and distribution (Fig. 15.30). Key ingredients of ERP systems are unified databases to store the data for the various system modules.

Thus ERP systems are universal standard software solutions to control and optimize business processes. Whereas early systems focused on intra-enterprise processes, interenterprise processes are also covered, and ERP systems are becoming web enabled with additional software modules, e.g., for supply chain management (SCM) and customer relationship management (CRM).

In manufacturing companies, the core of ERP is provided by software functionalities for production planning and control. This includes all customer demands indicating production areas as well as the demands resulting for subsequent planning steps, demand forecasts for products, and derived demands for aggregates or parts [15.74]. Deeper studies of ERP, especially current research projects in the field [15.75], focus on the data structures and the logical steps behind ERP procedures.

15.5.3 ERP Procedures

Enterprise resource planning systems are implemented to model, plan, and control resources that are required

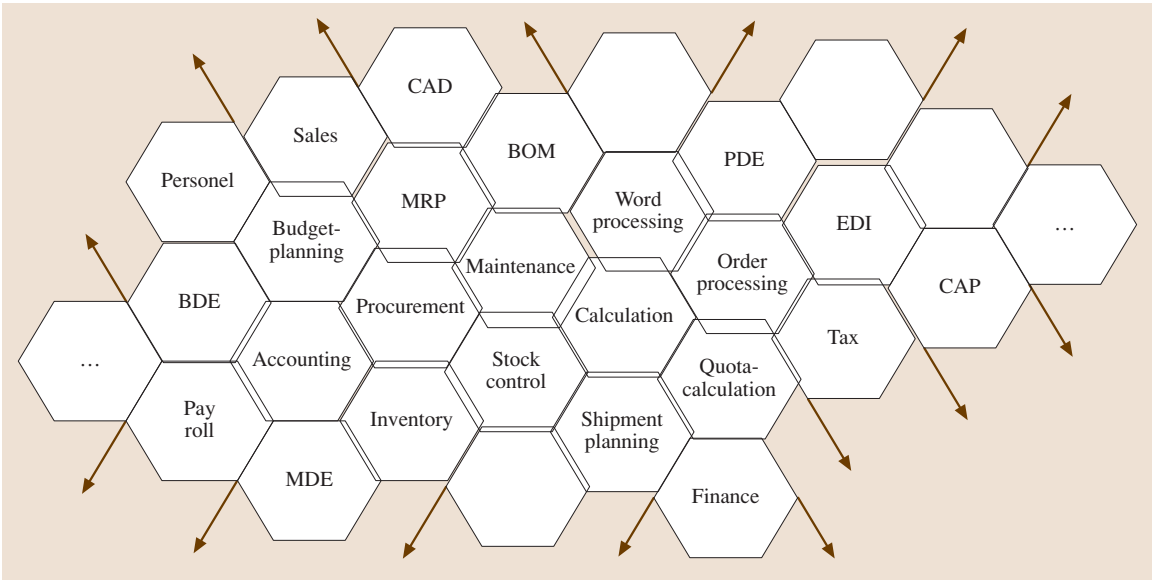

Fig. 15.30 Functionality configuration of an ERP-system (CAP – computer-aided planning; EDI – electronic data interchange) (after [15.76])

for the output and throughput of a company. The availability of resources is forecast and monitored over discrete-time axes (calendar dates, shift numbers, or hours).

Discussion about the data used and the logic steps of ERP may be based on the term

$$\text{ERP} := [R, S, T, (Rb(t), r(t), D, E, A)] ,$$

where R is a set of resources, A is the procedure pointer, S represents the relations between resources, E is a decision, T is the time scale, D is the diagnosis, $b(t)$ is the requirement time function per resource, and $r(t)$ is the availability time function per resource.

These elements constitute the pillars of all ERP core procedures according to Fig. 15.31. Forecasting is done along discrete time units (time scales are weeks, days, and shifts), delivering revolving plans for demands, order loads, inventory levels, and capacity availabilities. These plans are generally output as data columns and histograms.

Statistical Inventory Control (SIC)

The SIC procedure determines forecasts for inventories and orders by extrapolating past product demands and resource consumption (on a stochastic basis). Most frequently the methods used for forecasting are arithmetic averaging (in some cases weighed averages) and exponential smoothing. Based on actual and planned levels of inventories, demands are summed and transformed into orders. Volatilities in demand and errors in the forecasts are buffered by safety stocks; recommended levels are determined by statistical methods based on the variance parameter of the normal distribution of fulfilled orders.

Statistical inventory control (SIC) is applied to purchase materials and low-price parts as well as for internal company multistage requirement planning, in some cases to ensure the availabilities of equipment

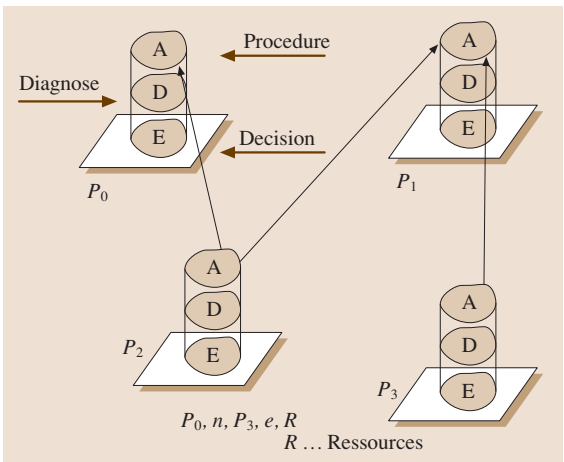

Fig. 15.31 ERP-model-basics

Table 15.9 Description of important ERP procedures (SCH – scheduling; EOQ – economic order quantity)

ERP procedures	*R*	*S*	*T*	*b*(*t*)	*r*(*t*)	Operators *D*	*E*	*A*
SIC	R_1	–	Discrete	Yes	Yes	Material requirement? Inventory?	Order EOQ	Next low inventory level
MRP	R_1	BOM	Discrete	Yes	Yes	Material requirement?	Order EOQ	Next BOM position
MRP II	R_1, R_2, R_3, R_4	BOM	Discrete	Yes	Yes	Resource requirement? Resource inventory?	Order release	Resource list
SCH	R_1, R_3, R_4	Time dependencies	Discrete	–	–	Order due date feasible?	Order release order split/ concurrent procedure	Subsequent time span (forward/ backward)
CSP	R_1, R_2, R_4	Working plan	Discrete	Yes	Yes	Resource requirement? (time, capacity, lot)	Load shift sequencing queuing	Subsequent process step
Kanban	R_1	–	–		–	Minimum inventory?	Card release	Next card

(e.g., tools). SIC application does not assume a complete bills of materials or other information detailing the setup of products or aggregates.

Material Requirement Planning (MRP)

The MRP procedure may consider all materials and parts that are listed in the bill of materials (BOM); the interrelations set up between the products are used for the computation of the requirements. A (given or forecasted) production programme is broken down into requirements at all levels of the product (on a deterministic basis). In order to determine throughput times and accurate quantities, delays and waste factors are added to the BOM relations (calendar dates, delay times, lot sizes, volumes, and economic order quantities). Generally the products, parts, and aggregates (BOM positions) that are considered by MRP are expensive, difficult to supply, or discontinuous in demand.

Two alternative modes are applied:

- Order-driven MRP, which breaks down the demand per order
- Program-driven MRP, which breaks down the demands for all BOM positions, using complex net requirement calculations on the basis of inventory levels

Manufacturing Resource Planning (MRP II)

As sketched above, MRP II extends MRP to interenterprise contexts. It uses universal descriptions independent of industry branches [15.77]. Planning and control is applied to multistage value chains. MRP II is characterized by a strong material focus as well, strictly separating lot sizing and capacity loading [15.78]. All process steps are planned and scheduled. Capacity planning activities are a part of standard software activity.

Scheduling Procedure

For an approximate determination of due dates and dates for execution of process steps the time consumptions to be expected for the order executions is considered. Resulting schedules for R_1 (materials, parts, final products, etc.), R_2 (machines, lines, etc.), and R_4 (auxiliary equipment, tools, measuring technology) anticipate order allocations as well as order execution and finish constellations (Gantt charts) [15.79]. One-of-a-kind production may require more elaborate (graph-theory-supported) procedures such as the critical-path method (CPM), the project evaluation and review technique (PERT) or the metra potential method (MPM) [15.14] for scheduling. The benefits of production scheduling include setup cost and inventory reduction, increased production efficiency, labor load leveling, and real-time order information.

Capacitated Scheduling (CSP)

Capacity requirement and scheduling generates detailed plans and schedules for machines, equipment, and materials, feasible to be executed in manufacturing areas [15.80]. A special case is the capacitated lot-sizing lead-time problem (CSLP), where smooth loads are generated by time and/or assignment shifts using sequencing algorithms as well as order-split logics and queuing rules.

Kanban

Kanban is a procedure that controls the flow of material by *pulling* parts as needed through the manufacturing system. A part is manufactured if and only if a part of this kind has been taken out of the buffer. The procedure allows minimum inventory, ensuring highest order availability at the same time. Kanban (Japanese for "card") is used for the control of mass production and large series throughputs. For each part a standard lot size and minimum inventory level are defined, represented by the number of cards released into the process.

Using the ERP formalization as introduced above, all described procedures may be categorized as shown in Table 15.9.

15.5.4 Conclusions and Outlook

ERP applications are widespread in enterprise organizations. Applied properly, they provide many advantages. Nevertheless the most elaborate ERP procedures also exhibit weaknesses regarding flexibility (dynamic routing or rush orders) and interoperability (with other systems, such as MES). Problems are caused by newly arriving high-priority production orders, since the running production cannot be modified. ERP implementations are often seen as too rigid and too difficult to adapt to the specific workflow and business processes of some companies [15.81].

Also, in areas related to software implementation, expected ERP benefits may not be fully attained as:

- Customization of the ERP software is limited. Some customization may involve changing of the ERP software structure, which is usually not allowed.
- Re-engineering of business processes to fit the *industry standard* prescribed by the ERP system may lead to a loss of competitive advantage.
- Many of the integrated links need high accuracy in other applications to work effectively. A company may achieve minimum standards, then, over time *dirty data* will reduce the reliability of some applications.
- The system may be overengineered with respect to the actual needs of the customer.

To improve ERP applications, potential is seen in more intensive cooperation [15.82]. Concepts such as built-to-order supply chain (BOSC), efficient customer response (ECR) [15.83], and continuous replenishment planning (CRP) [15.75] are discussed, aiming for smoother flows. Multiple forecasts within supply networks, changing demand patterns, and general synchronization problems call for collaborative planning, forecasting, and replenishment (CPFR) [15.84]. Nevertheless these approaches, even if accompanied by firm alignments via very rigid standards, as proposed by the Voluntary Interindustry Commerce Standard Association (VICS) [15.83] are still considered immature [15.85]. Their operation is laborious, as they ignore fundamental problems of collaboration involving diverse self-interested actors with conflicting motivations.

With changing organizations in enterprises, ERP logics and software solutions have to be redeveloped too. Currently the vendors of ERP software are working on solutions to avoid the shortfalls listed above [15.85]. The developments are oriented towards advanced industrial organization concepts [15.86], greater flexibility, and variability of product and process data [15.87]. First solutions draw from networked control concepts and the latest ICT devices, e.g., radiofrequency identification (RFID) and multi-agent systems (MAS).

15.6 Manufacturing Execution Systems (MES)

To manage the optimization and control problems accruing in larger manufacturing systems, which also include large amounts of numerically controlled (NC) equipment, manufacturing execution systems (MES) have been designed. Presently, manufacturing execution systems incorporate algorithms for short-term production planning and control. According to the specification of the Manufacturing Enterprise Solutions Association (MESA) [15.88], MES covers 11 functionalities, as listed in Table 15.10.

For efficient implementation of these 11 functions several specific architectures have been developed.

Table 15.10 Main functions of MES

MES functionality	Attributes
Resource allocation and status	• Shows resources, including reservation and dispatching of machines, tools, labor skills, materials, and other equipment • Provides read/write access to documents and data that must be available to enable the necessary work
Operations/detailed scheduling	• Performs sequencing of resource operations and functions based on priorities, attributes, characteristics, and/or recipes • Reflects specific features of the scheduled resources such as necessary activities for process setup and possible process sequences
Dispatching production units	• Prepares the flow of units to be produced such as jobs, orders, batches, lots, and work orders • Creates dispatch information presenting the sequence
Document control	• Manages the control of information containing units (forms, files, records, etc.) relevant for a manufacturing unit
Data collection and acquisition	• Provides an interface to collect all data such as interoperational production data and parametric data that are included in the controlled documents of a resource
Labor management	• Manages status information of personnel, including time and attendance reporting as well as certification tracking
Quality management	• Provides real-time analysis of measurements collected from the resources before, during, and after the manufacturing process
Process management	• Monitors the manufacturing process resources and automatically corrects resource behavior or provides decision support to operators
Maintenance management	• Controls activities to maintain resources to ensure their availability for manufacturing and ensure scheduling for periodic or preventive maintenance
Product tracking and genealogy	• Provides visibility of the current status of the manufacturing processes and the current state of resource activities • Creates a historical record
Performance analysis	• Provides up-to-the-minute reporting of actual manufacturing results and its comparison with past history and expected business results

The most popular class of systems focuses on resource allocation, scheduling, and dispatching on the one hand, and data collection and acquisition on the other hand. As the overall complexity of MES is increasing (as manufacturing systems become more complex), architectures have been adapted with distributed functionalities and to develop distributed MES systems [15.89].

Special effort has been invested in the field of intelligent distribution of the necessary decisions. One major technology used within this field is agent-based systems. All of these efforts reflect similar structures dealing with negotiating orders and resource entities [15.90].

Another field of major interest is the interfacing of data sources relevant for MES system behavior. An advanced architecture in this field is the open robot interface for the network (ORiN) – one of the most important data collection and acquisition architectures – which offers interoperability of different functionalities with the possibility of integrating systems from different vendors.

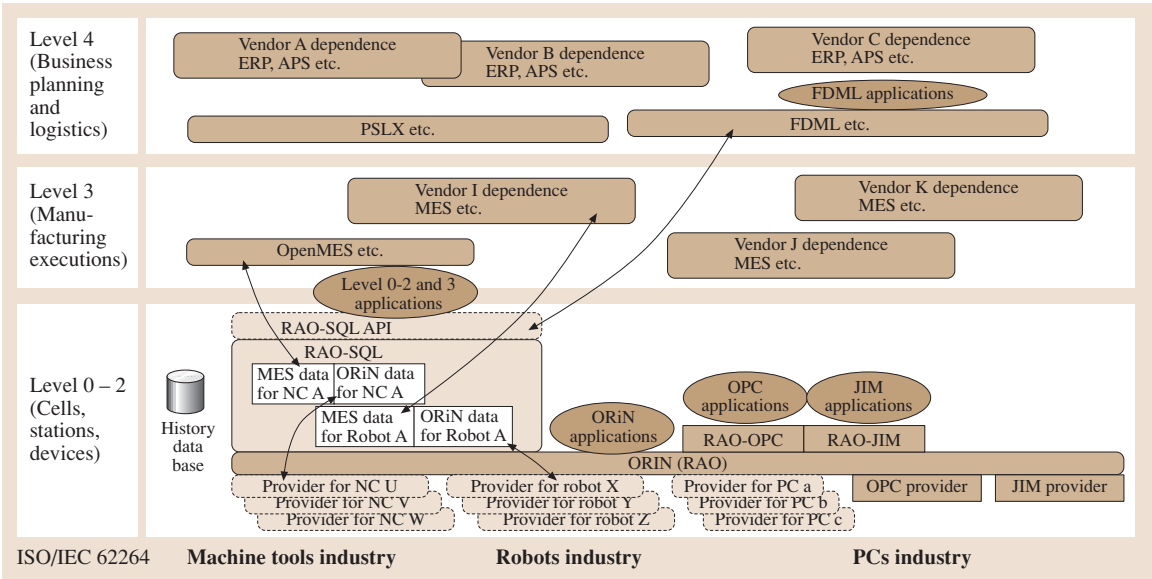

Fig. 15.32 Concept of the information-interoperable environment (FDML – flow description markup language; OPC – OLE for process control; OLE – object linking and embedding; PSLX – planning and scheduling language on XML specifications; RRD – robot resource definition; RAO – robot access object; SQL – structured query language)

15.6.1 Information-Interoperable Environment (IIE)

The open robot interface for the network (ORiN) [15.91] is an example of an open technology, developed by the ORiN consortium for robots. It has been extended through the development of gateway systems for other standards such as open connectivity via open standards (OPC) [15.92] and is currently active in the ORiN consortium. Therefore, the ORiN technology has been applied not only to robots and programmable logic controllers (PLCs) but also to machine tools. Additionally, an information-interoperable environment (IIE) that can interlink device-level information and MES-level information has been developed using ORiN.

A mechanism that can acquire device-level information and MES-level information corresponding to the needs of the user for increasing productivity on a daily basis is needed. Such an IIE has been developed using ORiN's middleware solution RaoSQL (RAO – robot access object; SQL – structured query language) [15.93], as shown conceptually in Fig. 15.32.

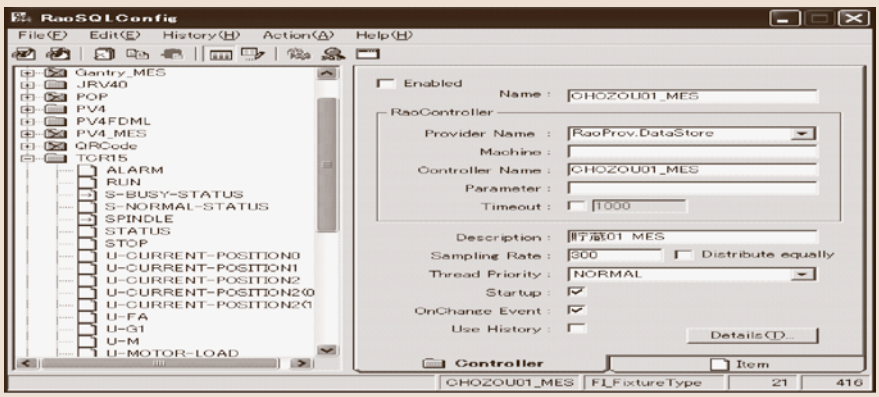

Fig. 15.33 Configuration tool of the environment

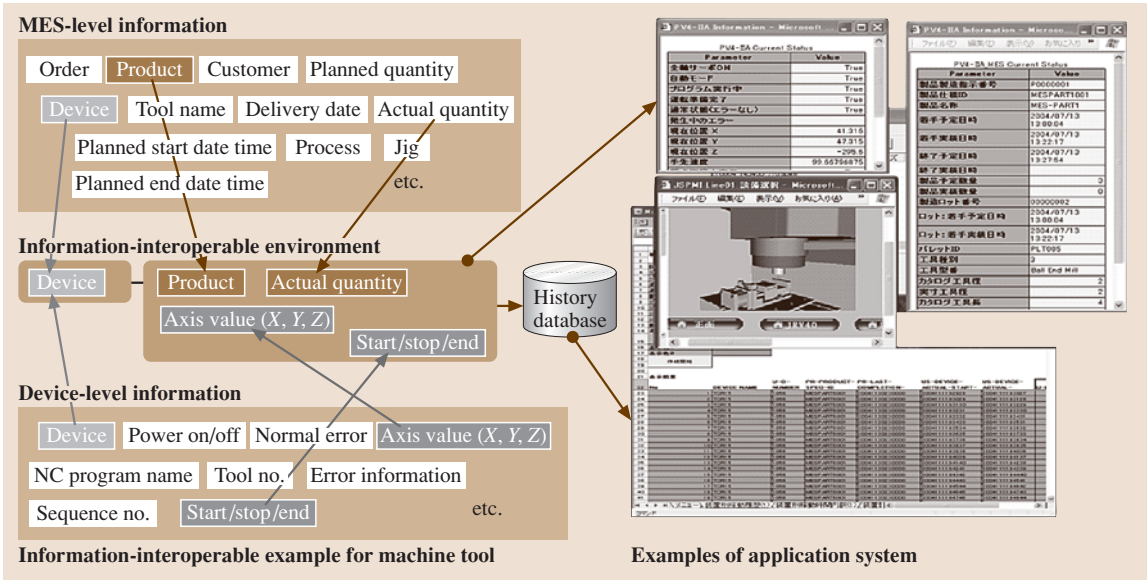

Fig. 15.34 Concept of applications

The RaoSQL has a RaoSQLController class for discriminating amongst different devices and a RaoSQLItem class for defining various types of information from the devices. Information corresponding to the robot access object (RAO), which is an ORiN model, can be defined in RaoSQLItem objects. That information can then be provided to application systems through the RaoSQL application programming interface (API). Additionally, the data variance history can be logged to market databases. In addition, RaoSQLItem

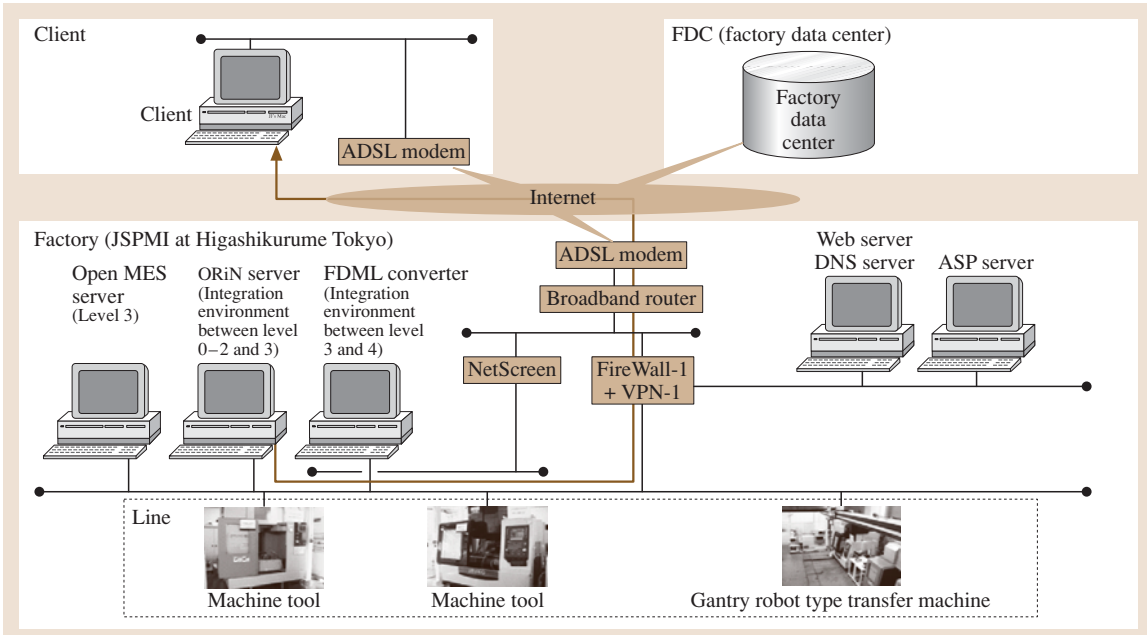

Fig. 15.35 System configuration of the prototype

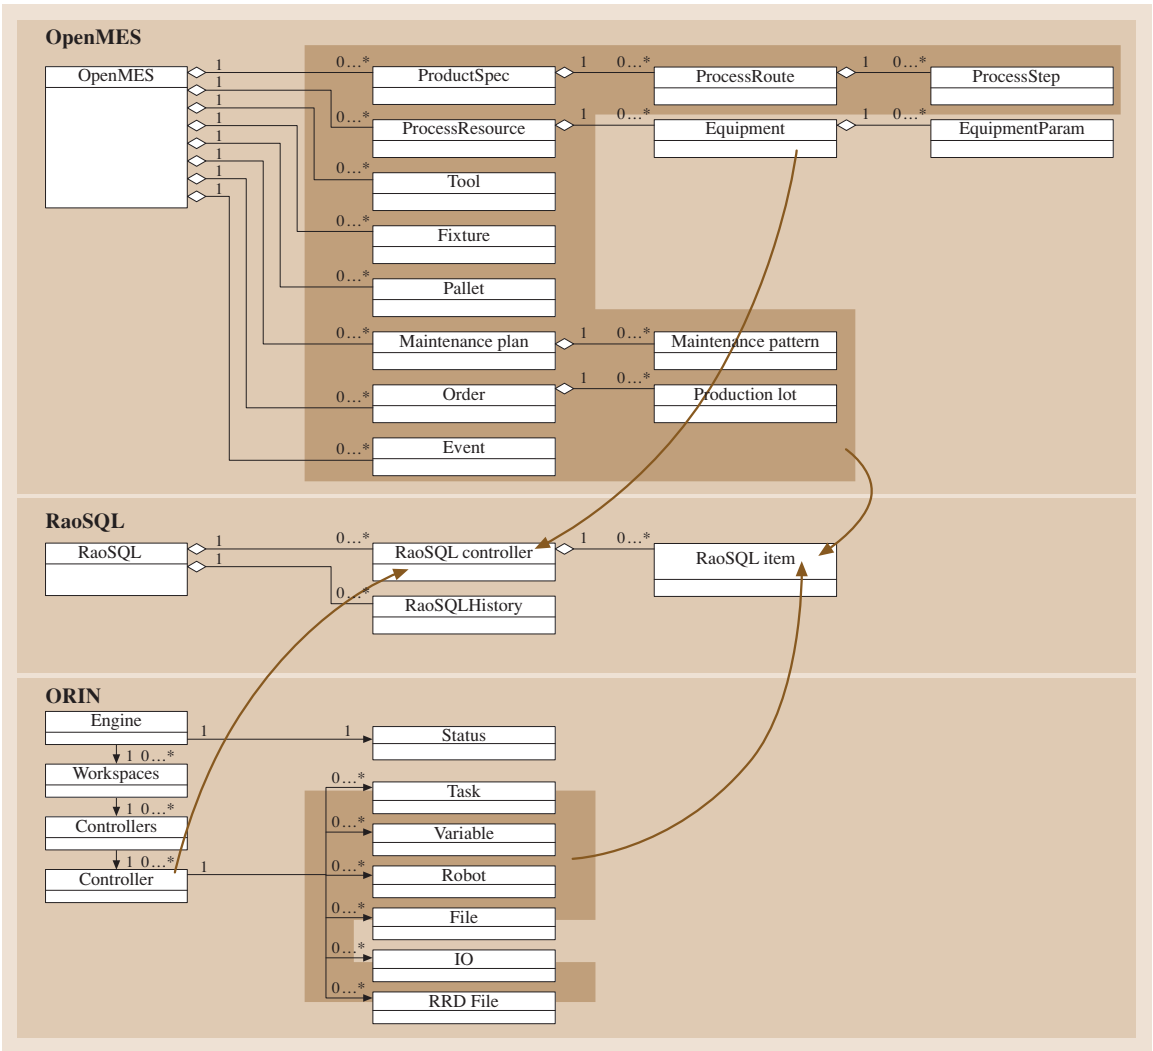

Fig. 15.36 Integration mechanism between Open MES and ORiN

objects can provide not only device-level RAO information but also MES-level information using the data store function of RaoSQL that handles optional information. Information exchange with the MES level of this IIE uses the RaoSQL API. Moreover, the configuration management tool of the IIE can manage both the RaoSQLController and RaoSQLItem objects. Dynamic reconfiguration by the user in order to make productivity enhancements is possible through the use of the configuration tool, as shown in Fig. 15.33. An application illustration using this system is shown in Fig. 15.34.

By using the IIE with a web server, remote monitoring of device- and MES-level information through web applications can be easily customized by the user. With the accumulation of data available from the device- and MES-level database histories other application systems such as an operation management system can be created using Excel, giving users even greater freedom in the computing environment. Custom-made applications for the purpose of increasing productivity are available through these methods without having to resort to commercial software.

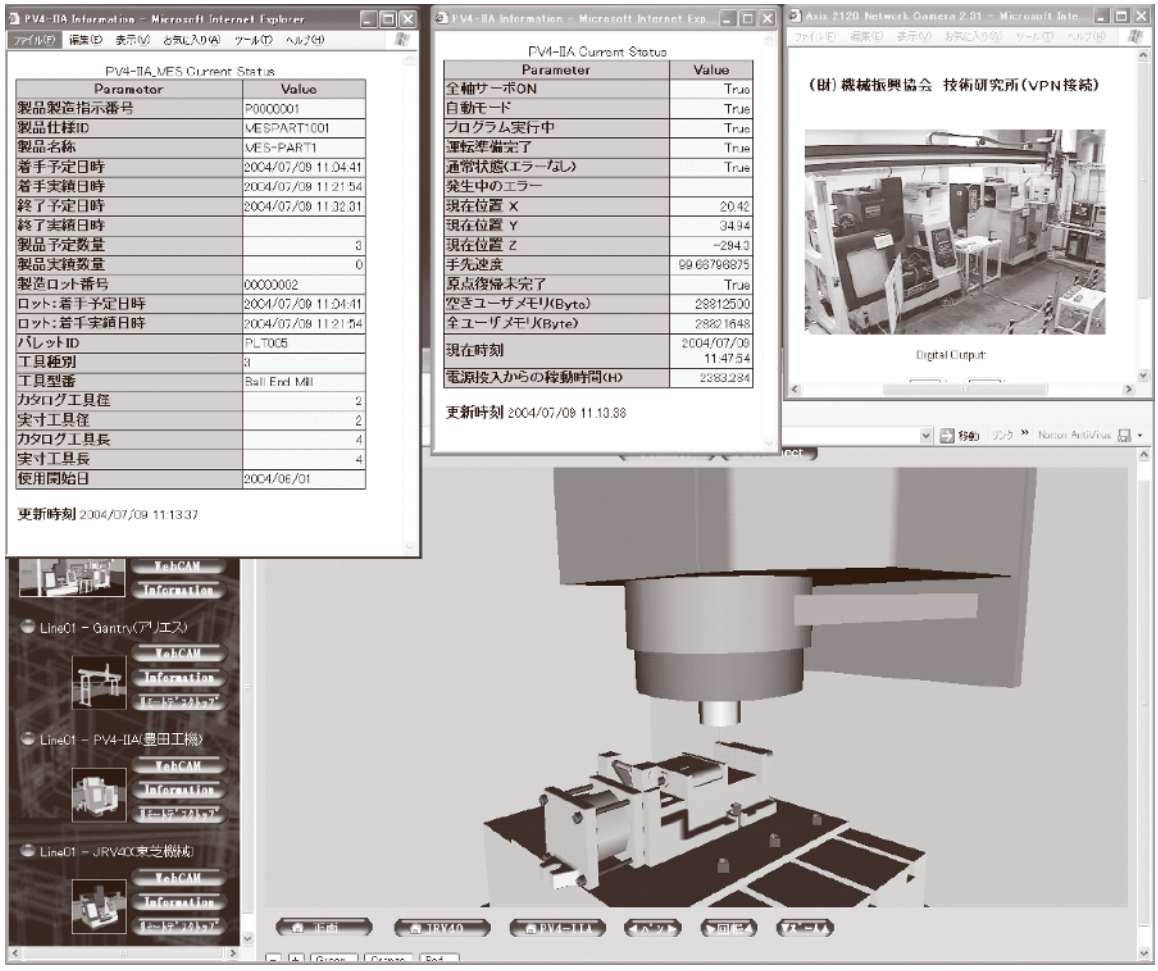

Fig. 15.37 Test operation of the environment

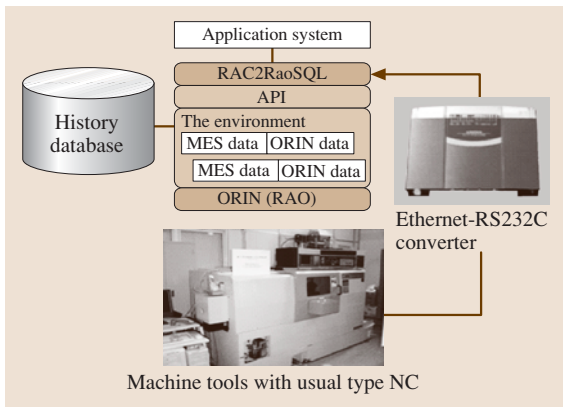

Fig. 15.38 Connection method used for usual type NC

Fig. 15.39 An example of application system

15.6.2 Development of Prototype Application Systems

An Application System for Open NC Machine Tools and MES Applications

For a manufacturing system line consisting of one transfer robot and two machine tools, integrated with OpenMES [15.94] as shown in Fig. 15.35, the mechanism of the interoperable system is shown in Fig. 15.36. The equipment class of the OpenMES has been mapped to the RaoSQLController class of RaoSQL. The other OpenMES classes and other ORiN classes have been mapped to the RaoSQLItem class of RaoSQL.

Provider software as interface software between devices and ORiN for the machining tool and the transfer robot have been developed using the APIs of each controller with Microsoft's Visual C++. However, because OpenMES uses Java, a software interface between OpenMES and RaoSQL using a Java wrapper was developed.

Test operation of the prototype was performed using the three-dimensional (3-D) layered information viewing environment (3-D LIVE) [15.95]) which was developed in advance. Conventional 3-D LIVE was developed as an application system that uses RAO information directly. The ability to show MES-level information together with device-level information became possible by changing the information reference source in 3-D LIVE to the IIE, as shown in Fig. 15.37.

Application System for Machine Tools Without Network Interface

Examples of accessing operational information from machine tools without network interfaces without a major conversion process include:

- Acquisition of operational status through the machine tools operation panel/switchboard or digital input output (DIO)
- Estimation of a machine tool's cutting load by measuring the electrical current of the spindle amplifier

NC controller comments as well as variables in the external output command of the NC program can be exported through the RS232C interface of the NC controller through the use of macro functions. Additionally an external direct numerical control (DNC) computer can manage the operational status of a machine tool if that machine tool is running a DNC system.

Accessing information using an external output with macro functions may be adopted for machine tools without a network interface. Ethernet-to-RS232C converters can be used to integrate this system as a very economical solution. The corresponding system configuration is shown in Fig. 15.38. There are also cases (such as when using a CAD/CAM system) where MES-level information such as product name, date of delivery, and tool information are known right after the NC program is made. In such cases, the external output commands from the macro function for the MES-level information can be inserted directly into the NC program. The format of the comment information from the external output is based on the robot action command (RAC) [15.96] specification that was developed by the ORiN consortium. Once the NC program has been prepared it is transmitted to the NC controller of the machine tool. The comment information can then be used for setting up the machine tool by viewing the display panel of the NC controller. The comment information is then output through the RS232C interface of the NC controller, which is synchronized with the execution of the NC program. Subsequently, the comment information is sent to the RAC2RaoSQL, which is an application system for receiving the RAC data through a transmission control protocol (TCP)/internet protocol (IP) socket or virtual COM port on a network using the Ethernet-to-RS232C converter. After the RAC2RaoSQL receives the comment information it is written to the IIE.

The configuration of the test system consisted of a factory site and a remote site. The factory site had a developed prototype system for a turning machine with an IIE. A client computer, using a web browser, was prepared at the remote site and connected to the factory over the internet using a virtual private network (VPN). Figure 15.39 shows an example of the indicator screen on the client computer. The NC program's name, executing sequence number, the product's name, date of delivery, scheduled production count, actual production count, and the process name of the executing NC program can all be seen in this example.

15.7 Advanced Organization Concepts

Continued trade liberalization and reductions in trade barriers are accelerating international flows of information, goods, and services. The major impact on enterprises has been the greater availability of resources as low-cost labor and manufacturing capacity, which has become an increasingly compelling reason to move towards sourcing parts and components globally. Other key driving forces can be identified as shortening product lifecycles, placing a premium on speed to market, and profiting from rapid declining costs of transportation and communication.

Companies, being cornered by these phenomena, have realized that just tuning operations and functions will not remove the difficulties. More integrated organization concepts, supporting the improvement of key performance indicators such as business process reengineering (BPR), the improvement of quality by total quality management (TQM), the improvement of work in process by just-in-time (JiT) production, and the improvement of productivity by total productive maintenance (TPM) have been regarded as sustainable solutions. However, these concepts only represent important steps towards rediscovering the organizations' strategic nature in enterprises. In order to face new global challenges, adequate organization structures turn out to become the most powerful and indispensable strategic instruments for companies (Fig. 15.40).

Fierce competition at all levels, first observed in the *triad* of North America, Europe, and the Far East and later experienced in many parts of the globe, enforces holistic thinking in industrial organization. Expanded objectives and volatile objective settings demand innovative, learning, open, networked, flexible structures. The assumption that industrial organizations are results of predictability and deterministic design no longer holds. Hierarchical organization structures become obstacles to market success.

More theoretically speaking, organizations and operations that are exposed to such complexity [15.98] induced a paradigm change [15.99], as their behavior and reaction become nonpredictable and do not coincide with proven and known patterns of management. Organizations and structures have to be redesigned and redirected; successful and sustainable solutions draw from generic approaches for new enterprise organization.

Lean manufacturing (lean production) is one such approach; later others appeared: the fractal company, agile manufacturing, and holonic and bionic manufacturing.

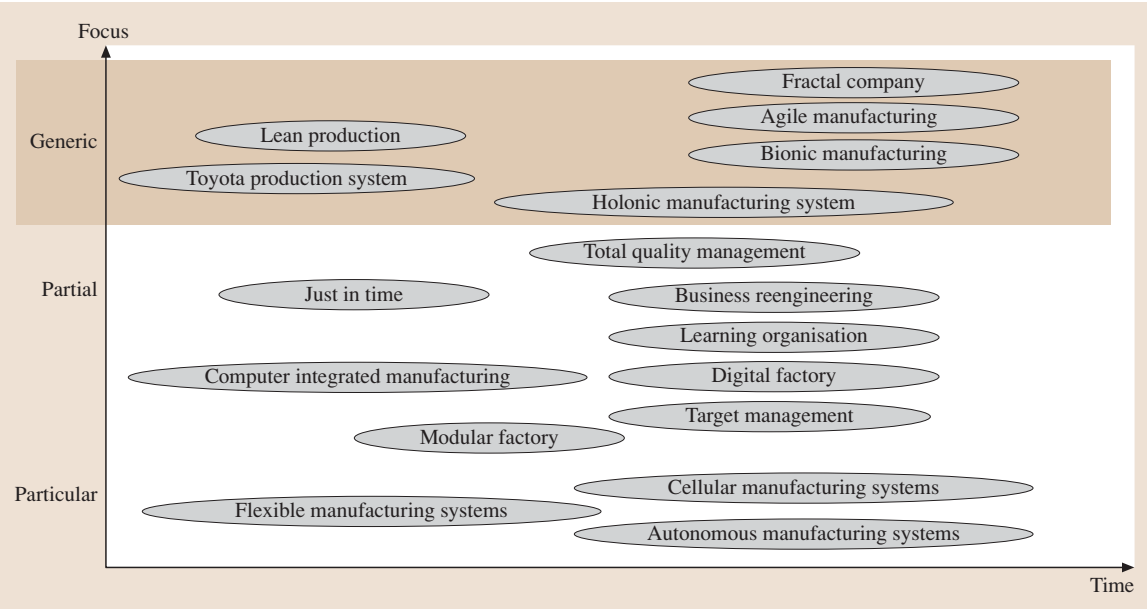

Fig. 15.40 Important management approaches due to paradigmatic shift (according to [15.97])

15.7.1 Lean Production

Since the MIT studies on *the machine that changed the world* [15.100] lean production has become one of the most frequently discussed organization concepts.

Lean production is an assembly-line manufacturing methodology developed originally for the manufacturing of automobiles, derived from the theory of constraints [15.101]. It is also known as the Toyota production system (TPS) [15.102]. Many practical approaches that are also referred to as lean manufacturing (lean management, lean company, lean enterprise etc.) are motivated by this methodology, or originate from Toyota production system blueprints. The guideline for lean production can be formulated as *to get the right things to the right place at the right time, first time, while minimizing waste and being open to change*. Lean manufacturing can be classified as a team-centered organization specification. While developing the principles of lean production [15.103], it was discovered that, in addition to eliminating waste, the methodology leads to improved product flow and better quality.

There is no established theory for lean production, but theoretical grounds may be found in the theory of constraints. However detailed methods and rules for the successful operation of *lean* are outlined. The most cited rules (simplified) are:

1. Produce only what is ordered and only when it is ordered. Apply this to product, organization, as well as product features; otherwise there will be waste.
2. Investigate any mistake with the highest priority and find solutions for strict mistake avoidance.
3. Everybody involved in production is obliged to improve products and processes continuously.

To implement these rules, a set of methods is proposed (frequently using Japanese language terms) that may be interpreted as patterns of lean production. The rules most frequently referred to are (not always strictly applied in the original *Toyota* sense):

- *Kanban* (use card), a material flow and inventory control procedure, supporting just-in-time production and minimizing lead time as well as inventory levels
- *Kai zen* (improve the good), prescribing the continuous improvement process (CIP)
- Six Sigma, calling upon statistical backgrounds to achieve waste ratios, measured in parts per million (ppm)
- The five S's: *seiri* (sort out), *seiton* (clean up), *seiso* (keep proper), *seiketsi* (make orders your rules), and *shitsuke* (improve all things continuously) as simple rules of behavior for everybody in the organization
- Management by view: all processes are visible and transparent in order to recognize irregularities immediately
- *Poka yoke*, technique to obtain error-free transformations and moves
- Quality circle (QC, TQM): readiness to improve the quality of all processes, executed by teams
- *Jidoka*, to stop process steps (including the impressive *pull the emergency line* option) if errors are detected/assumed

For the implementation of the methods and rules, ten steps to lean production are recommended:

1. Eliminate waste
2. Minimize inventory
3. Maximize flow
4. Pull production from customer demand
5. Meet customer requirements
6. Do it right, first time
7. Empower workers
8. Design for rapid changeover
9. Partner with suppliers
10. Create a culture of continuous improvement

Instead of devoting resources to extensive planning, the Toyota production system focuses on reducing system response time by enabling the production system to adapt instantly to market demands. All automobiles are made to order, resulting in a number of effects: delivery on demand, minimization of inventory, maximization of the use of multiskilled employees, flattening of the management structure, and concentration of resources where they are needed.

Lean production shows revolutionary attributes, providing an enormous productivity boost [15.104]. Therefore other companies (even competitors) have tried to adapt this methodology and integrate it into their corporate strategies, coining terminologies of *X*–production systems (where *X* is the company or brand name) that summarize rules and methods as mandatory parts of multisite company-wide standards (footprints).

15.7.2 Agile Manufacturing

Agile manufacturing [15.105] was developed from the synthesis of a lot of companies with individual abili-

ties or responsibilities, which come together in a joint venture. It was intended to be able to use the sum of abilities and resources of all the partners together. These joint-venture companies are called virtual companies, able to reshape and change quickly. The implementation of agility aims for intensive exploitation of organizational knowledge. For this purpose individuals are motivated to collaborate closely in dynamic teams focusing on clearly defined opportunities in the market [15.106]. Employees and information are the key factors that should ensure the superiority of agile companies compared with the surrounding competition.

Agile manufacturing aims to enable an increase in performance of companies by achieving major steps toward flexibility and time to market. Hence, the value chain has to be compatible with fast movement of products to market.

The main target of agile manufacturing is the development of durable success in an environment of continuous and nonpredictable change. For success the times of processes inside the value chain have to be in accordance with the fast movement of products to market. The agile approach aims to serve mass markets, but all individual wishes of the customers should be granted. Cooperation with other enterprises helps to produce new products faster and cut costs, reducing the risks for all partners. Usually joint ventures – vertical and horizontal mergers within the value chain – establishing virtual companies are the strategic aim.

A characteristic of this concept can be identified is the rapid change of the structure of the networked organizations. This includes all efforts to make use of the latest information and communication systems as well as the integration of fast reprogrammable technologies in production [15.107].

Within the agile concept the employee is the focus; the necessity for a high level of knowledge and education is clear. The employee must act as an entrepreneur in the company and must be actively engaged in all relevant processes, because of the low and simple level of organization. The dynamic development of a team actively helps to develop the creative and innovative talents of other members of the teams. Management assists by developing company culture, supporting creativity, and being open to experiments and risk-taking by the employees. Leadership is based on motivation, support, and especially on building trust.

15.7.3 Bionic Manufacturing

Recognizing that even so-called *flexible manufacturing systems* are not able to fulfil the demands of customer-specific parts production, the bionic manufacturing system (BMS) was developed [15.108]. BMS is an approach that aims to master the future demands of manufacturing systems through the application of technology that mimics the nature of living beings. The core idea of the BMS is the *creative system*, in which the materials provide the necessary information to the manufacturing equipment. Intelligent methods respond to this information using flexible and autonomous technical units.

BMS draws on the results of artificial life research, by embedding DNA-type information into the materials to be processed. Material with this stored information is passed onto the manufacturing system so the product can be built accordingly. Information is transferred to the operating manufacturing system, offering the following characteristics:

- Ability to learn and identify necessary tasks
- Ability for self-maintenance
- Ability for communication
- Ability for self-creation to acquire new product and technology knowledge [15.109]

The product collects further information and passes this on as recycled raw material back to the manufacturing system, which interprets the information again and develops further. The basic information (for example, the method to move = car) survives as DNA information, whereas the bionic manufacturing system information enables the system to develop independently and adapt to cultural and temporary demands.

This far-reaching vision has remained in fashion for a long time and currently miniaturized transponder technologies such as RFID are enabling powerful solutions of this kind [15.110].

15.7.4 Holonic Manufacturing Systems

Holonic manufacturing systems (HMS) may be envisioned as specific interpretations of BMS, as HMS are also able to adapt and incorporate new products, new organizational structures, and new technologies. Holonic organizations (or *holarchies*) support the setup of very

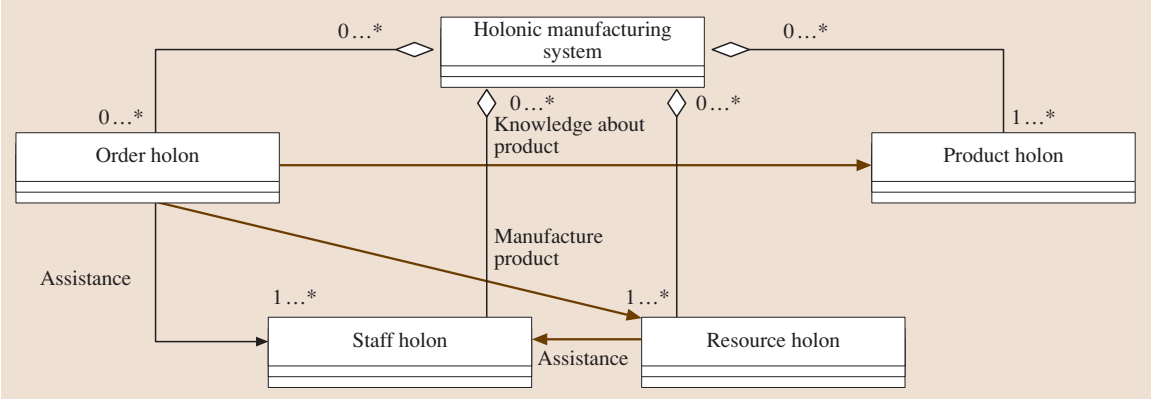

Fig. 15.41 Basic setup of a HMS

complex systems that are highly resilient to disturbances (both internal and external) and adaptable to changes in the given environment.

The basic ideas for this concept originate from *Koestler*, who identified behavioral properties of living organisms and social entities [15.111]. He stated that complex systems are adapted by evolution, where a holon (from the Greek meaning "whole", as coined by Koestler) is an identifiable part. The entity itself is made up of subordinate parts and in turn is always part of a larger whole. The self-reliance property ensures stability and abilities to cope with disturbances, as holons handle processes and problems on their particular level that do not involve higher-level holons. Holons may receive instructions and are therefore controlled (to a certain extent) by higher-level holons, ensuring the effective operation of the larger whole.

This idea can be transferred to manufacturing by introducing holonic manufacturing operations constituting a flexible manufacturing system Cooperating control units solve a common control problem by exploiting the self-reliance property of holonic systems, finally leading to what is known as *holonic manufacturing systems* (HMS) [15.112]. Progress in software engineering and numerical control allows full incorporation of holonic behavior into operations execution. The resulting HMS control product–resource–order–staff–architecture (PROSA) makes automated processes (the *shop floor* as well as the upper layers of the automation systems) more flexible by avoiding overheads on the control level [15.113].

Holonic development is still ongoing at the international scale. The HMS consortium has published the following list of definitions (among others) to specify the translation of holonic concepts into a manufacturing setting [15.114]:

- A *holon* is an autonomous and cooperative building block of a manufacturing system for transforming, transporting, storing, and/or validating information and physical objects.
- The capability of a holon to create and control the execution of its own plans and/or strategies is referred to as *autonomy*.
- The interaction of a set of holons to fulfil a common goal is referred to as *cooperation*. This will normally cover a process whereby a set of holons will develop mutually acceptable plans and will execute these plans.
- A system of holons that can cooperate to achieve an objective is called a *holarchy*. The holarchy defines the basic rules for autonomy of, and cooperation between, holons.

PROSA implements the HMS architecture by four main types of agents, implementing four main types of holons: the order holon, product holon, resource holon, and staff holon (Fig. 15.41) [15.115].

Based on the HMS approach and the PROSA findings, a number of holonic control architectures have been developed in recent years [15.116].

All architectures support steps toward more flexible manufacturing systems by additional implementation of interfaces on the field control level as well as to the ERP level.

15.7.5 The Fractal Company

A turbulent environment (market, surroundings, and resources) and acceleration (turbulence) of market shifts

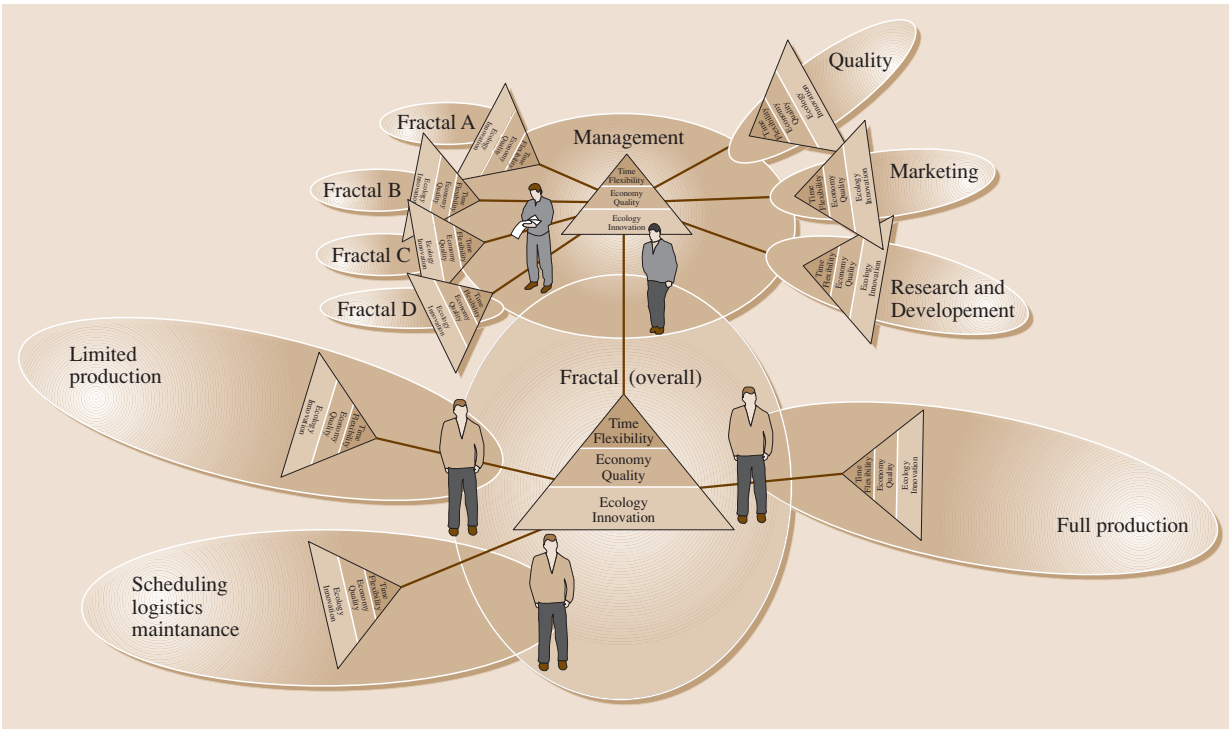

Fig. 15.42 Fractal company: A typical organization chart

lead to enormous complexity for companies. So, networks of autonomous units, forming versatile company structures, may be seen as an adequate organization structure [15.117].

Companies are decomposed (companies in the company) and transformed into networks of units [15.118]. In order to direct these networks of units or network organizations, additional instruments are engaged that master this complexity. For the management of complexity in geometry Mandelbrot proposed the fractal view, where complex geometrical structures and patterns are discovered as results of simple rules of self-similarity (e.g., Mandelbrot set, Koch's snow flake) [15.119].

This self-similarity property, found in geometrical structures, has successfully inspired organization theory [15.120], resulting in the fractal company concept [15.121].

The fractal company envisions enterprise organization as consisting of autonomous team units – so-called fractals. These fractals are attracted by (internal as well as external) market opportunities. Thus the companies' market opportunities are to be taken by the units directly; therefore the strategy parameters have to be *translated* into the units' language. The companies' objectives are self-similarly broken down into units' objectives to *guide* the teams (i. e., the fractals) [15.122].

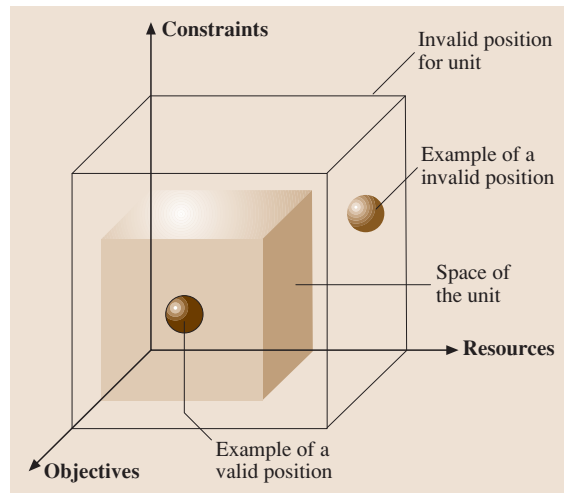

Fig. 15.43 Space of activity (SoA) by mappings for planning and control of production networks with position cases

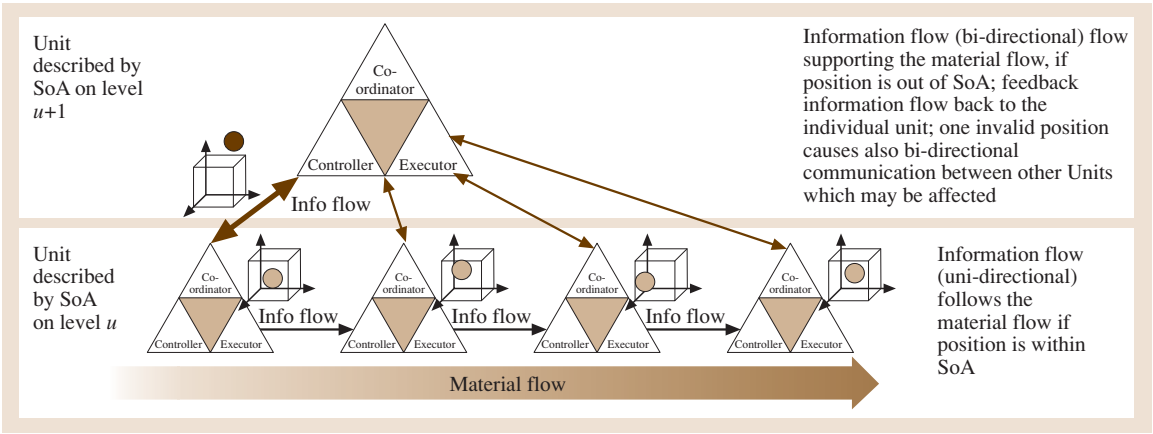

Fig. 15.44 Information flows for harmonising goal settings/SoA volumes caused by invalid position of higher level SoA

The fractal company is therefore defined as an organization consisting of goal-orientated self-similar team units – the fractals – that are described by the assigned objectives and outputs (Fig. 15.42) [15.123].

Resulting properties are structural versatility, dynamics, and vitality. Operating a fractal company is a continuous development, an objective alignment and improvement process. As the most important consequence, detailed job descriptions and schedules have to be abandoned and replaced by self-organization, visualization of the objectives' updates, and increased decision power of the employees.

Decision-making in network organizations such as the fractal company largely involves negotiation and communication between units, since there is no central control [15.124]. The decision support model used for the fractal units is the space of activity (SoAs) (Fig. 15.43), which describes the units' activities and success.

All units' objectives are to be harmonized with the overall company objectives. Therefore, consistency procedures for the networked company organization must be applied (Fig. 15.44). SoA parameters are the input for the decisions about maintaining the self-organization mode or calling for stronger company

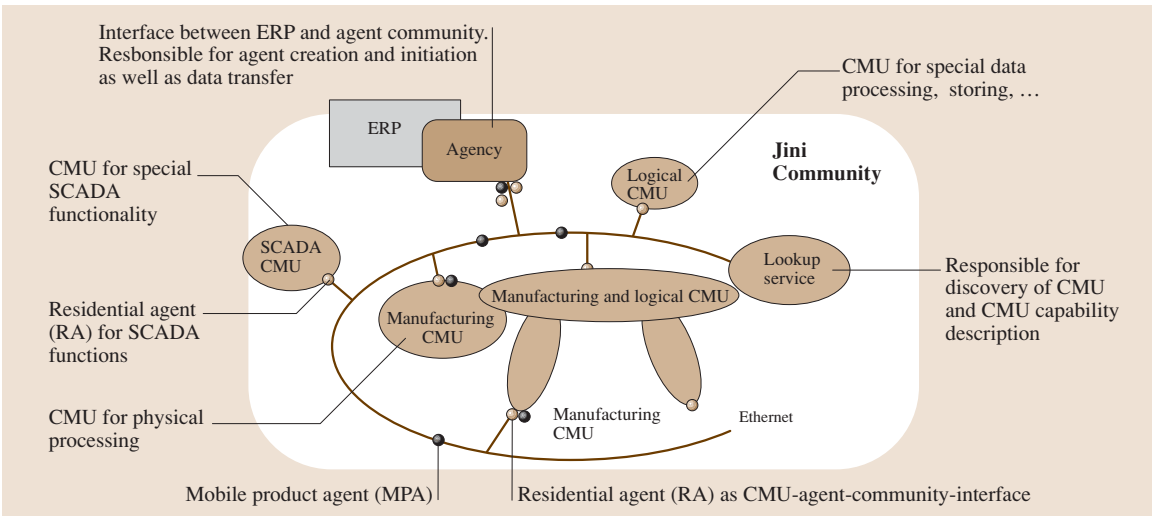

Fig. 15.45 PABADIS control architecture (Jini – Java intelligent network infrastructure; SCADA – supervisory control and data aquisition; CMU – cooperative manufacturing unit)

Table 15.11 Six key attributes of advanced organization concepts

	Fractal	Holon	Bionic	Agile	Lean
Origin	Geometry	Physics	Biology	Nature	Theory of Constraints
Analogy	Fractal	Molecule	Organism	Agility	Mechanics
Key principles	• Self-similar • Self-organization • Self-optimization • Process-orientation • Vitality and dynamic	• Self-similarity • Autonomy • Distributed intelligence	• Autonomy • Cooperation • Self-organization • Self-optimization	• Enrich the customer • Master change • Resources • Cooperate to compete	• Perfect first-time quality • Waste minimization • Continuous improvement • Pull processing • Flexibility • Long-term relationship with suppliers
Methods of structuring	• Product structure • Equipment • Employees • Flow of material	• Tasks and their similarity	• Knowledge base of autonomous elements	• Potential of supply and demand	• KAIZEN • POKA YOKE • KAN BAN
Objective	• Cohesive organization structure along the value chain • Minimizing interfaces	• Mutability • Ecologically sensitive • Robustness	• Dynamic adaptation and organizational ability to learn	• Adequate flexibility of the production system to react to market changes	• (MUDA) (Japanese for 'eliminate waste'
Appearance	• Divisions with variable organization structure	• Event-driven communication between machines	• Sender–recipient relationship between resources and material	• Flexible organization structure • Interdisciplinary teams • Flat management structures	• JIT • Pull • Value stream
Configurable resources	• Employees • Divisions	• Equipment	• Elements with inheritable knowledge (equipment) • Elements with learnable knowledge (material)	• Employees • Production and information technologies	• Objects • Equipment
Development of resources	• Skills and social competencies	• Distributed systems	• Evolution of knowledge	• Syntheses of resources	• Best-practice benchmarks

interference [15.118]. If objectives of an unit are not achieved, the company top level must be involved: However, depending on the unit's ability to profit from the opportunities in dynamic environments, the company may lower its influence on the unit, allowing or even supporting autonomous activities of (self)-optimization, (self)-organization, and (self)-structuring.

Figure 15.44 illustrates only one case of the companies' meshed control loops established by SoA interactions or interferences. Higher structure levels of the company are represented by SoAs, self-similarly containing all corresponding SoA structures. Increase of market complexity (uncertainty, turbulence, and unpredictability) may force the company to expand the spaces of activities. More-foreseeable steadier conditions reduce complexity. Such conditions make smaller SoAs more effective, in the limit degenerating to a point a the origin for uniform mass production. The SoA model can therefore be envisioned as a generalization of the job definition in the hierarchical organization.

Based on the SoA setup as outlined, negotiation and decision procedures between the units can be formalized and assigned to software agents. Making use of internet technology as well, a next-generation control architecture aiming at adaptable manufacturing equipment, flexible integration of different types of control systems, and distributed control devices for the execution of manufacturing orders can be derived: e.g., the plant automation based on distributed systems (PABADIS) architecture [15.125]. A PABADIS-compatible control system consists of four components (Fig. 15.45): the agency, the agent community, the CMU community, and the lookup service [15.126].

The main benefits of PABADIS are improved order and resource flexibility and the generic interface structures of the control units – the control building blocks. The integration of a new order or a new product only requires the specification of the related set of manufacturing process data. Product and order agents are generic and therefore valid for each possible application case. This avoids the implementation of new agent types when changes occur.

These properties and the internet compatibility of the PABADIS architecture has attracted the attention of leading vendors and users of planning and control systems for manufacturing. Within the PABADIS'PROMISE approach the PABADIS architecture will be improved and extended to all levels of control [15.110].

15.7.6 Summary

Fierce competition and saturated markets have forced enterprises to cope with the diversity in customer requirements and the speed of the demands of the markets. Organizations had to become more flexible, versatile, adaptable, and reconfigurable in structure.

It is evident that this paradigm shift has generated radical innovations in organization. Of the numerous progresses, the most important generic concepts have been outlined in this Section. These approaches are characterized and compared in terms of their key attributes in Table 15.11.

15.8 Interorganizational Structures

Individual organizations are characterized by a mission, which states the scope and principles of their business. A mission tends to have a restricted focus with respect to market and product/service, even though, particularly for large corporate companies operating in different market sectors and product/service areas, the mission statement may consist of a general statement of intent.

Throughout their evolution, companies continuously face new challenges derived from the evolution of products, technology, and markets, and face the need to acquire improved governance capability over the market and the product/service lifecycle, while being compelled to cope with limited resources in terms of finance, disciplinary competence, capacity, and risk sustainability.

Without addressing issues associated with monopolies and vertical trusts, this increase of control can be pursued either through internal growth of a company (possibly using merger and acquisition levers), or by seeking cooperation with external entities (Fig. 15.46).

Further progresses in ICT, especially the maturity of the World Wide Web (WWW), offering as-yet-unknown possibilities to transfer/store huge volumes of information throughout the globe, accelerates further decentralization. Dispersed production units may cover product segments, functional units or entire production stages, dissolving boundaries within and between

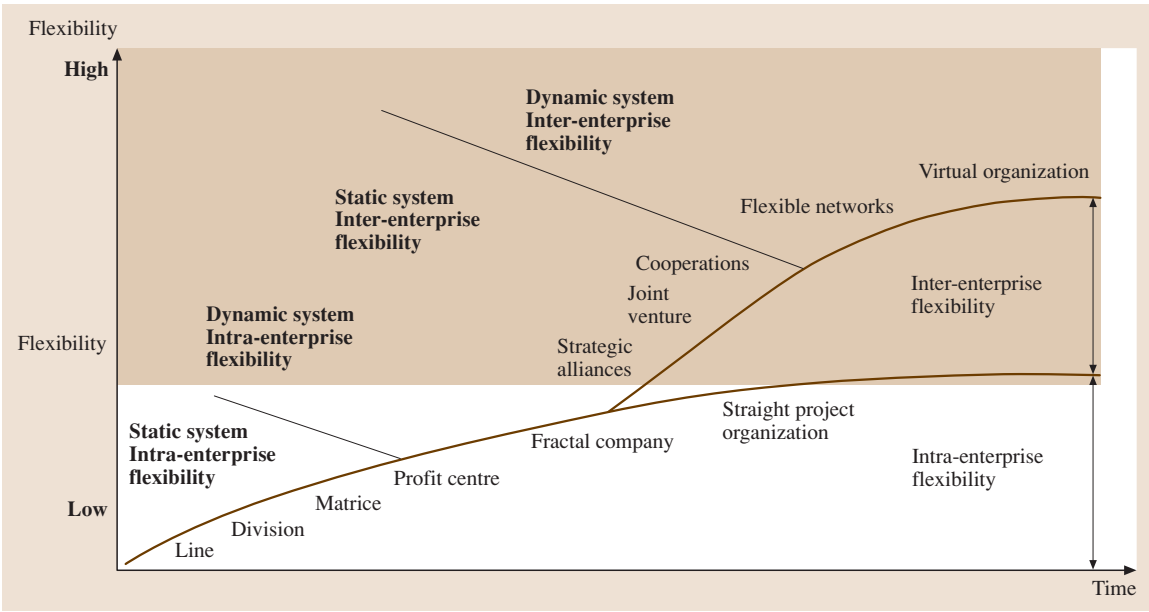

Fig. 15.46 Evolution of inter-enterprise flexibility (after [15.14])

organizations/companies completely. Such distributed structures, known as virtual organizations (VO) or extended enterprises (E2), are able to develop and deliver products and services faster and cheaper. Benefits result from combining complementary capabilities and experiences which would otherwise need to be acquired at high cost. Broken down into equipment units, objective fulfilment is executed by globally distributed networked operations resembling a production grid of communicating units.

15.8.1 Cooperation

Cooperation [15.127] is the practice of working in common, with commonly agreed-upon goals and possibly methods, instead of working separately in competition.

Cooperation mechanisms have been the subject of several studies in the area of theory of games [15.128, 129], providing theoretical support for the identification of behavioral principles both in the launch of cooperation and in the management of its operation.

Depending on the relationships among the collaborating entities, cooperation may take different legal and organizational structures:

- When there is a clear lead by one of the participants, cooperations are shaped and managed according to hierarchical schemes (Fig. 15.47), typical of the supply-chain environment, with organizations that

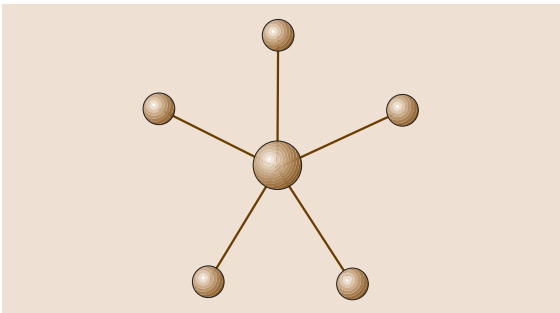

Fig. 15.47 Dominated co-operation

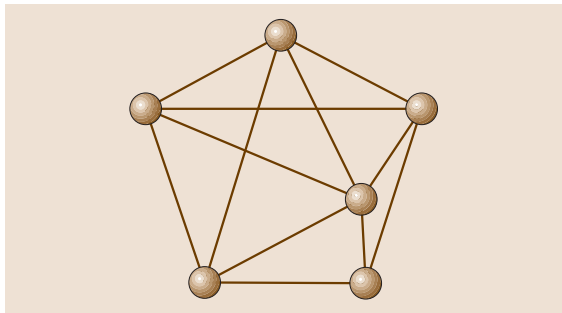

Fig. 15.48 Co-operation among equals

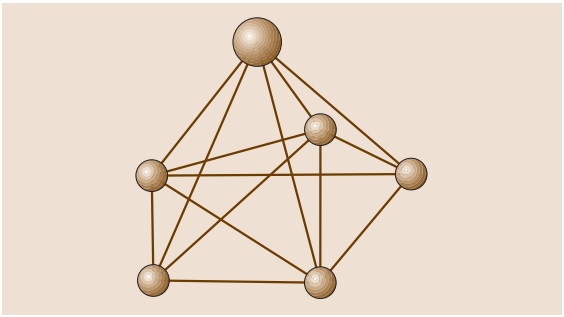

Fig. 15.49 Extended enterprise relationships

tend to be based on contractual agreements and normally resemble the work breakdown structure (WBS) defined and set for the achievement of the collaboration goal.

- In the case of cooperation among equals (Fig. 15.48), organizations are shaped using a wide degree of freedom, depending on applicable law and on the scope of the collaborative initiatives.

Cooperative structures have a quite wide variety, and identified classes are not mutually exclusive, as some blending may occur, as in the case of extended enterprises (see below), where dominated cooperation is mixed with cooperation among equals to allow for peer-to-peer cooperation among nonleading partners (Fig. 15.49).

In the following, reference will be made to six classes of interorganizational structures (Fig. 15.50):

- Alliance
- Network
- Supply chain
- Virtual organization
- Extended enterprise
- Virtual enterprise

which overlap and may actually be a substructure of wider types, as in the case of virtual enterprises with respect to alliances.

15.8.2 Alliances

The term *alliance* is a generic term used in business to refer to several kinds of cooperation frameworks, mostly characterized by a *peer-to-peer* partnership condition.

Alliances mostly respond to the need of individual companies to minimize the risk in initiatives that may

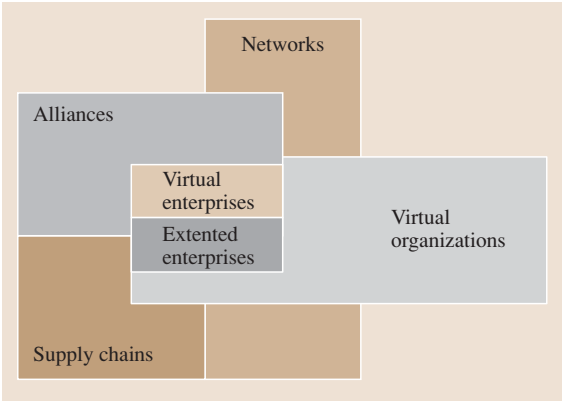

Fig. 15.50 Co-operation structure types

substantially impact the health of the organization in case of failure.

Three main drivers have been identified [15.130] for the launch of an alliance:

- Globalization: the reduction of trade barriers and subsidies pushes toward larger scale and international presence.
- Time to market: speed of competitors is growing, and traditional organic growth cannot keep pace with it.
- Diversification: companies tend to open a second, third or fourth business to spread the risks of investors in company's stock. The idea is that, by entering a business that does well in recession of other company *legs*, the stock price and cash flows will hold up during business-specific contingencies.

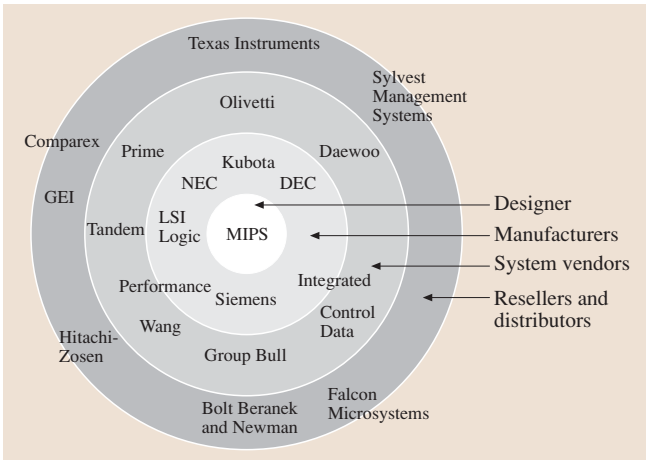

Fig. 15.51 The MIPS RISC constellation

An additional consideration is cost to market to develop new products or services at lower risk and shared risk to retain market share, where market share is traded against development cost, or to penetrate new markets, possibly by working with a recognized partner in a market segment to open opportunities at lower risk and cost.

When alliances involve several partners, it is usual to refer to them as *constellations*, as in the example of the alliance setup by MIPS in the early 1990s for the development of the innovative reduced-instruction-set computer (RISC) technology (Fig. 15.51).

Alliances imply the joining of companies to pursue common, shared objectives, tend to have a limited number of partners, and are usually associated to particular kinds of cooperation:

- Alliances are the mechanism used to achieve results that would not be within the reach of individual entities, or in general to minimize risks and organizational costs of particularly challenging or expensive initiatives.
- An alliance may also be a safeguard mechanism through which otherwise competing entities perform a high-risk activity together so that failure of the initiative cannot lead to a strong competitive edge for nonparticipating parties (as in the development of radically new technologies).

Sometimes alliances represent a real alternative to mergers and acquisitions, to enable greater market competitiveness, as in the case or commercial airlines, which enter code-sharing agreements to improve their market reach and their capability to satisfy the requirements and expectations of their own customers. In some cases, alliances provide a trial environment for mergers, allowing for testing and tuning of evolved, integrated business processes for the new integrated company. Conversely collaboration on specific products and services allows organizational cooperation without the risks and inherent costs of merger or acquisitions.

From the point of view of management issues, the establishment of specific collaborations schemes with external entities meets several objectives:

- Keeping the focus of interaction on specific business objectives
- Allowing for the control of advancement and efficiency of activities
- Improving the interaction capability between different entities, focusing on joint strengths in the alliance
- Achieving cost-effective routes to market

Alliances can be managed through joint legal entities, i. e., separate companies with stock-holding shared among the partners, or on a pure contractual basis (typically assuming the contractual form of *joint ventures*).

While in any case partners maintain their individual business focus, they allocate resources to the common initiative, and tend to establish an independent management office so to ensure that agreed mutual obligations and business focus is maintained throughout the life of the alliance through a central point of control, communication, and responsibility.

The business concept for the alliance, particularly when in the form of joint creative developments (as in the case of alliances for the exploration and development of radically new technologies), may change over time, and the existence of an independent management entity helps to identify the most appropriate organization evolution strategies that are capable of accommodating the needs and expectations of all partners.

Whether through actual or virtual collocation, human resources are usually allocated to alliances on a full-time basis, as in the case of large projects in integrated companies. This is likely to raise several issues in partners' personnel management strategies associated with the possible loss of feeling of belonging by deployed personnel and to frequent problems in the management of professional careers and the difficulty of ensuring adequate recollocation of personnel within partner companies at the closure of joint operations.

Even in the case of alliances that may lead to substantial benefits to partners and to significant evolution of core business (so-called *strategic alliances*), partner companies maintain their individuality. They are driven [15.131] to frame their cooperative initiatives within the global company strategy, which may well include an *alliance strategy* as a policy to achieve company vision and goals, but which cannot be substituted by a single strategic alliance, as that would de facto result in the same level of risk for the company as before, thus missing out on the main benefits yielded by the alliance.

As a final note, it is worth quoting the top ten factors identified by *Benjamin Gomes-Casseres* [15.132] for the success of an alliance:

1. Have a clear strategic purpose: treat alliances as tools of a business strategy.
2. Find fitting partners: select partners with compatible goals and complementary capabilities.
3. Specialize: allocate tasks and responsibilities in accordance with each party's best capabilities.

4. Create incentives for cooperation: the cooperative attitude must be nurtured, particularly when partners were formerly rivals.
5. Minimize conflicts between partners: allocate roles in such a way to avoid pitting one against the other in the market.
6. Share information: communication develops trust and keeps projects on target.
7. Exchange personnel: personal contacts and site visits are essential for maintaining communication and trust.
8. Operate with long time horizons: sharing a vision strongly supports the solution of short-run conflicts.
9. Develop multiple joint projects: successful projects can help when other projects enter critical phases.
10. Be flexible: alliances are open-ended dynamic relationships that need to evolve in pace with their environment and in pursuit of new opportunities.

Those factors imply an underlying company strategy based on time to market, cash flow, investment, the availability of resources, and the capability to manage alliances in line with organizational investment cycles for new products and the natural lifecycle of products to secure maximum revenue.

15.8.3 Networks

Compared with alliances, networks provide a looser kind of relationship [15.133], as they imply multiple close but nonexclusive relationships, whereas alliances imply the creation of a joint enterprise, at least over a limited domain.

Networks generally exist on the basis of complementarities and potential synergy among members, which lead joining companies to associate with the network a greater opportunity for acquiring and retaining a competitive edge in the market:

1. To reduce uncertainty: the relationships developed through the network allow for avoiding the uncertainty associated with impersonal, nonrepeatable, and purely exchange-based market transactions.
2. To provide flexibility: the network provides a greater expectation of immediate resource reallocation, and allows for looser constraints in the establishment of joint product/service-specific initiatives.
3. To provide capacity: the likely availability of individual network members' spare capacity allows companies to reliably pursue opportunities that lie beyond their own contingent capacity while improving the management of contingencies in day-by-day operations. Furthermore, the network allows for the rapid provision of resources and skills which are lacking in a company through access to qualified resources from other known members.
4. To provide information: members of networks have easier access to industrial intelligence, as open information constitutes one of the mechanisms for establishing relationships and one of the principal reasons for members to join.

A network is expected to offer to its members relationships that can lead to profits in the future. Based on this motivation to join, the power of a member has [15.134] five main sources: economic base, technologies, range of expertise, trust, and legitimacy, i. e., the characteristics that are most likely to support the success of initiatives by other members.

Such expectations lead to governance principles that are close to historical socioeconomic organizations founded on reputation (both individual and acquired through belonging to groups of qualified members, such as a family or a clan) and on the provision of services and favors, which do not offer immediate reciprocity but which are aimed at strengthening relationships in view of future opportunities.

The networking principle is applied as a mechanism for both dominated cooperation and for cooperation among equals. Cooperation domination is typical of advanced supply chains and extended enterprises (see below), whereas *peer-to-peer*-based networks constitute a characteristic dynamic entity which needs specific management provisions to be maintained.

The peer-to-peer network is not a substitute organizational form for the integrated firm, even though collaborative business operations are usually conducted in accordance with classic customer–supplier relationships; roles are nonetheless dynamic and vary with business opportunities, and depend on contingent conditions that are mainly related to commercial positioning, competence ownership, dimension, and geographical location.

As there is no stable leadership in these structures, the relationship glue tends to vanish with time, even for networks which are strongly focused on specific market sectors or composed of members with close geographical locations. There is therefore a need for a *network entity*, which is in charge of representing the network identity and of nurturing network relationships, typically through the provision of shared services at the technical, technological, commercial or legal level.

Challenges that must be faced in networks are those typical of closed systems: network relationships may evolve towards the exclusion of newcomers and the limitation of the search for partners to the group of network members, with overemphasized trust that might cause ineffective global performance when compared with a supplier search in the wider market. On the other end, too loose relationships may actually render the network itself ineffective and closer to a *club* than an efficient business organization, even though some national regulations, as in the case of Italian Districts, may nonetheless prize formal membership to such a network.

15.8.4 Supply Chain

The complexity of modern products and services is rapidly growing, and no company can afford to manufacture its product efficiently and fully alone. During the development phase of a product, each part is analyzed for a *make or buy* decision, and an increasing number of components (both material and immaterial, such as analytical services) are procured/sourced from other companies. A similar approach can be taken for the development of a service by either using internal capability or outsourcing where more cost effective, or where a specific capability or capacity is needed to achieve the offering. Furthermore, there is currently a trend towards company downsizing, where internal noncore functions are replaced by subcontracted providers, often constituted as an independent company through the outplacement of salaried workforce.

The sequence of suppliers that contribute to the final product or service (both in direct and overhead activities) is usually called the *supply chain*.

The configuration of the supply chain for a product or service is the result of a selection among alternative suppliers, performed in accordance with a strategy that is certainly based on price considerations, but must also account for several characteristics derived from the overall company strategy:

- Qualification: suppliers are critical for the final result, and therefore need to enjoy a sufficient level of trust in their capabilities; furthermore, specific compliance to regulations and standards is often required for various market and product sectors, and such requirements must be met by all suppliers. The qualification process is normally long and expensive, and must be repeated over time, both to re-register the supplier against currently procured capabilities, but also to consider its possible new capabilities and its potential for evolving technologies and business processes.
- Capacity and stability: the size of suppliers and guarantees of continued operation over the lifecycle of a product allows companies to avoid planning investments for the allocation of internal resources and facilities.
- Reliability and performance: the quality of supply and its timeliness, whenever possible combined with superior knowhow deriving from specialization, together with a consistent level of performance and with the provision of robust results allow for smooth management of operations by the contractor, and minimizes the risks associated with fractionated development and manufacturing.

In the supply chain, responsibility and risk for the final results remains with the lead company, so that interaction among supply-chain participants is typically hierarchical, with relationships between entities that are associated to the product and work breakdown structure that are consequently classified into sequentially ordered tiers.

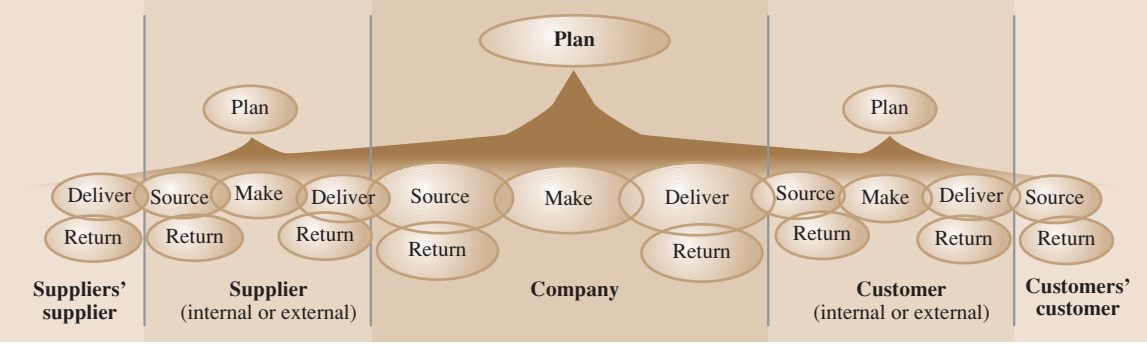

Fig. 15.52 The SCOR processes [15.135]

It is becoming frequent in modern supply chains built for particularly complex products, such as aircrafts, that the manufacturer and first-tier suppliers enter into risk-sharing agreements that provide the manufacturer with additional financing sources in the development phase and reduce the risk that it must sustain; to balance this additional risk, suppliers require higher visibility on strategic decisions and on the reliability of market projections, which tends to strengthen the relationships and the mutual trust, at least for upper-tier levels.

The manufacturer keeps in any case the role of architect, which implies responsibility for the specification of component requirements (as a minimum at a functional level) and of boundary and interface requirements.

The supply chain is then governed through contractual agreements/orders, which specify the scope of provisioning and the conditions for supply (planning and scheduling, delivery methods, invoicing and payments, etc.).

Management of the chain is consequently driven by contractual provisions, with communication flows that are usually associated with expediting and advancement reporting, as well as on compliance of deliveries with requirements.

Operations in a supply chain and its effectiveness [15.136] can be evaluated through its modeling in accordance with the supply-chain operations reference (SCOR) approach. This methodology was developed in the late 1990s by the Supply Chain Council to model and evaluate supply chains. The value chain is described as a sequence of standard processes, namely the *make*, *source*, *deliver*, *plan*, and *return processes*. The contribution of each participant in the value chain can be described by at least one of these processes, which leads at the top level to the general architecture of the supply chain. Figure 15.52 provides an example of how SCOR describes a supply chain. This top level can be specified at the level of process categories (level 2) and detailed process elements (level 3). It is obvious that SCOR also focuses on supply chains to describe and monitor existing value chains with the objective of achieving optimization.

The benefit of the SCOR model is that it provides standardized processes which allow one to model the whole intercompany value chain with a single method – if, of course, all network partners agree to this standard.

15.8.5 Virtual Organizations

The term *virtual organization* appeared in the 1990s to qualify groups of companies that establish cooperative operations through the extensive use and exploitation of new information and communication technologies.

This classification does not imply a specific kind of relationship, so that both dominated cooperation and peer-to-peer cooperation are included.

In particular, when the paradigm of virtual organization is applied to supply chains, the expression *extended enterprise* is used, whereas for virtual organizations among equals it is common to use the terms *virtual corporation* or *virtual enterprise*.

The paradigm of virtual organizations responds to the need to improve the effectiveness and efficiency of cooperation among multiple organizations. In fact, unless the scope of the collaboration is particularly simple, the interaction among independent organizations (and possibly individual professionals) results in a huge number of problems, resulting from the need for harmonization of cultures, processes, and policies.

Virtual organizations leverage the capabilities of ICT to enforce advanced work methods in the partners' organizations, with the aim of establishing operations that use all mechanisms available to the vertically integrated enterprise, while maintaining the greatest level of flexibility in terms of capacity and capability.

The role of ICT is particularly relevant for ensuring team working through virtual collocation, integrated management of development and manufacturing planning, rapid administrative management and efficient cost controlling, and information sharing as well as knowledge management.

This capability allows virtual organizations to have geographically dispersed partners which are selected to have the best capability as required by the scope of the organization, compatible with existing constraints, and pursuing maximum mutual profitability.

Due to their openness and dynamics, virtual organizations are particularly subject to the issue of trust creation and maintenance, unless they can leverage pre-existing relationships as in the case of partners belonging to the same network.

Special care is needed in particular for the management of knowledge in virtual organizations, as the increase of communication flows requires that knowledge is more freely exchanged among participants. Nonetheless, one of the most beneficial characteristics of this type of structure, i. e.,, its capability to evolve

dynamically by changes in partnership according to performance requirements, may be a restraint to the willingness of individuals and organizations to open up some of their knowhow. From this viewpoint, it is important to note that this issue is less critical for product sectors that undergo rapid technological changes, thus rapidly making knowhow obsolete, whereas market sectors with mature technology are confronted with greater reluctance to exchange knowledge due to its relevance for the power, positioning, survival, and progression of the individual and company involved.

However within supply chains and partnerships where the exchange and interaction of knowledge is fundamental to business processes, it is also important that the knowledge available and applied within each organization is comparable, complementary, and well maintained.

Such criticality is reflected in the degree of formalization and standardization of interactions in a virtual organization, which provide support for coupling and decoupling partners with ease.

From the work developed in the European project ARICON (standardised assessment of readiness and interoperability for cooperation in new product development in virtual organization) [15.137], a set of six critical areas (Fig. 15.53) are identified as prerequisites for the success of virtual organizations devoted to new product development:

- Business models and strategies: the sharing of common goals and vision for the cooperation, with compatible business models among the partners is the basis for motivation and effectiveness in decision making.

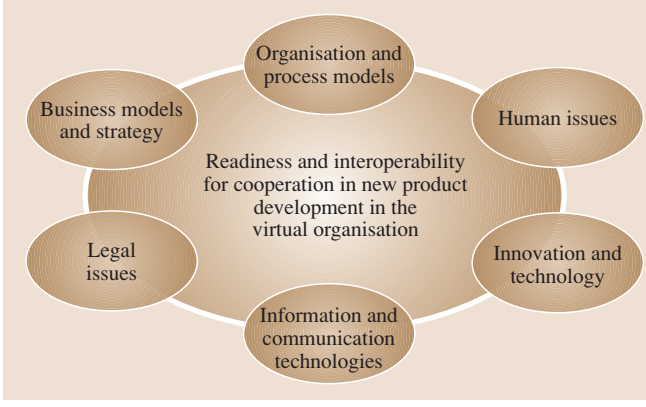

Fig. 15.53 Critical areas in virtual organizations

- Organization and processes: roles, responsibilities, and communication lines to be transferred into operational ICT must be in line with harmonized processes and well-specified interfaces.
- Legal issues: multinational organizations need to have clearly established behavioral rules and contingency management policies and contractual relationships.
- Human issues: complementary, regulated, harmonized partner companies' cultures, individual motivation, professional growth, and operational and motivational training provide a common framework for efficient collaborative work and the option for personnel exchange opportunities for business reasons, cultural exchange or personnel development purposes.
- Technology and innovation: complementarities and alignment among partners' technologies ensure the capability to develop, manufacture, and maintain common products and services.
- Information and communication technology: the basic capabilities for correct organization's working fall in the ICT environment, which should ensure interoperability among the partners' systems and effective collaborative functions.

15.8.6 Extended Enterprise

The extended enterprise is an evolution of the supply-chain environment, and is characterized by the propagation of technical methods, tools, and processes along the supply chain.

The principle of the extended enterprise is harmonization of processes and practices by the propagation of a client's standard way of working towards its suppliers. This kind of harmonization tends to be substantially embedded in the information technology framework that is adopted for the operations, which in the case of the lack of de facto standards is normally specified by the extended enterprise leader, which applies a predefined organizational strategy.

The increased participation of suppliers is evident in the practices of co-design and risk sharing. Co-design, at the relevant level of responsibility of each actor, is the practice of participation in the development of a product within the supply chain. Such an approach is already in use in most complex chains, but with the limitation of physical collocation of personnel, so that only a small part of the development activities could actually be subject to co-design, and therefore with a specific focus on the early phases,

where deviations and misunderstandings may have a larger impact on final cost and time to market. The ICT infrastructure of the extended enterprise allows the collaborative phases to be extended through the life-cycle, resulting in a substantial improvement in effort alignment.

Due to the increased responsibility allocated to suppliers through the process of co-design, extended enterprise leaders tend to adopt a risk-sharing strategy to ensure organizational motivation for best performance. While being enforced through legal agreements, the additional risk taken on by suppliers is enacted through greater openness of strategic information, which flows from top to bottom of the hierarchical chain of suppliers.

The improvements achieved through the extended enterprise concept are therefore related to the establishment of common methods, reflecting harmonized interfacing at the boundaries of individual supplies and leading to:

- Increased ease of communication in the hierarchical path
- The capability to allow for cross communication among suppliers to improve cooperation capability

From the point of view of performance and cost, extended enterprises tend to leverage digital procurement systems not only for the exchange of administrative information during operations, but also for bidding and auction phases, even though such practice is applied with particular care for supplies that cannot be classified as commodities, due to the relevance of co-design contributions.

Thanks to the degree of digitalization and to the increased information flows, the extended enterprise is expected to perform substantially as an optimized single integrated vertical enterprise, with significant improvements in the capability of:

- Improving reaction time to contingencies
- Simulating and planning operating conditions
- Monitoring and controlling flows of materials and associated product data.

15.8.7 Virtual Enterprise

The virtual enterprise (often referred to as a *virtual corporation* [15.133]) is a particular form of virtual organization that is characterized by the precision of its scope/mission and by the actual creation of an organizational structure that can be substantially independent of original organizational structures in the participating companies.

The enterprise is typically composed of companies that provide different functions, in accordance with their capabilities and individual strategic goals.

A virtual enterprise constitutes a *single electronic business entity* [15.133], without a *physical* structure.

Although the enterprise is presented as a real company, it is not typically associated with a legal entity, as outlined in the European research project ALIVE (advanced legal issues in virtual enterprise) [15.138], where the contractual framework of *joint ventures* was found to be most appropriate for this kind of cooperation. The partnership composition of a virtual enterprise is essentially dynamic, to better fit evolving requirements and market contingencies; the greatest benefit of this feature is to ensure that the competitiveness conditions sought at the establishment of the enterprise are maintained throughout its life, but calls for specific formally agreed policies to ease the replacement of partners due to the *democratic* character of the enterprise.

A virtual enterprise is not dominated by one partner, but is a cooperation among equals, with governance systems that must ensure equal participation in strategic decisions.

The virtual enterprise organizational structure is orthogonal to the partners' organization; by its very nature, the virtual enterprise's organization and process can be ideally fitted to the product/service to be developed and/or provided to customers; nonetheless, due to the enterprise's temporary nature, it is not possible to establish and empower hierarchical relationships, and personnel hierarchical dependencies and power at partner companies must be reflected in the roles and processes of the cooperative corporation in order to prevent conflicts due to the allocation of responsibility for tasks.

The constitution of a virtual enterprise is usually associated with the identification of a business opportunity by a company which does not have the capability individually to pursue such an opportunity, the equivalent of the role of the *architect* for networks [15.139], i. e., the entrepreneur and possibly the provider of the inspirational vision.

Based on the opportunity identified a new role has been introduced for virtual enterprises: the business integrator [15.140], i. e., the role devoted to:

- Selection of partners
- Setup of governance structure, methods, and tools

Table 15.12 Comparison of integrated and virtual corporations [15.133]

Organizational dimensions	Integrated corporation	Virtual enterprise
Organization structure	Formal and flexible	Flexible network, flat
Decisions	Ultimately by fiat	By discussion and consensus
Culture	Recognizable, encouraging employees to identify	Pluralist, linked by overlapping agendas
Boundaries	Clear *us and them*	Variable
Management	High overheads	Minimal overheads
Power	From the board, ex officio	Through possession of competences in demand; being the brand company

- Guidance to align internal partners' processes to the operation of the virtual enterprise
- Management of operations for the enterprise

More than in other types of cooperative work, the virtual enterprise derives its effectiveness from the motivation of the partners, which is usually founded on a shared vision and complementary individual goals, and from a high level of trust and confidence among the partners. This is why networks are the natural breeding environment for virtual enterprises, which can work on existing relationships, whereas specific methods have been developed [15.137] to assess objectively the readiness of potential partners to join specific common business opportunities.

More so than for extended enterprises, in which (at least) the *systemic* knowhow for a product is held by the single leading organization, virtual enterprises show criticalities in the management of pre-existing and generated knowhow that must be mastered to allow for dynamic reconfiguration of the partnership as required for the best chance of success.

To summarize, it is worth reporting the table proposed by *Child* [15.133] for comparison of integrated and virtual corporations (Table 15.12).

15.9 Organization and Communication

Organizations constantly exchange information. By means of their manifold interactions, information and communication become determining factors in their competitive performance. Organizations that learn create more knowledgeable workforces for operations and process innovation, generating highly flexible organizations in which people will adapt to new ideas and changes through shared visions.

15.9.1 Terms, Definitions, and Models

Every kind of successful development of a company is based on the intra-organizational acquisition of knowledge, the development of knowledge, and its economical realiation. Basically, knowledge can be characterized by two features. On the one hand, knowledge represents information provided directly by the brain, or that can be retrieved quickly from information memories available to human beings. On the other hand, knowledge is related to the context of the acquirer. People must be able to display their information directly by means of a model-like illustration of realistic relations, conditions, and procedures – referring to means of intermediation (i. e., language) – in such a way that the information is purposeful and can be applied in a practice-oriented context.

The obtainment of knowledge by means of purpose-related handling and application by employees occurs in two fundamental acquisition modes:

- Original acquisition through one's own experience
- Derivative acquisition of knowledge through communication

In this respect, communication comprises all relations and tools of communication both within and outside a company, serving as the interaction with the system's surrounding or further units within the enterprise. It is characterized by the influence that one organism exerts on another with the intention of purposeful and targeted

exchange of information through a common interaction space (operational task).

The amount (and also the intensity) and quality (and also content) of possibilities for communication are mainly determined by the organization model in the enterprise. In addition to various structuring criteria resulting from different types of activities (depends on the production program) and its *interrelations*, this often depends on technical, technological, and economical necessities (utilization). Only in recent times have communication-oriented criteria for production gained significance, due to the increase of more-complex products and production programs in conjunction with the parallel extension and increased development of technology.

The foundation of communication is information, which is defined as a purposeful extract of applicable issues, aiming for the achievement of a target or the solution of a problem. The amount of information – clustered and purposeful, specifically directed towards an issue, processed in such a way that it will be generally accepted, checked and transferable – becomes knowledge. Furthermore, nonpurposeful, latent issues are also labeled as information since this kind of information can at any time be combined or condensed into knowledge by means of purpose-related references. Information therefore constitutes an image of the environment surrounding us and the various components and procedures used by humans to orient themselves in the world and to recognize and influence it [15.141].

Information as the basis for communication and the development of knowledge linked with it can be standardized according to different features and consequently evaluated by form-oriented methods. Some of the most important features are:

- Derivation (internal or external information)
- Degree of formalization and structuring (formal and conditioned, or informal and unconditioned information)
- Condition (primary or secondary information)
- Area of embodiment and application (special or general information)
- Quantifiability (quantifiable or nonquantifiable information)
- Programmability (programmable or nonprogrammable information)

The degree of formalization of information is essential for the internal embodiment of the information process and, accordingly, for the reliability of information processes in the course of operations. Structured information and its formal, i. e., organizationally ruled, course of communication includes all communication procedures, which by means of structuring, purposefulness, and repetition are related to the entrepreneurial task. Informal communication describes those communication contacts which are not conditioned by organizational regulations. They influence the social relations between the interlocutors and the atmosphere of the communication. In the case of largely consistent circumstantial conditions this is characterized by a *balance* that is typical for enterprises, which in the case of changing conditions often drifts to the disadvantage of informal communication. Informal communication is frequently one of the first measures taken to respond to altered circumstances within the production process [15.142]. As a result, typical phenomena that appear include:

- Increasing bustle and consultations within production and attached areas
- Accumulation and temporal extension of meetings (for example, production conferences)
- Increase of the error ratio due to an increasing proportion of informal communication

Being carried by the aforementioned established procedures for information processing, information can be subdivided into data, signs, and signals and thus transferred by coded means. The fundamental information process – as a preliminary stage of communication and knowledge development – is executed in three steps:

- Information gathering
- Information processing
- Information transfer

Based on the information process and the information gathered through it, the communication process can be explained according to the model by *Shannon* and *Weaver* (Fig. 15.54) [15.143]. Production and the necessity to organize the corresponding information and communication processes lead to the need to establish appropriate information processes and communicative relations, which should contain as high a fraction of formal communication as possible.

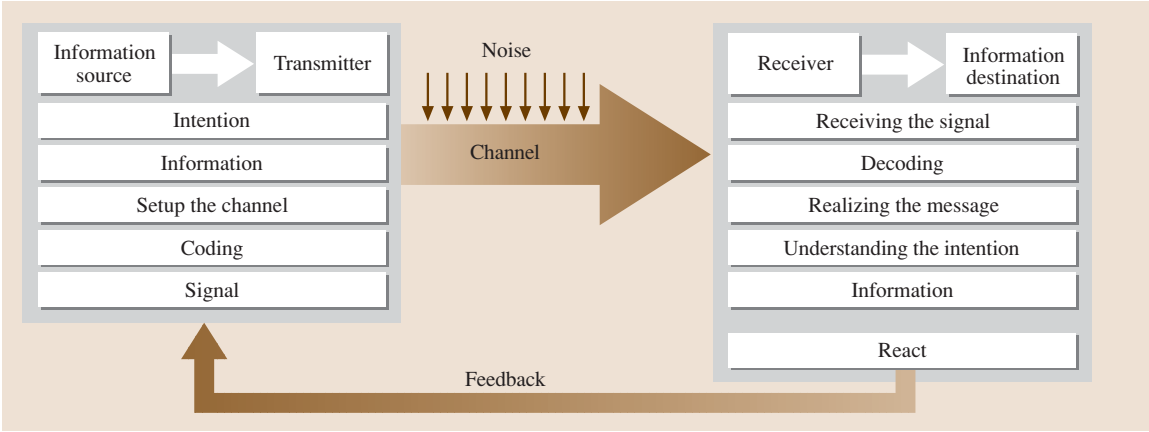

Fig. 15.54 Enhanced model of communication (after [15.143])

15.9.2 Challenges Concerning the Internal Embodiment of Communication Processes

For the embodiment of internal communication processes it is necessary to combine the diverse information demands required for the goal under consideration with the available information. To achieve this, logistic principles should be provided, such as:

- The correct information (related to purpose and target)
- The proper quantity (a random sample or full check)
- The proper quality (i. e., content, significance [processing], measurement errors, error ratio, etc.)
- The correct time (i. e., up-to-date)
- The right location (local availability and possibility to make accessible)

Cost-related considerations as well as the optimal employment of capital must be taken into account in this respect.

During the conceptual design of communication processes, the following specified and thematically grouped problem areas arise:

- Content–conceptual problems
- Organizational–structural problems
- Resistance in personnel and corporate culture [15.144]

These obstructions can be specified more closely and form the basis for the application of a systematic approach when conceptualizing internal communication processes.

The most frequent content–conceptual problem areas are facts such as:

- Fundamental neglect of internal communication
- Lack of coordination of the company's objectives with the means of communication within the company
- Incomplete or even nonexisting description of the target group for the communication (i. e., employees)
- The lack of verification of the result of applied measures as well as insufficient assignment of effort to certain measures

Content–conceptual problems frequently arise from methodically inadequate approaches of installing communicative tools in the operational routine. In addition to these methods being one-dimensional, certain tools are often not harmonized with each other and commu-

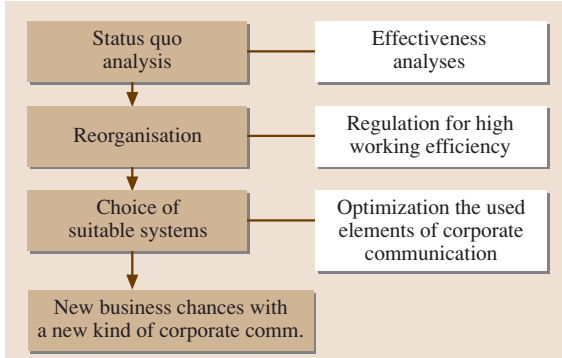

Fig. 15.55 Basic procedure of the corporate communication analysis

nication is not a successive process. An apparent sign of this is the neglect of the corporate identity (CI) concept during the internal communication, for instance. Moreover, further approaches for avoiding problems arise from the existing company structures and organizations described above, which are caused by:

- The lack of institutional and formal rules for voting and decision (such as, tasks without continuance, definite rules as job instructions, obligatory nature)
- The lack of organizational fixation and improper handing over of responsibility when coordinating diverse communication tools (contact point)
- Problems in the case of prompt integration of subsidiary companies with increased independent status (content-related summary)

This is accompanied by obstructions in personnel and corporate culture such as:

- Incomplete understanding of integrated communication in top and middle management
- Existence of subcultures with highly different ways of thinking and behavioral patterns
- Fear of loss of competence
- Lack of feeling for integration
- Lack of professionalism of the responsible personnel
- Lack of willingness to cooperate and coordinate, and to receive information
- Fear of supervision

15.9.3 Methods of Embodiment, Organization Models, and the Management of Communication

The following elements of embodiment are regarded as the result of corporate development in the company and as general limitations to this embodiment:

- Using ambition for reward (striving for gratification, meaning not only money)
- Response to individualization and regional peculiarities (considering individual and regional–cultural behavior patterns)
- Participation and integration of all people concerned (integrating employees into the process of embodiment)
- Focusing on dialogue (mental stimulation, identification, and appreciation)
- Credibility, objectivity, and comprehensibility of both information and the communication process [15.145]

Furthermore, the following assumptions apply to its conception and realization:

- Feedback marks the core of communication.
- Information also means the obligation to acquire it.
- The information portfolio within the company has to be transparent.
- A communicative infrastructure forms the basis for systematic communication.
- The combined employment of media and tools is essential for successful communication.
- Transfer of information is related to the demand and target group.
- Information ought to be clear, intelligible, and restricted to the essential facts.
- Communication complies with an integrative appearance of the company.

Being a decisive factor, the mode of organization of operational procedures has a major impact on the design options for communicative processes within an enterprise. Basically it is the case that, the higher the degree of autonomy of an organizational unit, the higher the demands concerning the availability of information and, accordingly, concerning the required communication process (see also Sect. 15.1) [15.146].

Based on these preliminary remarks, the organization of the structure and procedure of corporate communication gains special importance in securing the realization of the company's objectives on a long-term basis. The corporate vision of the company in conjunction with the strategic goals and the development of resulting essential achievements lead to significant input parameters for the purposeful embodiment of communication processes [15.147].

The need for steady improvement of corporate communication requires frequent changes of structural and procedural organization patterns, since these – as described above – significantly determine the embodiment options, efficiency factors, and effects of communicative media. Generally, the procedure in this respect occurs as presented in Fig. 15.55.

Methods used for these analyses are:

- Portfolio analyses
- Cross-impact-analyses
- Questionnaires, for instance, concerning employee satisfaction

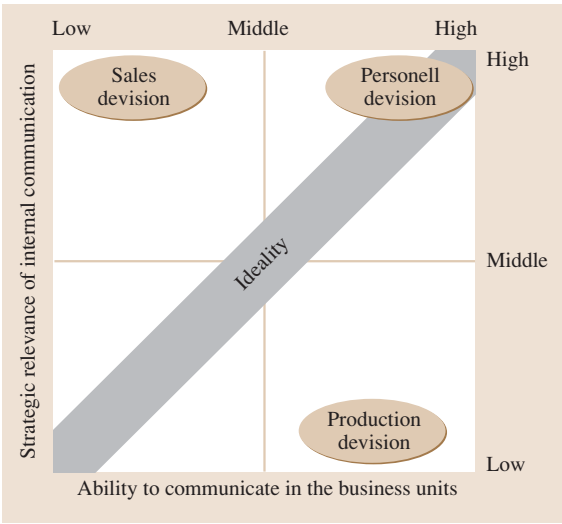

Fig. 15.56 Portifolio analysis for the evaluation of tregetic business units

- Document analyses and analyses of the flow of information
- Checklists concerning the corporate culture
- Analyses of strengths and weaknesses
- Surveys concerning management behavior or methods

Whereas portfolio analyses aid in the alignment and embodiment of business units, cross-impact-analyses are used for the prioritization and consideration of different communication measures for a preassigned goal. Checklists concerning the corporate culture and analyses of strengths and weaknesses confront demand-related rating scales with the rating that had currently been drawn, thus indicating the necessity for development and activity.

Portfolio analyses are used for the observation of strategic business units regarding compliance with communicative demands to fulfil strategic goals. Relations between the strategic significance of a business unit and its determined capability for communication are evaluated by using this subjective method [15.148].

By compiling evaluation items and their *attributes*, a group of experts determines the dimensions of the portfolio's axes. After assessing the strategic business units, the actual value is compared with the desired value (ideality). From the items' deviations from ideality, indices and prioritizations of basic measures can first be extracted (Fig. 15.56) [15.149].

Main result of the portfolio analysis is the extraction of a generic communication strategy to allocate the best improvement measures the company's business units. The success of these measures mainly depends on their probability of occurrence.

Evaluation matrix

Exertion of influence \ Level of impact	Commercials	Promotion	Public relations	Personnel connections	Direct-marketing	Sponsoring	Event-marketing	Exhibitions	Internal communications	AS	Q
Commercials (1)		4	3	2	2	1	0	0	0	12	1,71
Promotion (2)	2		0	2	1	1	1	1	0	8	0,73

P	84	88	90	91	10	231	156	90	49		
AIS	9,66										

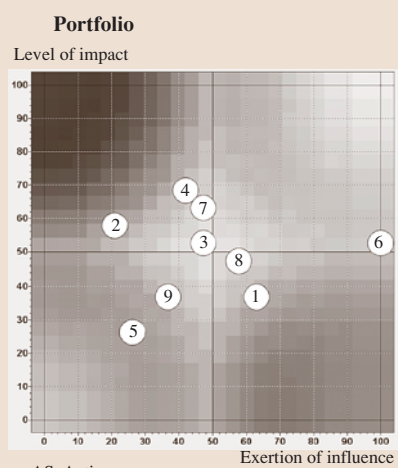

Fig. 15.57 Evaluation matrix and portfolio of the cross-impact-analysis (AS – active sum; PS – passive sum; Q – level of impact (Q = AS/PS); P – exertion of influence (P = AS · PS))

The cross-impact-analysis addressed that problem. By means of a formalized, qualitatively supported method, it enables the evaluation of different incidence rates of states by experts, making it tangible as the embodiment method at the same time. The observed incidents (measures) are evaluated depending on the direction and strength of the context and the diffusion period. Accordingly, the probability of an incident occurring and its impact on another incident can be related.

A team assembled of mainly interdisciplinary experts evaluates:

- The incidents considered to be relevant
- The individual rates of each incident
- The moment of occurrence of each incident in the case of a given incidence rate of 0.5
- The influence of an incident on another

Based on this evaluation, an influence matrix can be constructed, thereby recording the intensities of the incidents with respect to each other (Fig. 15.57). For the evaluation of the influence intensities, a closed discrete rating scale is used.

From the summation of the line or column sums – respectively labeled as active and passive sums – and their relation to the average influence sum (that is AS or PS/number of elements), conclusions can be drawn about the influence probabilities of certain measures. Based on the relation between these figures, the elements can be subdivided into *active* elements, *reactive* elements, *critical* elements, and *inactive* elements, thereby providing clues for the utilization of the measures. Thus, the term of active elements (AS < AIS, PS < AIS) for instance means that the measures have to be changed deliberately, since these determine the entire system in question [15.150]. The elements are characterized by cross-impact-analysis as follows

$$\begin{aligned}
\text{active elements} \quad & \text{AS} > \text{AIS}\,, \ \text{PS} < \text{AIS}\,, \\
\text{reactive elements} \quad & \text{AS} < \text{AIS}\,, \ \text{PS} > \text{AIS}\,, \\
\text{critical elements} \quad & \text{AS} > \text{AIS}\,, \ \text{PS} > \text{AIS}\,, \\
\text{inactive elements} \quad & \text{AS} < \text{AIS}\,, \ \text{PS} < \text{AIS}\,.
\end{aligned}$$

As a result of this analysis, a realization plan can be issued.

For the realization of communication strategies, a multitude of options are currently available. Some example communication media are:

- Worker and information journals
- Postings, blackboard announcements, info systems, wall newspapers
- Internal information services, circulars, newsletters, infomails
- Specific as well as interdisciplinary information sessions
- Press reviews
- Company broadcasting
- Events such as open days and information sessions concerning the company
- Videos, pictorial documentation, compact discs (CDs)
- Annual reports
- Internet presentations, intranet platforms
- Introductory texts
- Trade-fair stands

15.9.4 Conclusions and Outlook

Production systems constantly exchange relevant information with the external environment. As a result, the quality of internal and external communication is of inestimable value for companies. Following the current thrust towards innovation caused by the widespread usage of information technology, information processes as well as the availability of information as the basis for acquiring knowledge have been accelerated. As a consequence, conceptual and creative solutions are becoming increasingly important, purposefully integrating the new options for the embodiment of communication processes within organizational structures (Fig. 15.58).

Much attention is being paid to interorganizational learning. Through *learning alliances*, firms can speed up capability development and minimize exposure to technological uncertainties by acquiring and exploiting knowledge developed by others. However, learning introduces self-organization, which makes it difficult to guide.

Modeling agents [15.151] help discover such emergent behavior inherent to a multi-agent situation consisting of large groups of loosely coupled agents that work together on tasks. Interoperability of agents is required, and their negotiation strategy will depend on their organizational role (motivational quantity) [15.152].

Collaboration may be expanded beyond the current concepts into complex organizations spontaneously emerging from dynamic versatile environments [15.153,154]. Self-organization and self-similarity help to reduce organizational and process complexity by fractalization. By using topological and systemic methods, supported by the theory of complexity, power-

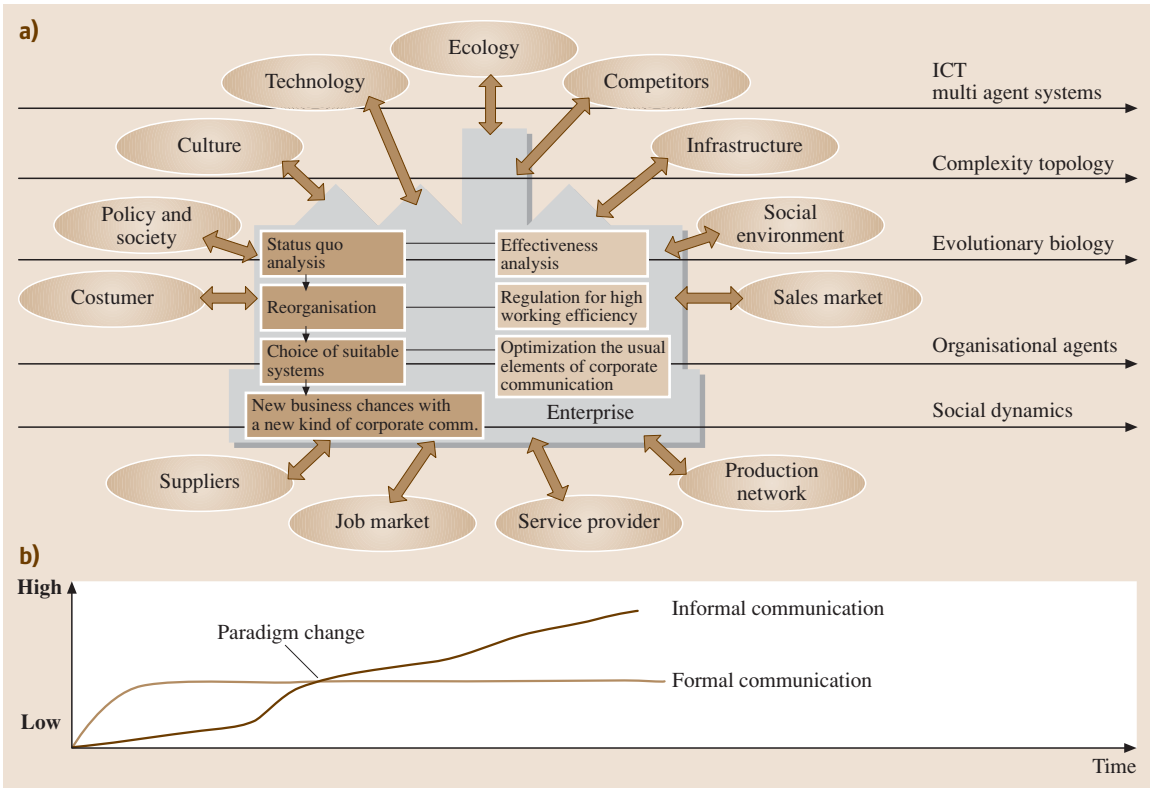

Fig. 15.58a,b Communication impact and research strains in organization and process engineering

ful organizational production network optimization and control conjectures may be provided. The steady need for improvement of corporate communication assumes versatility of structural and procedural organization patterns [15.155].

Self-organization is also a specific topic in social dynamics between organizational entities envisioned as populations of interacting agents in a given structure [15.156]. At the level of departments or even whole firms unofficial structures may emerge from the social interactions of individuals. Collaborative teams may increasingly turn the enterprise into densely interconnected networks whose evolution is driven by simple universal laws that may resemble evolutionary patterns [15.157]. In this sense, collaboration is envisioned as a strategy for the fitness selection of an entity.

Relations between the strategic significance of a business unit and its determined capability of communication are evaluated by impact analysis [15.150]. Procedures for corporate communication and negotiation gain special importance in securing the realization of enterprises objectives on a long-term basis [15.158]. The corporate vision of the company in conjunction with its strategic goals lead to significant input parameters for the purposeful operation of strategic networks [15.147].

The huge field of enterprise organization and operations is anything but static and is composed of numerous threads of research. Technology is changing,0 therefore significant changes in organizations are most likely in the future. Ultimately information and communication technology seems to be the key driver determining how and when future developments will occur.

15.10 Enterprise Collaboration and Logistics

15.10.1 Dimensions of Enterprise Networks

Industrial collaborations occur because of economic necessity. Modern manufacturing imperatives are the production of complex goods in a highly competitive market environment where cost, quality, and time to market are *facts of life*. In this, so-called buyers', market of sophisticated goods a single enterprise can hardly successfully compete without collaborating with other enterprises that complement its competencies, goods, and/or services. To meet these challenges, companies have learned to focus on their key competence features (the *focused factory*) and collaborate with complementing enterprises to produce a complete range of products and services to meet ever-changing market needs.

The increased dynamic of changes demands quicker orientation in dynamic, unstable markets. To achieve economies of scale global markets have to be addressed. Products and production processes have to be adopted according to the emerging diversity of these new markets. Based on the increasing complexity and heterogeneity of products the critical size of a single enterprise for autonomous engagement with the market has changed dramatically. This problem can be solved by appropriate industrial cooperations. Especially for small and medium-sized enterprises (SMEs) or even medium-sized companies, cooperation with other enterprises, whether they are competitors or not, often seems to be the most promising approach for success in future markets. As the impacts, motivations, and requirements for industrial cooperations are subject to alterations, the variety of real-life applications will increase dramatically in the future and will become more difficult to anticipate.

Industrial collaborations are not new; they have been well known for many years, even decades. In the one-of-a-kind business, product- or project-specific industrial cooperations were introduced many years ago. One-of-a-kind-production (OKP) companies very often see themselves more as system integrators for customer-specific products and less often as manufacturing companies dealing with the whole range of industrial manufacturing including all parts and component manufacturing activities. This has been recognized as a critical asset for serial and mass production only in the last 5 years. Accordingly many approaches as well as methods have been known for years, with their roots in the one-off domain. Well-known examples are the formation of temporarily limited enterprises in the large-scale engineering, construction, and shipbuilding industries.

However, the relevance, need for, and chances of success of industrial cooperations have changed dramatically and will become increasingly important in today's information society.

Industrial cooperations are a complex multidimensional phenomenon. As there are finally no restrictions at either political, economical or technological level that could prevent certain types of industrial cooperations, the potential variety is almost unlimited. Accordingly an unambiguous and clear distinction or classification of typical types of cooperations will become difficult or even impossible. However, the reduction of today's vast variety of cases to a small number of types is not sufficient to gain a better understanding and systematic overview of the phenomenon of industrial cooperations.

Analyzing typological issues of enterprise networks will support:

- Systematic problem analysis and solution synthesis with respect to cooperating enterprises
- A more structured view of the vast amount of possible real-life cases of industrial cooperations through systematic characterization of these cases
- The analysis of cases and relevant types of industrial cooperations with respect to typical problems related to decision-making, production planning, etc.

Nature of Cooperation

In general to cooperate means to act or to work together. Cooperation between companies materializes for one purpose and one purpose alone: self-interest. Potential motivations for setting up a network of cooperating enterprises are short-term opportunities as well as an intended optimization of cost, time, and/or quality. Accordingly the added value of a cooperation must be measurable for the cooperating companies. Cooperation will usually involve the exchange/sharing of goods or services or any imaginable combination thereof. According to the literature, there is no common understanding about the term *cooperation*. However, with

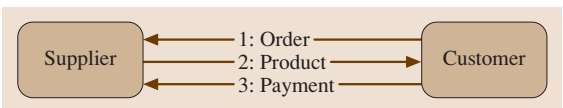

Fig. 15.59 Steps of a fundamental market transaction

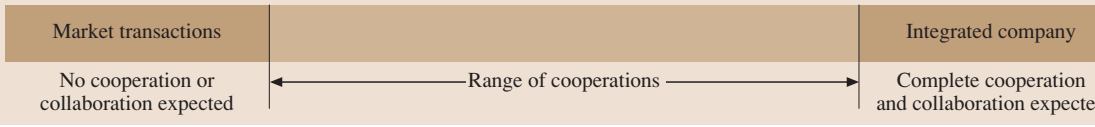

Fig. 15.60 Range of cooperations

respect to production management, two major specifications can be distinguished:

1. Cooperation in a broad sense comprises all types of collaboration between organizations that participate in the economic life.
2. Cooperation in a narrow sense characterizes the close interorganizational collaboration between autonomous organizations.

One of the fundamental market transactions is between two parties that agree to conduct a one-off market transaction. This transaction (Fig. 15.59) consists of the customer placing the order, the supplier supplying the product/goods, and finally the customer reimbursing the supplier for the goods received. Of course, this three-stage transaction could be conducted in one single step as transpires when an individual makes a purchase in a shop, or, based on the credit worthiness (as judged by the supplier) of the customer, during an agreed time scale. For the purposes of our discussion, the issue here is not the time scale or whether the transaction is conducted face-to-face, but the freedom to conduct the business once this transaction is complete. In the fundamental market transaction, the customer is free to seek another supplier for the following transactions for the same products/goods.

The concept of a contract in this scenario is fairly straightforward. When goods and payment are exchanged it is implied that the goods conform to some *expected standards*. These standards could be mutually understood or defined by the supplier or by legislation (consumer protection); for example, if the product is a software program, it is mutually understood that the supplied program will work according to the given specifications and that it will not contain any bugs.

Similarly, claims made by a supplier for its products in advertising form an implicit part of this transaction. Therefore, if the goods exchanged are foodstuffs, legislation dictates that such goods are of edible quality. The term *expected standards* is never fixed, since there is no explicit written contract. Hence, based on the perspective of the supplier and customer, it could be disputable. In those cases, one normally needs the services of an intermediary party or eventually the courts to ascertain the facts and resolve the dispute.

Aiming at a detailed systematic specification of types, attributes, dimensions, etc. of industrial cooperations, the term cooperation will be understood as an alternative type of transaction, bounded by the transaction types *market* on the one hand and *integrated company* on the other hand (Fig. 15.60). These two types of cooperations, market and integrated company, depicted in Fig. 15.60 are the idealized extremes. All possible types of cooperations that can materialize between any two enterprises lie within these two extremes.

At the market level only single market transactions occur. The parties have no obligation to repeat the transaction or continue the business. However, if they continue to conduct transaction-based business over time, confidence between the parties could increase, re-

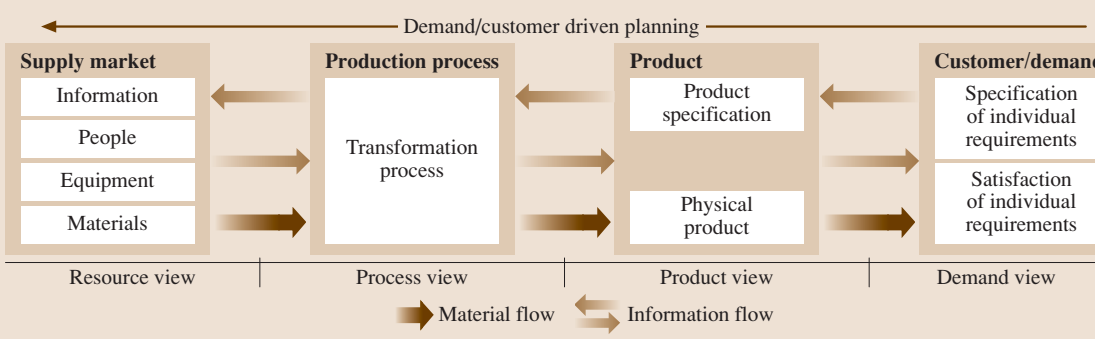

Fig. 15.61 Information and material flow in a demand/customer-driven manufacturing system [15.159]

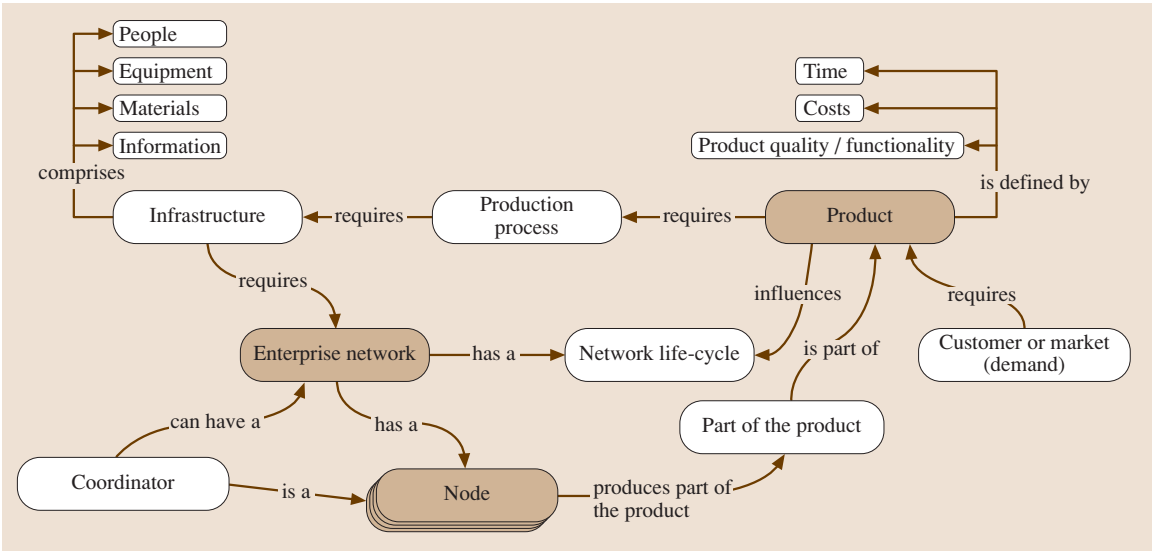

Fig. 15.62 Conceptual model of a generalized enterprise network

sulting in the breakage of the explicit link between the exchange of goods and the payment; for example, once the credit worthiness of the customer is established, the invoicing and payment cycles need not synchronize with the dispatch of goods. On the other extreme, all parties belonging to a single enterprise are expected to cooperate fully and direct their efforts towards a single goal.

Conceptual Model of Enterprise Networks

Figure 15.61 depicts the interrelations between customer (demand), product, production process and manufacturing resources from a system point of view.

In general, products can be described by three significant attributes: quality and product functionality, time (availability on market), and cost (price on market). The underlying demand for a product can occur in two ways: A customer requires the product and comes to the market for its purchase. Secondly, a market survey by a manufacturer ascertains a need (a potential market) for a product, which triggers its production. Since the trend is towards customer-driven manufacturing, these three attributes will be influenced directly or indirectly, by the end (or perceived) customer. Once the attributes and saleability of a product are established, a production process is required for its manufacture, which will in turn require manufacturing infrastructures to manufacture it to the specified attributes.

For decades the classical approach of an enterprise was to invest in the required resources and thus to realize production process using its own resources. This has changed dramatically. Today no single enterprise is able to provide all manufacturing resources as well as competencies necessary for the realization of ever-changing customer demands. Enterprise networks as a dynamic, interenterprise configuration of manufacturing resources and competencies have become a promising alternative to offer the required manufacturing infrastructure. In the following the term *enterprise network* characterizes a suitable collaboration of two or more cooperating enterprises, aiming at a common and collaborative realization of a certain product and/or service. Thus, the term enterprise network is always related to a specific product and/or service.

Different partners of the enterprise network take responsibility for the different elements of the value chain. Therefore, the generation of added value can take place simultaneously and at various locations. In an interlinked manufacturing environment, customer and supplier relationships becomes critical assets. Knowledge about the capabilities of potential partners is becoming a part of the knowhow of an enterprise.

Based on the dependencies within a customer-driven manufacturing system, as depicted in Fig. 15.61, a conceptual model of a generalized enterprise network is documented in Fig. 15.62. Elements highlighted in the figure are discussed in detail in the following sections.

Each enterprise network will have distinct and clearly defined set of members (nodes), which are

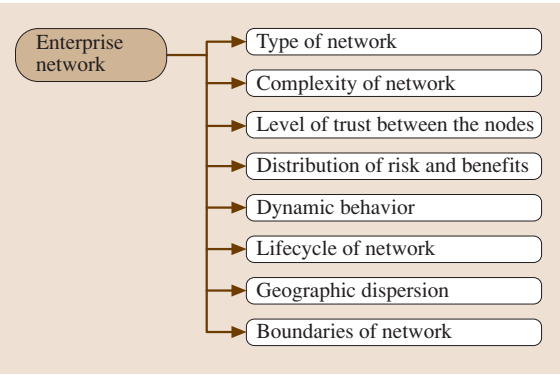

Fig. 15.63 Enterprise network-related attributes

usually independent enterprises. Once a network of enterprises decides to cooperate, this network will have a distinct lifecycle, which will be influenced not only by the corresponding priorities of the cooperating nodes but also by the product–market combination. Furthermore, each node will have its own objectives, which will influence the primary product–market combination that brought this node into play in the first place. The function of the coordinator is to manage the dynamics of the enterprise network. Quiet often the role of coordinator of the whole enterprise network is taken over by the final assembler. However, there may be circumstances in which an external specialist agent can perform this role more effectively.

The goal of this model is to act as a baseline for a systematic view of enterprise networks and to give a systematic structure to the vast number of attributes to be considered while forming a new or analyzing an existing enterprise network. However, it is not intended

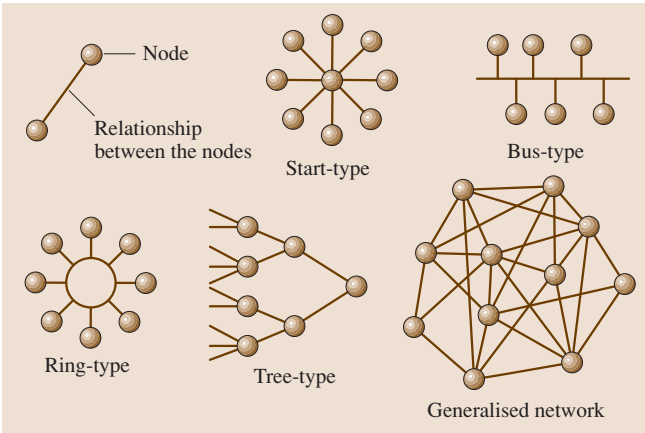

Fig. 15.64 Basic enterprise network types

that the conceptual model be used as a baseline for an overall model including all possible aspects of enterprise networks.

Enterprise Network-Related Attributes

Aspects that characterize the overall network from a systems perspective are considered under the category of *enterprise-related attributes*. This discussion is restricted to the attributes given in Fig. 15.63.

Type of Network. In general, networks are defined by nodes and relationships between these nodes. As already stated the minimum amount of nodes in a network is two. By considering more than two nodes various types of enterprise networks are possible. Figure 15.64 depicts some well-known types of networks.

The communication between any two peripheral nodes in a star-type network will always be conducted through the central node. Therefore the central node could be considered as a *controlling* node of a star-type enterprise network. A bus-type enterprise network implies some form of flow of goods or information from left to right. In ring-type enterprise networks there is no unique direction of the flow of information or products, which instead can take any path. Furthermore, the feature distinguishing the ring from the star type of enterprise networks is the absence of the central controlling node. Therefore, in ring-type enterprise networks, all nodes are hierarchically equal and any two can communicate directly. Tree-type enterprise networks can be converging (as shown in Fig. 15.64) or diverging (a mirror image of the converging type). In either case of tree-type enterprise networks, the flow of information and goods is usually assumed to be from left to right. The controlling node in a converging tree-type enterprise network is often the one downstream to the operations, with overall responsibility taken by the extreme right-hand node. Diverging tree-type networks are often distribution-type networks. In this case the controlling node if more often than not the extreme left-hand node. A generalized network is a complex interrelationship among several nodes. The connections between the nodes and the issues of controlling node cannot be generalized and predefined, and they are situation and case dependent.

Complexity of a Network. In a broad sense the complexity of a network, as a multidimensional attribute, can be characterized by the number of nodes, the number and types of the relationships between these nodes, the dynamic behavior of the relationships, and the num-

ber and types of products and services provided by the network. By its very definition, there is no physical limit to the technical complexity of the network. However the number of relationships might be limited by the technology to be applied, and the dynamic behavior within the network might limit the optimal number of nodes in a network. The greater the number of partners, the more difficult it will be to manage. Usually, in such complex cooperative networks, the node downstream (customer) will initiate or chase the node upstream (supplier) for goods/services. This request may be triggered internally from within the customer's operations or externally by a third party.

Bilateral relationships are used as elementary building blocks to create complex cooperative enterprise networks. Real-life enterprise networks can be seen as more or less complex combinations of various types of bilateral relationships. In general, networks may be composed of equal or different types of bilateral relationships (homogeneous versus heterogeneous networks). To reduce the various types of interorganizational relationships known from the literature according to *Jagdev* et al. five basic types are distinguished in the following [15.1]. Accordingly enterprises delivering/supplying parts or components based on a market transaction will not be considered as being a member (or a node) of an addressed enterprise network.

Figure 15.65 depicts the decompositions of a large heterogeneous network (A). Network A is decomposed into a series of subnetworks within the defined terminologies of SE (a single enterprise located at two different geographical locations), VE (network D), EE (network C), SC (network B), and MT (network A).

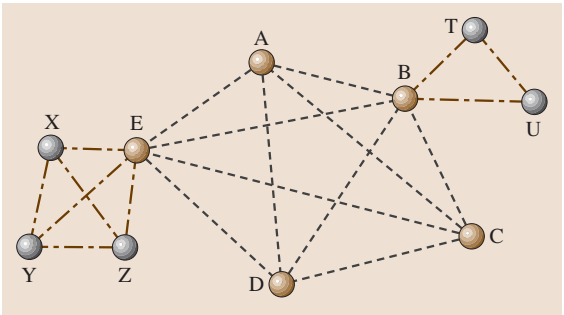

Fig. 15.66 Direct and indirect relationships of the nodes of a network

The complex dependencies within complex networks or between networks are illustrated in Fig. 15.66. Although there is no direct link between node A and nodes U and T, via node B both nodes might be important for the success of the network in which A (and B) is involved.

Level of Trust Between the Nodes of a Network. Trust between the cooperating partners is a prerequisite for a successful partnership within an enterprise network. Usually, when two parties start a partnership (i. e., agree to do business together), they start with some basic level of trust as expected by the norms of the business environment. However, as the partnership flourishes, trust builds and forms a foundation for an

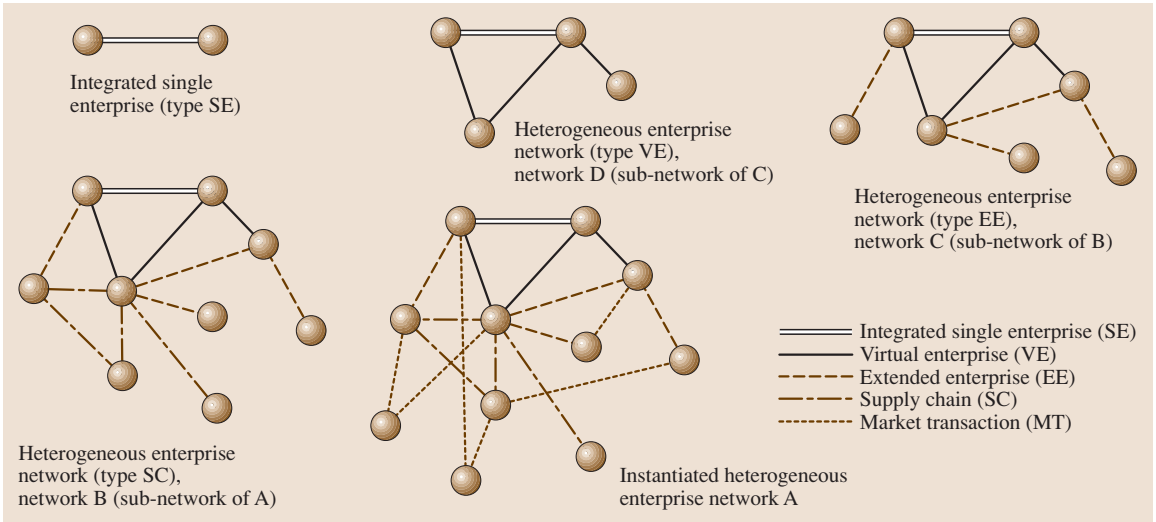

Fig. 15.65 Describing the complexity of enterprise networks

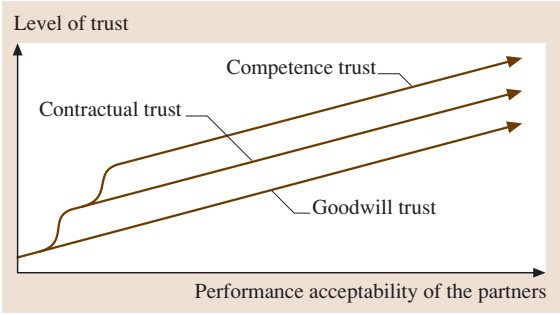

Fig. 15.67 Levels of trust

ever-closer and mutually dependent business relationship. Apart from the *basic trust* expected by business ethos (and presumably understood by the parties involved), the level of trust – which can have, for all practical purposes, no limit – is closely linked to the behavior of one party towards the other. Real trust builds under extraordinary circumstances in which one partner is willing to meet exceptional requests, above and beyond the agreed terms of business, so that the other partner is not let down. It is such particularly testing situations that establish the real level of trust between the partners. For example, partner A has agreed to supply partner B with an agreed amount of goods per week. Because of exceptional circumstances (such as a new important customer for partner B), partner B suddenly requires way above the agreed amount of goods for the following few weeks. If partner A is willing to go to extra lengths (say, by increasing overtime levels) to meet partner B's increased requirements, then partner B will perceive partner A to be more reliable and hence more trustworthy.

These subtle behavioral responses of partners play an essential part in the development of trust. This is particularly so in the development of perception of trust. Authors believe that perceived trust is often more important that trust itself. It is the perception of trust – i.e., how one party perceives (never mind the reality) the trustworthiness of the other party – that determines the evolution of longer-term and ever-closer business partnerships.

Childe [15.160] classifies trust into three headings: goodwill, contractual, and competence trust. *Goodwill trust* is that by which a partner is trusted to take decisions without unfairly exploiting the other partner. *Contractual trust* is the keeping of promises, such as delivering goods or making payments on time, or maintaining confidentiality. *Competence trust* depends upon the technical and managerial competence of the company to perform a function, such as delivering components within specifications.

Normally the development of various types of trust follows a clearly defined trajectory, as depicted in Fig. 15.67. Companies agree to do business based on some level of goodwill trust. As the partnership progresses, the performance of each partner becomes validated by the other and, if acceptable to both parties, they agree to formalize their collaboration in the form of longer-term contracts. As the contractual agreements progress, competence of the partners comes into play, together with the resulting evolution of competence trust. Therefore, a high level of competence trust would need to exist for a supplier to be allowed to make deliveries direct to the assembly line with no inspection.

Distribution of Risks and Benefits. As for a chain, a network is only as strong as its weakest node. Therefore, to optimize the performance of the whole enterprise network, one not only has to optimize individual nodes but also to optimize the network as a whole. Hence, a balanced distribution of risks as well as profits within the enterprise network is a prerequisite for successful cooperation. As an enterprise network can deliver a broad range of products and/or services the distribution of added value achieved within a network might vary from order to order. Examples are the increasing number of networks of SMEs, craft organizations, etc. offering full services in the area of building construction and maintenance of energy/water supply systems.

The survival of a network is endangered if there is no added value to be achieved by the overall activities of the network. In general partners who cannot perceive any added value by cooperating with others will concentrate on their individual activities and will not put sufficient effort into the network. Mutual benefits in terms of shared added value become a stabilizing factor for cooperative behavior in a network [15.161]. Accordingly, by supporting improvement at the supplier rather than trying to drive down the price, the principal company in a supply chain assists in reducing costs rather than reducing the profit at the supplier [15.160].

Dynamic Behavior of a Network. Bilateral relationships as well as the network itself will often change over time according to the maturity of a product, the stability of a market, the priorities of the partners, etc. Depending on their mutual interests, two independent companies could merge into a single enterprise. On the other hand, market conditions may compel a large company to sell of its noncore divisions. Between these two

extremes an almost infinite variety of *getting together* and *going apart* scenarios is possible. A network need not be stable over time; indeed it rarely is. The functions of a node may evolve over time, which may influence its place/role in the network. Even though the scope collaboration between the nodes of a network may be very large, the relationship can be categorized within well-defined paradigms, such as supply chain, extended enterprise, and virtual enterprise. Section 15.7 elaborates further on these categories.

Lifecycle of an Enterprise Network. Just as a product has to pass through the various stages of its lifecycle (from idea to recycling) the lifetime of an enterprise network also depends on the success of the offered good or service and can be described by at least four significant lifecycle phases (Fig. 15.68):

1. Preparation (sourcing of partners)
2. Setting up (legal issues, contracts, etc.)
3. Operation (day-to-day management of the network)
4. Decomposition

A prerequisite for frictionless operation is efficient interorganizational product data and process management [15.162]. The duration of the operational phase of an enterprise network can be classified based on the premise and understanding under which the nodes of the network cooperate.

Formal Duration

The formal duration of a cooperation describes its contractually fixed duration. It can be classified as unique if the intention is to realize just one product/offering based on a specific customer request. The cooperation can be classified as limited if the intention is to realize a fixed series of products or a product line, or it can be unlimited. Accordingly groups of enterprises might cooperate in a network environment with the aim of offering an additional product or service to the market. An enterprise network can be seen as a problem-oriented configuration of competencies according to market/customers needs [15.163]. Based on an actual request, some nodes of the network will fulfil the order along on order-specific value chain.

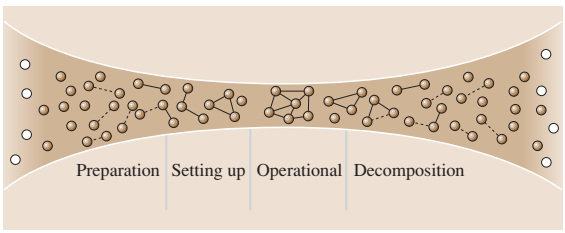

Fig. 15.68 Significant lifecycle phases of an enterprise network

Traditionally the duration of a cooperation between companies is linked to the execution of a customer-specific order and the delivery of the related product. As, especially in the capital goods domain, problem solutions instead of *pure* products tend to be requested, product-related responsibilities are extended into the operational phase and the disassembly of the product as well. Relationships of cooperating enterprises and the related cooperation may change over time, either improving or deteriorating. In other cases, a cooperation might be the preliminary stage for an integrated organization (e.g., the takeover of a cooperating partner). Nevertheless, one can expect that the variety of cases will still increase whereas the formal stability and the formal duration will decrease. However, if the formal duration of a cooperation is coming to an end the dissolution of the enterprise network should be clean, amicable, and with the minimum of damage to either partner.

Informal Duration

The informal duration of a cooperation is characterized by the mutual confidence that enterprises put into the cooperation. Whereas a formal cooperation is actually restricted to the delivery of one product, the informal agreed cooperation might be unlimited. In this context it should be mentioned that, from the game-theoretical point of view, the repetition of an interaction or even the expectation of a repetition is essential for someone's cooperative behavior. People act in a cooperative manner if they expect an additional interaction; if not, noncooperative behavior might be more effective and more successful [15.164]. Taking learning effects into account, both the first and second cooperation (even if it is a *second unique* one) will make a profit from a cooperation based on mutual confidence. The informal duration of a cooperation might be supported by contractual agreements such as cooperation agreements, letters of intent, etc.

15.10.2 Analysis of Enterprise Collaborations

Bilateral Relationships and Enterprise Networks

When two or more enterprises collaborate, they could form an enterprise network. Any enterprise network, however complex, is composed of a series of bilateral

relationships. Each of these bilateral relationships can be either hierarchical or nonhierarchical (Fig. 15.69). The relationship is hierarchical in nature when one party (who could be a buyer or a seller, depending on the market environment) is clearly superior to the other and makes the rules of engagement. In a nonhierarchical partnership, the two parties are equal in status, operate as partners (such as those engaged in codevelopment), and neither of them dictates the other. In this case, all decisions affecting the partnership are mutually agreed on.

The relationship between the parties is never static (Fig. 15.69, middle column). Quite often (though not always) partner B would like the relationship to be nonhierarchical in order to have more control over its own destiny. Therefore, it will try to improve its negotiating position, say by offering improved solutions or services. The eventual terms of engagement will be determined by the market conditions of the product or service in question and any *trump cards* the parties may hold. Reputation, knowledge, and technology within the organization, the type and uniqueness of products, and brand names and patents held by the enterprise are some of the examples of trump cards by which an enterprise can leverage its negotiating position to its advantage.

Individual enterprises are therefore required to extend their resources, their control structures, and their information systems, while protecting their market niche, in such a way that they become an attractive partner for organizations that offer products that are complementary to their own. They therefore need criteria that allow them to decide with whom they need to cooperate, and in which means and structures they need to invest. In so doing, they are configuring their own network.

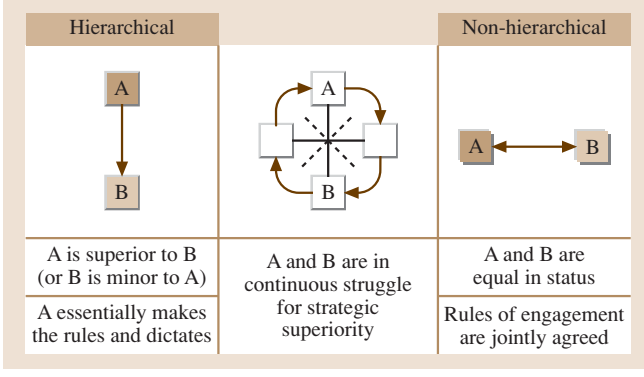

Fig. 15.69 Elementary types of bilateral relationship

Evans and *Wurster* [15.165] illustrate the complexity of interenterprise interactions and interdependencies in their *hyperarchy* model (Fig. 15.70). In a hierarchy each enterprise depends on one superior enterprise, which has access to information that is, by definition, not available to its subordinates. Here the term *hierarchy* refers to the structure of an enterprise network as opposed to a structure within an enterprise. In a hyperarchy type of enterprise network, the communication links can be complex and can take any direction.

Since the bargaining power in buyer–supplier relationships strongly depends on this asymmetry of information, such relationships will drastically change if information technology (IT) eliminates this asymmetry. Evans and Wurster claim that, under the influence of information technology and standardization of communication, hyperarchies will challenge, and eventually replace, hierarchies.

Interorganizational relationships in hierarchies are, by definition, bilateral. When considering networks, thinking in hierarchies therefore typically leads to a strict distinction between customers and suppliers. Customer-oriented effort (i. e., marketing and sales) is directed at ensuring selecting, whereas supplier-oriented effort (i. e., purchasing and procurement) is directed at selecting the right suppliers. However, selecting the right customers can be equally important as being selected by the right suppliers. The hyperarchy model consequently seems a much more accurate representation of interorganizational interdependencies.

The hyperarchy model can be compared to the network models of the International Marketing and Purchasing (IMP) group, which has published widely on networks of organizations cooperating in partnerships [15.166–168]. The IMP group views interorganizational networks as constellations of relationships. Its viewpoint is that each relationship between companies is heavily influenced by the relationships the companies have with other companies. In this view networks are infinitively large, never balanced, never optimal, and have unique perspectives for all their members. The IMP group is not so much studying individual networks, but rather sees networks as a way of looking at the world.

Networks in the IMP view consist of actors and relationships. Relationships are the result of enactments carried out by the actors and can be characterized by factors such as technology, knowledge, social relations, administrative routines, and legal ties [15.167, 169]. Actors are indirectly connected to other actors through relationships. This is called *connectivity*.

Due to connectivity, an actor can only partly identify the networks in which they operates. There are always indirect relationships to other actors, of which the actor is not aware. These unknown relationships can however be essential to the functioning of the actor in question. The IMP group criticizes traditional marketing and purchasing research that primarily focuses on bilateral and direct relationships, whereas they make it clear that multilateral and indirect relationships should also be considered.

However, despite this connectivity, no organization should try to control all relevant relationships, or even be aware of them. It should make a selection of the ones it considers most important and should direct its investments in terms of resources, control structures, and information systems towards these. In order to be able to make this selection, it should be able to identify the various relationships it has, and the alternative forms of cooperation it can use to maintain each relationship. The following subsections describe a typology that helps to characterize and recognize various modes of enterprise collaborations.

Continuum of Enterprise Collaborations

The possible scope of collaboration among enterprises is infinite. There is a plethora of literature on the classification of relationships [15.166,167,170–175]. Many of these classifications are based on the transaction-cost theory, in which transaction costs are weighed against coordination costs. One possible way of locating any collaborative relationship on a continuum is depicted in Fig. 15.71. The motivation behind this classification is to isolate those types of collaborations that can be considered as a part of the enterprise network. By enterprise network we mean *two or more participating enterprises that are engaged in the supply and receipt of goods or services on a regular and ongoing basis, with partners relying on each other, and between which the supply of goods (or services) is constrained by the associated logistics, manufacturing commitments, and operating dynamics of the participating enterprises.*

In the case of market transaction-based operations, the parties involved have one goal: maximizing their own profits from the transaction in question. Basically, if they do not consider the transaction sufficiently profitable the only measure they can take is not finishing the transaction and finding alternative sources. At the other end of the continuum, intra-organizational cooperation may directly influence the continuity of the organization. Their goal is to remain in business; their dependence on the intra-organizational structures gives them very little room for manoeuvre. From market to integrated company, the strength of interorganizational bonds increases. Consequently, organizations have to put more effort into setting up and maintaining such a relationship. Characterizations of the positions on the continuum may therefore serve as indicators of the sophistication of interorganizational relationships. The strength of interorganizational bonds is often analogous to the duration of the collaborative relationship.

Market Transaction. A market transaction occurs between two parties, and the nature of the relationship between the participants is strictly transaction based; there need not be any continuity in cooperation. Even for a market transaction there can be a range of collabo-

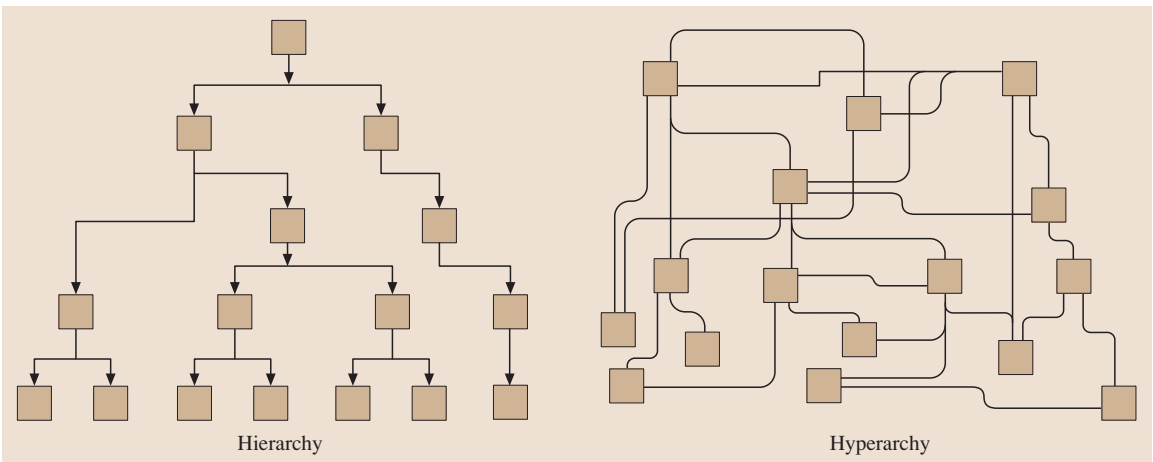

Fig. 15.70 Hierarchy versus hyperarchy

rations; for example, a market transaction could entail a range of collaborations based on the credit worthiness and payment schemes (ranging from payment in advance to mutually negotiated overdrafts and/or discounts) agreed between the parties.

Noncontractual Agreements. Agreements based on trust frequently exist in real life. In a network of enterprises, noncontractual agreements are essentially longer-lasting market transactions. They exist because the customer is happy with the supplier (in terms of pricing, delivery commitments, after-sales service, etc.) and finds no reason to search for alternative sources. Even though there is no formal commitment, favorable prices could be negotiated. The products in such transactions are either standard and readily available in the marketplace, or are not part of the core operations of the customer, for example, a hospital purchasing all of its stationery from one source. For products that are part of the core operations, noncontractual agreements normally evolve into contractual agreements.

A group of companies engaged in noncontractual agreements in the same end-product sector will form a cartel. Cartels are often formed to avoid competition and to maintain a noncompetitive marketing environment. Terms such as *restrictive practices* and *price fixing* are often associated with cartels. Cartels rely on informal understandings that share strategies for mutual benefit; they rarely, if ever, share resources. The relationship between the cartel partners is equal (as opposed to hierarchical) and they are not deemed to be part of enterprise networks.

Contractual Agreements. Contractual agreements between the manufacturers of complementary products and services are very common. Once these agreements materialize the partners will become part of an enterprise network. In a competitive environment formal contracts between the companies engaged in the same end-product sector and competing in the same market should not exist. Some agreements that come close in this category include airline alliances of code sharing, thus *virtually* extending the number of destinations available to prospective passengers of each partner airline. This scenario is only attractive to partner airlines if there is only marginal intersection of the corresponding networks and the union of the new enlarged network complements their existing services, otherwise monopoly and antitrust issues will apply. There can also be a supplier–buyer type of relationship between the producers of similar product, such as BMW supplying engines to Rolls Royce. This again is possible because the customer base for these two car manufacturers is distinct. This type of arrangement, if and when it occurs, will become a part of an enterprise network.

Joint Ventures. A joint venture implies a group of companies supplying complementary services that join forces for mutual benefit. Joint ventures frequently lead to new enterprises with joint ownership, for example, Mercedes Benz and Swatch pooling their respectively unique skills to develop the *Smart Car*. Similarly, Ford and Volkswagen set up a joint venture in Portugal, called Auto Europa, to produce their Sharan and Galaxy vehicles. Such joint ventures normally result in new enterprises that could very well form their own enterprise networks with noncontractual and contractual agreements.

Integrated Company. Due to the fact that, by definition, a single company is supposed to have a single shared ownership, in this case there is unlimited duration of cooperation. The relationship among various hierarchies and divisions of a single company will always take the form of an enterprise network. Even in a single enterprise there can be different levels of integration and cooperation between different subsidiaries or indeed between different departments located within the *four walls* of the enterprise. Although one expects complete cooperative confidence between different de-

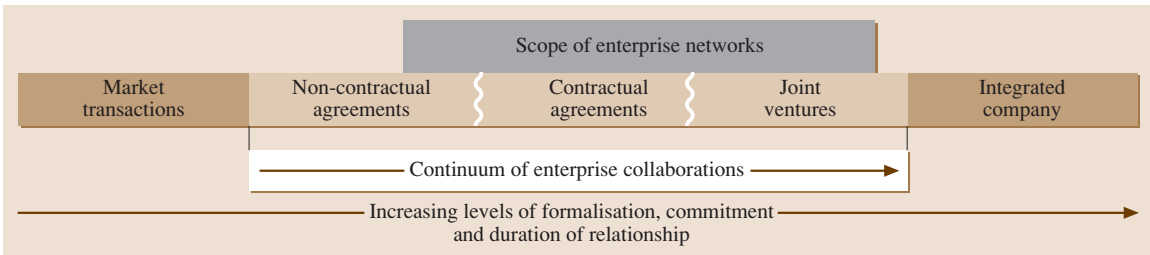

Fig. 15.71 Continuum of enterprise collaborations

partments of a single enterprise, in reality this may not always be the case. Individual aspirations and personalities will play an important part in the building (or hindering) of cooperation.

The types of collaborations described above are neither complete nor exhaustive. The only function of these descriptions is to identify those types of collaborations that can contribute to the formation of enterprise networks; for example, licence agreements could be considered as a form of collaboration, however they are left out of the classification above because they occur between parties engaged in the same product sector or frequently the same product. Partners in licence agreements are rarely part of the same enterprise network and barely share resources. A classical example is that of franchising. Franchising frequently focuses on the *brand name*. In this scenario (for example the fast-food sector), the brand-name owner allows a third party to manufacture/supply products/services under that brand name. In this agreement the brand-name owner will dictate the quality and price of the end-product/service. The relationship in licence agreements is almost always hierarchical.

Types of Collaborations within Enterprise Networks

Formation of enterprise networks is principally dictated by the rule of *return on investment*. This involves the decision of making or buying (outsourcing) some of the components required to complete the product. Two investment areas that can influence this are to avoid the costs of investing in one's own skills (or competencies), and to guarantee the availability of specific products/services. Investment in skills will have to take into account the investment in suitably skilled personnel as well as the associated investment to carry out necessary research and development to keep abreast with the cutting edge of technological developments – indeed push the frontiers further to gain technological advantage. Investment in production resources will be influenced by total in-house production requirements and thus whether economies of scale can be realized. In either case, one way or the other this boils down to the question of whether there is enough internal demand to justify investment in either (or both) of these two areas. Another factor that could influence outsourcing is the issue of time scales: under certain circumstances one could outsource the supply of certain parts, even though they may have the capabilities of making it in-house, simply because an outside supplier can do the job quickly. Whatever the reasons, once the decisions regarding the make, buy or outsource have been made and the supplier selected, this partnership will be a part of the enterprise network.

In this section, the focus of our attention is on the noncontractual, contractual or joint-venture type of collaborations among independent enterprises pooling their core competencies to form enterprise networks. Within the continuum of enterprise networks (Fig. 15.72), three key types of collaborations that can form a component of an enterprise network can be identified:

1. Supply chain (SC) type of collaboration
2. Extended enterprise (EE) type of collaboration
3. Virtual enterprise (VE) type of collaboration

Because there can be an almost infinite number of possibilities according to which companies can collaborate and form enterprise networks, one cannot discretize the space between market transaction and hierarchical

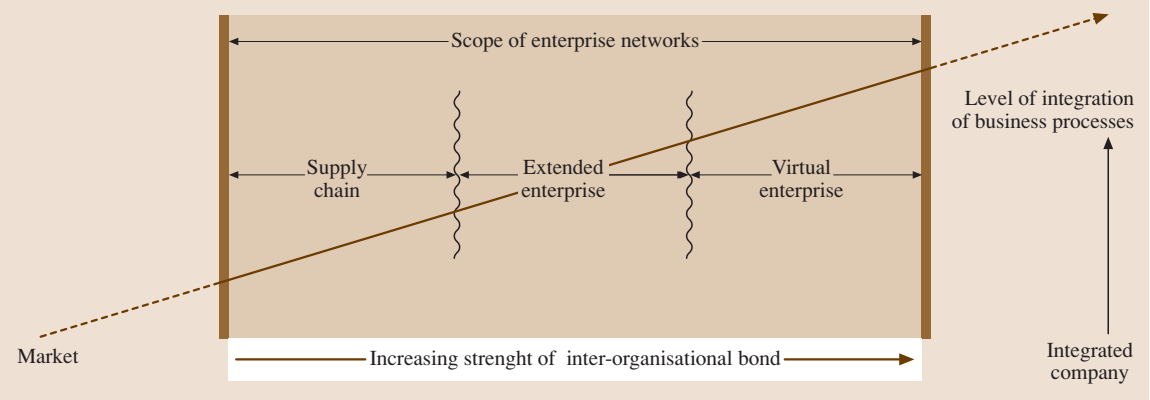

Fig. 15.72 Types of collaborations within enterprise networks

relationship into clearly defined and distinct compartments of SC, EE, and VE. Hence, the types of bilateral relationships depicted in Fig. 15.72 indicate (and should be taken as representing) a *trend* in the closeness of relationships between the cooperating enterprises. By working together, the level of confidence may improve and the relationship may evolve to a closer cooperative level. It is not possible to define a single criterion or demarcation when the collaboration evolves from an SC type of relationship to EE, or from EE to VE. To a large extent the boundary could vary with the product sector as well as the market environment. Indeed, there can be a wide region between two classifications where arguments will persist regarding the name of that collaboration. It is also worth pointing out that Fig. 15.72 does not strictly represent evolution in collaboration, as the following sections will make clear.

While the concept of supply chains has been well established, it is the emergence of information technology (IT), which deals with the sharing or exchange of information between two parties, and communication technologies (CT), which focus on the tools required for the actual transfer of information between any two parties), that has expedited the nature and scope of collaboration to new higher levels. In this section the terms *supply chains* and *distribution chains* are used interchangeably. Even though the mechanisms of setting up supply chains (materials/products sourcing) and distributions chains (customers sourcing and distribution center location) could be different, the only difference perceived by us is the perspective from which one is looking at. Delivery from enterprises upstream to one's operations is via supply chains (a *pull system*) and the distribution of completed products will require distribution chains (a *push system*). The logistics involved in either case is similar. The formation of extended enterprise and virtual enterprise are very recent developments. Therefore, *extended and virtual enterprises are merely new paradigms reflecting the extent to which the information systems of the collaborating enterprises are integrated with one another and the way in which they actually communicate and collaborate with one another. In other words, extended and virtual enterprises are different (and more sophisticated) manifestations of the supply chains. Hence, most of the underlying principles and operational issues prevalent in a supply chain will be present in extended and virtual enterprises. Indeed, the supply chain between the collaborating enterprises has to be setup before they* switch *to extended or virtual enterprise mode* [15.176].

Theoretically extended and virtual enterprises could occur in any manufacturing environment. However, current trends indicate that certain environments are more conducive to their formation, where the partners can clearly identify the resulting benefits. Within traditional manufacturing environments, one could locate the sectors, based on the product complexity and lot sizes, in which the formation of extended and virtual enterprises will be more prevalent. Figure 15.73 attempts to approximately locate such regions. In this diagram, when we talk about the complexity of a product, we mean not only the number of components it has or how complex it is to assemble but, more importantly, how technologically sophisticated its subcomponents are and to what extent they will require external core competencies in their own right for their manufacture. Typical examples of technologically complex components could be graphics cards for personal computers (PCs), fuel injection systems for automobiles, etc.

ICT (IT and CT) technologies can be seen as major enablers for modern enterprise collaborations. Without appropriate ICT-based approaches and infrastructures,

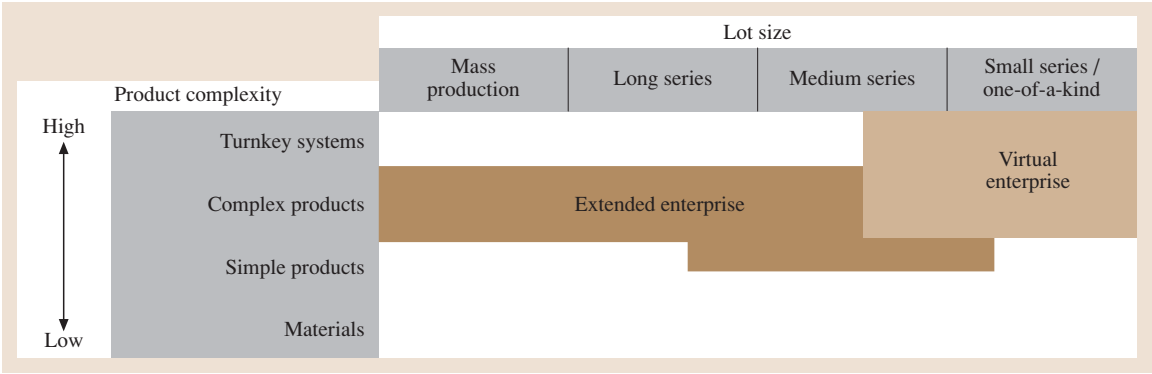

Fig. 15.73 Locating EE and VE within traditional manufacturing environments

cooperative relationships between enterprises, as dictated by modern-day market conditions, would not be possible. By improving the transparency of interorganizational infrastructures and implementing the advanced organizational approaches, cooperative and flexible solutions can become feasible. These technologies have now become a prerequisite for highly economic enterprise cooperations. Whereas classical IT solutions supported mainly the rationalization of the production process, ICT solutions of the 1990s tried to reduce the transaction costs as well, thus forming an integral part of the collaboration. Without appropriate ICT-based approaches and infrastructures, effective cooperative relationships between enterprises would not be possible. This has given the manufacturers more choices in terms of in-house product development and outsourcing. By improving the transparency of interorganizational product development as well as order processing ICT enables cooperative and flexible solutions.

Various studies have shown that ICT could reduce the coordination costs that result from outsourcing activities and therefore stimulate cooperation between firms [15.177]. Important IT developments that enable interorganizational cooperation also include the development of standards for exchanging information, e.g., EDIFACT (electronic data interchange for administration, commerce and transport) and STEP (standard for the exchange of product data) [15.178], the reduction of prices for computational power of processors, and the interconnectivity of communication networks, resulting in the Internet and the like. *Williamson*'s transaction cost theory also predicts that weighing economies of scale against transaction costs leads to the outsourcing of activities that have been carried out so far inside the organization [15.175].

Enterprise collaborations have also driven the requirements and developments in the information and telecommunication technologies; for example, developments in EDI (electronic data interchange) technology and STEP protocols to facilitate the transfer of design data and indeed product models between partners has redefined the concept of collaboration to new levels.

Supply Chain Type of Collaboration. A supply chain is a set of activities by which several enterprises (termed nodes) agree to contribute their expertise towards the completion and supply of a common end-product. A simplified model of a supply chain is depicted in Fig. 15.74. Each node in the supply chain acts as a customer as well as a supplier. In the customer mode, it receives (buys) unfinished goods from upstream suppliers, uses its core competence to add value to the product, and passes (sells) them onto the next node downstream in the chain. In traditional manufacturing, the supply chain could span raw-materials suppliers right through to the consumer of the end-product, thus encompassing all the intermediate activities of manufacturing, storage, distribution, and delivery. The *supply-side* limit of the supply chain is dictated by the criticality of the raw materials. The term *raw materials* is relative and highly dependent on the market and product sector. It also includes the issues of how readily the raw materials are available in the marketplace in which the supply chain is operating. The distribution side of the supply chain need not be restricted to the final consumer. Indeed, with the emerging environmental and associated recycling issues, enterprises involved in the disposal of the product at the end of its useful life may well form part of this supply chain. A supply chain need not be a sequential set of nodes. In fact, in real life it will often take the form of an enterprise network.

The concept of supply chains evolved long before the advent of ICT. Basic research related to supply-chain management (SCM) has been carried out since the 1960s. However, it was in the 1980s that market pressures on producers and suppliers, and the emerging ideas of just-in-time (JIT) manufacturing, gave impetus to the study of SCM and its wider acceptance; thus it formally became an integral part of manufacturing and operations research jargon. SCM entails coordination with customers and suppliers. In order to operate efficiently all nodes across the supply chain must operate in a synchronous mode, providing a rapid and high-quality response to the events.

In the dynamics of real life, perturbations to planned events will *always* occur. Unplanned events (changes in the customer order, delayed delivery of materials, machine breakdown, etc.) *will* cause deviations from scheduled activities. Furthermore, it is the accumulation of perturbations across the supply chain that can make the whole venture very inefficient. As an example, consider two cases:

1. The customer changes the order composition: this effect will ripple and amplify upstream in the supply chain as other nodes sequentially readjust their operations to incorporate this change.
2. Materials are not delivered according to agreed schedules: this effect will ripple and amplify downstream in the supply chain as other nodes sequentially readjust their operations to incorporate this change. Like the market, the production floor is

also dynamic. Therefore, the same effect will be observed if there was production perturbation, say due to a machine breakdown at one of the nodes.

In either case, the only way to counteract either of these effects is to have larger inventories. Perturbations occurring at two different nodes (due to different reasons) will further amplify the *noise* in the system. Hence, information lags, delivery lags, demand volatility, unsynchronized ordering, over- and underordering, lumpy ordering, and chain accumulations will all contrive to make demand become more volatile further along the supply chain.

The primary requirements of the operational phase of any supply chain are the minimization of inventory and lead times across the whole chain. To achieve this:

- Partners in the supply chain need to have a clear understanding (contractual or otherwise) as to what is expected from each partner. This is also true for the respective expectations.
- Both material and information flow systems need to be streamlined.
- Various functions within a node, such as marketing, sales, purchasing, production planning, and production control, must communicate effectively with one another.
- Information exchange among the nodes must occur efficiently for a supply chain to operate effectively.
- Information and decision support systems at nodes must be able to respond dynamically to meet the ever-changing needs and communicate accordingly to the affected nodes of the supply chain.
- The industry is moving from being product led to being customer led, and those in the supply chain will need to change their ways of operating to respond to this change.
- Issues such as quality management and continuous improvement are often part of the contractual agreement when the supply chain is set up.

This can only be achieved through excellence in communications among the supply-chain partners. This requires an open, scalable, flexible communications solution that provides both seamless communications and the ability to adapt rapidly to changes in supply-chain structure. The Internet is one possible solution because it has the distinct advantage of being a completely open, global communications system, with deep market penetration.

As we will see in the following sections, the emergence of affordable Internet-based ICT technologies is pushing the frontiers of enterprise collaboration to new levels and, as a result, the emergence of new paradigms from the supply chain type of collaboration: extended and virtual enterprises.

Extended Enterprise Type of Collaboration. The traditional view of business organizations is no longer valid [15.179–181]. Instead of speaking of industrial collaboration, however, one uses the term *extended enterprise* when referring to a new paradigm for manufacturing. The extended enterprise is a term frequently used in today's business literature to reflect the high level of cooperation between organizations. *Browne* et al. [15.179] argue that computer-integrated manufacturing (CIM) will enable interenterprise networking across the value chain. Manufacturing systems are no longer confined to a single factory, but cross enterprise boundaries. Integration of operations of independent organizations with the operations of suppliers and customer can result in extended enterprises. Furthermore, the market sector is not restricted to manufacturing but many other business areas such as financial services, distribution, and information services have formed closer relationships that can be termed as extended enterprises.

Extended enterprises are evolutionary in nature. Let us take an example. Two organizations have known each other and conducted business in a supply chain for some time. During this period of collaboration a sufficient level of trust has developed to automate the sharing of day-to-day operational data. This integration will be preceded by the realization of the importance of each organization of the other in its business plans. Therefore, each of the organizations will be prepared, if necessary, to invest in modern ICT tools for the effortless sharing of information. The fact that they are willing to invest in their collaboration will imply that they are committed to a long-term relationship. It is this seamless exchange of relevant operational information on top of an existing long-term (and successful) relationship that distinguishes the extended enterprise form other forms of long-term collaboration such as a supply chain. It should also be noted that ICT are enabler technologies and a necessary (though not sufficient) condition for an extended enterprise to exist. It is the integration of the respective information and decision systems and the respective production processes that link them closely enough (within the agreed bounds) to be analogous to the be-

havior of a single enterprise operating within the *four walls*.

The extended enterprise can be regarded as a kind of *enterprise* which is represented by all those organizations or parts of organizations, customers, suppliers, and subcontractors, engaged collaboratively in the design, development, production, and delivery of a product to the end user [15.182, 183]. Key suppliers become almost a part of the principal company and its information infrastructures, with frequent exchange of status information. This is echoed succinctly in the definition of extended enterprise given in *Jagdev* et al. [15.184] as "the formation of closer coordination in the design, development, costing and the coordination of the respective manufacturing schedules of cooperating independent manufacturing enterprises and related suppliers." The key term in this definition is the *coordination of the respective manufacturing schedules*. This coordination of respective schedules, which includes not only the production schedules but also dispatch, transportation/delivery, and receipt notifications, which is supposed to be performed seamlessly through the use of ICT technologies, is a necessary condition for the formation of an extended enterprise, because only then can one truly realize the integration of respective IT infrastructures, which again is a necessary condition for the formation of an extended enterprise.

The baseline for an extended enterprise is always two or more willing enterprises which have chosen to concentrate on their core competencies and wish to extend their activities into other enterprises to increase their competitiveness by achieving cost-, time- or quality-related advantages regarding their respective offerings. Extending activities implies that an enterprise is enhancing its existing capabilities or adding additional facilities, by outsourcing, which have not been at its disposal so far. Outsourcing encourages both the manufacturer and its suppliers' competitive ability and enhances their mutual dependency.

Taken from this perspective, we can identify the following as major characteristics of the extended enterprise:

- The partners in the extended enterprises are willing to form long-term relationships and treat each other as business partners. Each partner understands and accepts other's requirements and priorities.
- Within the scope of collaboration, partners share vision and work towards shared goal.
- Decisions are jointly arrived at by making best use of the competencies among the partners.
- The primary mode of communication and sharing of information between the collaborating enterprises will always be through telecomputing. It is therefore important to have available advanced ICT tools to support the extended enterprise [15.185].
- The efficiency of the extended enterprise is greatly determined by the speed and efficiency with which information can be exchanged and managed among business partners. Efficient collaborative engineering, production, and logistics require effective electronic management of engineering and production information. Thus it is important that the participating enterprises have sufficiently sophisticated IT and decision support tools and mechanisms to make this integration possible. It is also important to have the maximum degree of compatibility among partners' IT systems.
- Day-to-day communications between the respective IT systems of two enterprises will always be real time and online and without human intervention; for example, if there are production schedule perturbations in the *customer* enterprise, these changes will (and should) be automatically communicated to the *supplier* enterprise IT systems, thus triggering the processes necessary for updating of production schedules at the *supplier* end.
- Extended enterprise can occur between any two enterprises across the value chain of any product or service. Enterprises across the whole value chain can be involved in the extended enterprise. However, the concept of the whole value chain is neither a necessary nor a relevant condition for the formation of extended enterprises. If this were the case, we would enter a very slippery slope of defining the

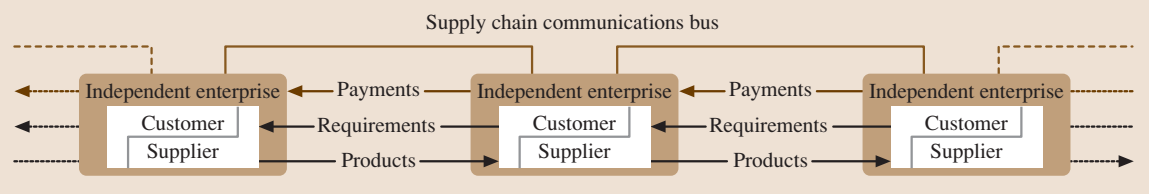

Fig. 15.74 Simplified model of a supply chain

boundaries of the value chain; for example, why restrict the starting point of the value chain to raw materials; why not extend it to their mining? Furthermore, *raw materials* for one value chain could very well be a *finished product* for another value chain, e.g., ball bearings, electric motors, transformers/power supply units, etc.
- Technology permitting, an extended enterprise can take the form of a complex enterprise network in which each enterprise can be seen as a node.
- The relationship between a set of nodes in an extended enterprise can be hierarchical or nonhierarchical.

Virtual Enterprise Type of Collaboration. Unlike the extended enterprise formation in which, more often than not, existing supplier/buyer (or supply chain) relationships are strengthened through the usage of ICT technologies, the availability of ICT technologies can initiate the formation of entirely new enterprise networks.

A virtual enterprise is one manifestation of organizational response to the dynamism and globalization of today's markets. The baseline for a virtual enterprise is the customer needs. These needs can be extensive and unique (e.g., a large project-based contract) or small but with numerous variations; for example a number of complementary companies specializing in the repair and maintenance of household items may form a virtual enterprise to provide a comprehensive service to their potential customers. These services might include the maintenance of house structure, all forms of energy supplies, telecommunication and entertainment links, repair/maintenance of household durables such as cookers, washing machines, refrigeration equipment, and the recycling and waste disposal. Each of these services will require unique core competencies. Thus, several small specialist companies can increase their potential customer base by pooling their competencies. The attractiveness for the customer of such an enterprise will be that there will be only a single contact point for most of their household-related problems.

From the above argument we can note that there needs to be pooling of more than one core competence for the formation of virtual enterprise. Taken literally, there is nothing new in small companies joining forces to strengthen their marketability. However, it is the availability of ICT technologies that has given small enterprises entirely new platforms to collaborate efficiently to supply effective product/service. Thus, it should be noted that ICT are enabling technologies and a necessary (though not sufficient) condition for a virtual enterprise to exist.

Business partners in virtual enterprises can retain the individual agility of the consortium members to undertake their own business operations and quiet possibly participate in other EE or VE type of projects simultaneously [15.184, 186]. As information and communications technologies overcome the constraints of time and distance, it has become possible to create virtual organizations. Those independent companies, temporarily linked by ICT networks, share skills and costs, and can access each other's markets.

Some authors define virtual enterprises as temporary networks of independent companies engaged in providing a product or service. *Childe* [15.160] defined the evolution of virtual enterprise as: and "... in the extreme, the principal company may have no premises and may not perform what is generally seen as manufacturing work – it may only consist of functions such as design and production management, acting as the co-ordinator of activities in the cooperating companies. In this case, the company becomes a virtual enterprise, appearing to its customers as a supplier of goods and services, but with no internal production activities." In such a scenario, virtual enterprises are often project based and usually operate in niche markets. Thus they form, reform, and dissolve based on the market dynamics and the opportunities it provides.

Forbairt [15.187] depicts the virtual enterprise as a response to the speed and globalization of the digital age. It is an enterprise that may have no physical head office or center and very few full time workers, and that exists as a combination of specific skills and competencies of individuals or enterprises. A virtual enterprise may be set up with the objective of providing one particular type of product or service. When the market for that product or service declines, the virtual enterprise dissolves, its members finding new partners to pursue new opportunities. In the global village, companies who survive and prosper are agile, flexible, and adaptable and constantly seek to maximize their unique advantages.

Compared to an original enterprise, according to *Scholz* [15.188], a virtual enterprise is always characterized by the absence of specific physical attributes/features such as a common administration or a common legal status. These features are replaced by the application of sophisticated information and communication infrastructures and mutual confidence (common understanding).

Skyrme [15.189] emphasizes the growth of networking, both human and technological, and argues that this

is creating a virtual world with virtual products and services, virtual workplaces, and virtual organizations. The virtual products and services are produced, delivered and sold through electronic networks, e.g., telebanking and telemarketing, significantly reducing the costs of many activities and creating opportunities to reach distant markets easily. The virtual workplaces include teleworkers, who work in a location-independent manner (sometimes at home), and flexible offices. Virtual organizations work in teams and cooperate across company boundaries to create the organization necessary for and appropriate to specific projects, thereby gaining significant flexibility in the use of people. This virtual world is the broad social environment for the establishment of the virtual enterprise in manufacturing.

The intelligent manufacturing systems (IMS) project [15.190] defines the virtual enterprise as the next generation of manufacturing enterprise, which consists of a globally distributed assembly of autonomous work units linked primarily by the goal of profitably serving specific customers and operating in an environment of abrupt and often unanticipated change.

Davidow and *Malone* [15.180] echo a similar sentiment when they suggest that networks of cooperating manufacturers are the industrial strategy for structuring and revitalizing corporation for the 21st century. They term these networks *virtual corporations*. We believe that this definition of virtual corporation is rather generic, as it also encompasses many of the principles of electronic commerce. The virtual enterprise described in this section is a more formal definition depicting the nature of relationship between two (or more) organizations engaged in providing a real product or service, as opposed to some virtual product. Our interpretation of virtual enterprise can be considered as a subset of virtual corporation as defined by *Davidow* et al. In their book *Virtual Corporation* [15.180] they present their vision of 21st century industries, which will be built around "a new kind of product, delivering instant customer gratification in a cost-effective way." These products have a very rich service component that is often more important than the tangible characteristics of the product. They can be produced in several locations and offered in a great number of models and formats. Davidow et al. call these products *virtual products*. They believe that a manufacturing company will not be an isolated facility of production, but rather a node in the complex network of suppliers, customers, engineering, and other service functions. The real-time adaptation of the virtual product to customer needs requires the virtual corporation to maintain integrated and ever-changing data files on customers, products, and production and design methodologies. They therefore speak of it in terms of patterns of information and relationships that will appear less as a discrete enterprise and more as an ever-varying cluster of common activities of suppliers and their downstream customers in the midst of a vast fabric of relationships. These relationships will be built on principles such as *joint destiny, trust, and sharing information*.

The virtual corporation of Davidow and Malone is described as almost edgeless, with permeable and continuously changing interfaces between company, supplier, and customers. Nevertheless, Davidow and Malone stress the importance of brand names and product identity. A virtual corporation is identified by the activities carried out and the products delivered. In fact, a virtual corporation is defined through the product or product line it produces.

Møller [15.191] defines the virtual enterprise from the supply-chain point view. This concept is used to characterize the global supply chain of a single product in an environment of dynamic networks of companies engaged in many different relationships. The companies in a virtual enterprise coordinate their internal systems with other systems in the supply chain, and simultaneously participate in other virtual enterprises and adapt to changes.

In principle, small and medium-sized companies participating in a virtual enterprise gain access to the resources of a large organization while retaining the agility and independence of a small one. *Skyrme* [15.189] suggests that the following benefits may be obtained through the construction of a virtual enterprise:

- Access to a wide range of specialized resources
- Presentation a unified face to large corporate buyers
- That individual members retain their independence and continue to develop their core competencies
- Reshaping of the enterprise and changing of members according to the project or task in hand
- That there is no need to worry about *divorce settlements* as in formal joint ventures

Therefore, a *virtual enterprise can be defined as a network of independent organizations that jointly form an entity committed to provide a product or service*, because from the customer's perspective as far as that product/service is concerned, these independent organizations, for all practical and operational purposes, are *virtually* acting as a single entity/enterprise. Taken

from this perspective, we can identify the following as major characteristics of the virtual enterprise:

- The (two or more) partners in the virtual enterprises are individuals and independent companies who come together and form a *temporary* consortium to exploit a particular market opportunity.
- Within the scope of collaboration, partners share vision and work towards shared goal.
- Partners in virtual enterprises make extensive use of ICT technologies for communication and sharing information. Most of the day-to-day information exchange among the partners will almost always be automatic and without human interference.
- Virtual enterprises assemble themselves based on cost effectiveness and product uniqueness without regard to organization size or geographic location.
- Unlike SCs or EEs, virtual enterprises, once formed, will have a unique dynamics, new identity, and quiet possibly a new name.
- The efficiency of the virtual enterprise is greatly determined by the speed and efficiency with which information can be exchanged and managed among business partners. Efficient collaborative engineering, production, and logistics require effective electronic management of engineering and production information. Thus it is a prerequisite that participating enterprises have sufficiently sophisticated IT and decision support tools and mechanisms to make this integration possible.
- Virtual enterprises pool costs, skills, and core competencies to provide world-class solutions that could not be provided by any one of them individually. Therefore, virtual enterprises often focus on complete products or solutions as opposed to providing partial solutions in a value chain.
- Decisions are jointly arrived at by making best use of the competencies among the partners.
- Virtual enterprises will often be complex networks in which each enterprise can be seen as a node.
- The relationship between a set of nodes in a virtual enterprise will mostly be nonhierarchical in nature.

Part C Complementary Material for Mechanical Engineers

16. Power Generation

Dwarkadas Kothari, P.M.V. Subbarao

The chapter contains 32 sections. Section 16.1 gives an introduction to the principle of energy supply. This section also provides the state of the art of the economics of various energy resources. Different types of fuels and their characteristics are discussed in Sect. 16.3. The conversion of different forms of energy has been explained in Sect. 16.5. Working principles of different power plants like gas turbines, the internal combustion (IC) engine, fuel cells, nuclear, and combined cycle system are discussed in Sects. 16.6–16.10.

Section 16.11 explores the inherent features of the integrated gasification combined cycle system. Various types of gasifiers and their working procedures are explained in this section. Section 16.12 provides updated information about magneto-hydrodynamic power generation and detailed information about various types of cogeneration system is also explained in Sect. 16.13.

Sections 16.14 and 16.15 explain the transformation of regenerative energies. These sections are mainly devoted to wind and solar energy conversion. Harvesting solar energy using solar ponds and solar chimneys is also explained in this section. The concept and working principle of the heat pump is explained in Sect. 16.16.

Section 16.17 contains the information about energy storage and distribution systems. Energy storage is used to offset the adverse effects of fluctuating demands for electricity and to assure a steady output from existing power plants. Various energy storage devices like pumped hydro, thermal energy, and hydrogen energy are described.

The furnace is the heart of a power generation system. Understanding its internal features and working principle is very important for a power plant professional. Section 16.18 satisfies these needs. It not only provides the characteristics of furnace combustion, but also provides the emission characteristics of furnace. Recent combustion technologies like fluidized bed combustion, bubbling fluidized bed combustion, and circulating fluidized bed combustion are also explored in Sect. 16.19.

Section 16.21 provides more details about the working principles of various types of burners. Inside the furnace the fuel must be evenly dispersed in the combustion airstream such that the fuel and air can come into intimate contact. Failure to achieve this results in unburnt or partially burnt fuel. The burner design attempts to achieve this by using a variety of techniques. Sections 16.22 and 16.23 facilitate understanding of various furnace accessories and technologies available to control emission.

The boiler is a key component in modern, coal-fired power plants; its concept, design, type, and integration into the overall plant considerably influence costs. The operating behavior and availability of the power plant are discussed in Sect. 16.24. Details of the various components of a steam generator are provided in Sect. 16.25.

Energy balance analysis and the efficiency calculation of furnace are described in Sects. 16.26–16.28. Thermodynamic calculations such as furnace design, boiler strength calculations, and heat transfer calculations are discussed in Sects. 16.29 and 16.30. Various types of nuclear reactors and their working principles are elaborated in Sect. 16.31. Finally, Sect. 16.32 is devoted to a discussion of future prospects and conclusions.

16.1 Principles of Energy Supply

Energy exists in many forms such as thermal energy, chemical energy, mechanical energy, potential energy, kinetic energy, and nuclear energy. Electrical energy is a desirable form of energy, because it can be generated centrally in bulk and transmitted economically over long distances. The requirement for energy is the demand for so many tonnes of coal, barrels of oil, cubic meters of gas, and so on. With the ever-increasing per-capita energy consumption and exponential growth in population, technologists already foresee the end of the Earth's non-replenishable fuel resources.

16.1.1 Planning and Investments

Investment planning for power plants requires a long-term plan, which covers facility investment such as the construction of new power plants or the replacement of existing plants with a newer one in an uncertain environments. Capital investment is a prerequisite for energy development as it is highly capital intensive. Investments in energy plants, equipment, and infrastructure (transportation, availability of fuel, water, communications, environment compatibility etc.) must be viewed

in the framework of economic growth, savings, and the size and degree of liberalization of capital markets.

According to the International Energy Agency (IEA), investment in electricity generation capacity will be about $4.6 trillion and installed capacity will rise from 3498 GW in 2000 to 7157 GW by 2030. As around 1000 GW of capacity is likely to be retired over this period, a total of 4700 GW of new build is required, costing around $4.28 trillion.

16.1.2 Economics of Gas

The yearly world demand for natural gas was 95.50 trillion cubic feet in 2003 and is rising gradually. In the year 2001 the consumption of natural gas was only 89.31 trillion cubic feet. Figure 16.1 provides information about the shares of electricity generation by fuel. Electricity generation from gas increased from 12.1% in 1973 to 19.4% in 2003.

Natural gas has the advantage over most other energy resources because of its great operational flexibility and the ease with which incremental gas supplies can be moved to generators. Various studies have revealed that gas is a preferred energy source for new generating capacity.

According to the statistics of the International Energy Agency, worldwide electricity production using gas in the year 2003 was 3 224 699 GW h out of a total electricity production of 16 741 884 GW h. According to the results of an IEA survey natural gas is tending to gain and coal to lose market share as the industry moves from a regulated position to a competitive environment.

Gas-fueled power plants have low capital cost. In 2003, 16% of the world's electricity was generated by natural gas. Technology transfer from developed countries will be required to meet this need. Pipeline transmission of gaseous fuel is capital intensive and allows less flexibility in the choice of buyers and sellers.

16.1.3 Economics of Electricity

A power plant should provide a reliable supply of electricity at minimum cost and minimum pollution to the consumer. The total price we pay for energy from power plants consists of:

1. Capital cost
2. Operating costs

Capital cost depends entirely on plant investment and includes:

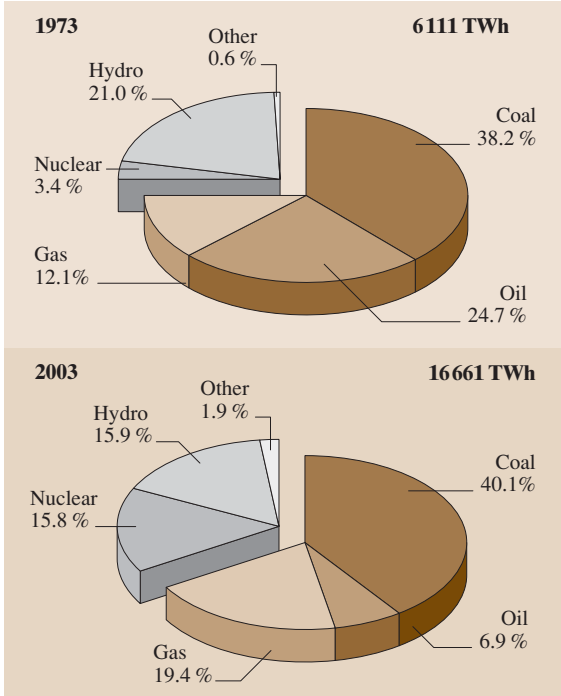

Fig. 16.1 Total energy shares of primary energy for electricity 2003 (Source: energy statistics from the IEA)

1. Interest
2. Depreciation
3. Taxes
4. Insurance

Operating cost includes the cost of operation, maintenance, and fuel.

Operating costs are inversely proportional to the capacity factor. Operating and maintenance costs mainly depend on the type of unit and the fuel used. Maintenance costs may be reduced if the unit is not operating or is operated at low load.

With the increase in economic growth, the consumption of electricity also increases. Electricity demand in India has been increasing rapidly, and the 534 billion kWh produced in 2002 was almost double the 1990 output, although it represents only 505 kWh per capita for the year. The amount and cost of electricity depends upon the fuel used.

16.1.4 Economics of Remote Heating

The cost of generating useful heat should be identified with the value of the *lost* electricity. The total

cost of waste heat has two components: the production cost at the plant and the distribution cost. The distribution component is calculated from the capital charges and maintenance expense for the pipeline system conveying warm water or steam from the plant to customers.

District heating is already widely used in central core areas of large cities. Many large buildings can be heated by steam or hot water from a single large central combustion plant. Also, space cooling can be provided by using the hot water or steam to actuate an absorption-type refrigeration plant.

16.2 Primary Energies

Primary energy is contained in raw fuels and any other forms of energy received by a system as input to the system. Primary energy is transformed in energy conversion processes to more convenient forms of energy and cleaner fuels. The most important primary energy sources are the carbon-based fossil energy sources. Fossil fuels (oil, coal, and natural gas) are called nonrenewable energies, and come from the long-term decomposition of plant and animal matter over millions of years. Sun is the main source of energy from which all of the above energy resources are derived.

16.3 Fuels

Fuels are chemical substances which may be burned in oxygen to generate heat. They mainly consist of carbon and hydrogen and sometimes a small amount of sulfur or minerals, and may be solid, liquid, or gaseous. Coal and coke are examples of solid fuels. Petroleum oils are usually a mixture of several liquid fuels. Gaseous fuels may be a mixture of gases such as methane (CH_4), ethane (C_2H_6) and so on.

16.3.1 Solid Fuels

Solid fuel is a term given to various types of solid materials that provide energy. This energy is usually released by combustion. Coal and coke are examples of solid fuels.

16.3.2 Liquid Fuels

Most liquid fuels are derived from fossil fuels. These can be classified according to their volatility (the ease with which they evaporate and turn into vapor). The most volatile fuels are gasoline and kerosene. Less volatile fuels are used in diesel engines and residual fuels, of varying viscosities, are often used in boilers. Ethanol produced from the fermentation of sugar is a prominent liquid fuel.

16.3.3 Gaseous Fuels

Gas is a preferred fuel, the combustion of which offers more environmental friendliness over the other fossil fuels. It burns more readily and completely than other fuels. Gaseous fuels are the most convenient, requiring the least amount of handling, and are the most maintenance free. Gas is odorless and colorless. Because gaseous fuels are in a molecular form, they are easily mixed with the air as required for combustion, and are oxidized in less time than is required to burn other types of fuel. A mixture of methane (CH_4) and ethane (C_2H_6) is an example of a gaseous fuel.

16.3.4 Nuclear Fuels

Fuels such as uranium or thorium that can be used in nuclear reactors as a source of electricity are called nuclear fuels. The energy derived during fission or fusion processes is called nuclear energy. Examples of nuclear fuels are: ^{235}U, ^{238}U, and ^{239}Pu.

16.3.5 Regenerative Energies

Regenerative or renewable energies are those energy sources or energy carriers that naturally renew themselves within human timescales. Regenerative energies

are available everywhere. Effective utilization of these resources is a very challenging task [16.1]. The renewable sources of energy include hydropower, solar, wind, and biomass [16.2].

16.4 Transformation of Primary Energy into Useful Energy

Energy has become an essential driving force of the economy. In fact, it assumes numerous forms: chemical energy in fossil fuels or the biomass, kinetic energy in waterfalls or the wind, electromagnetic energy from the sun, nuclear energy in uranium, as well as the electrical or thermal energy that is put to numerous uses. The sun is the major source of energy from which all energy resources are derived. Figure 16.2 shows the various forms of energy derived from the sun. It represents all the fossil fuels (oil, gas, and coal) derived from the sun by various means of transformation such as vegetation, chemical energy conversion, and finally fossilization.

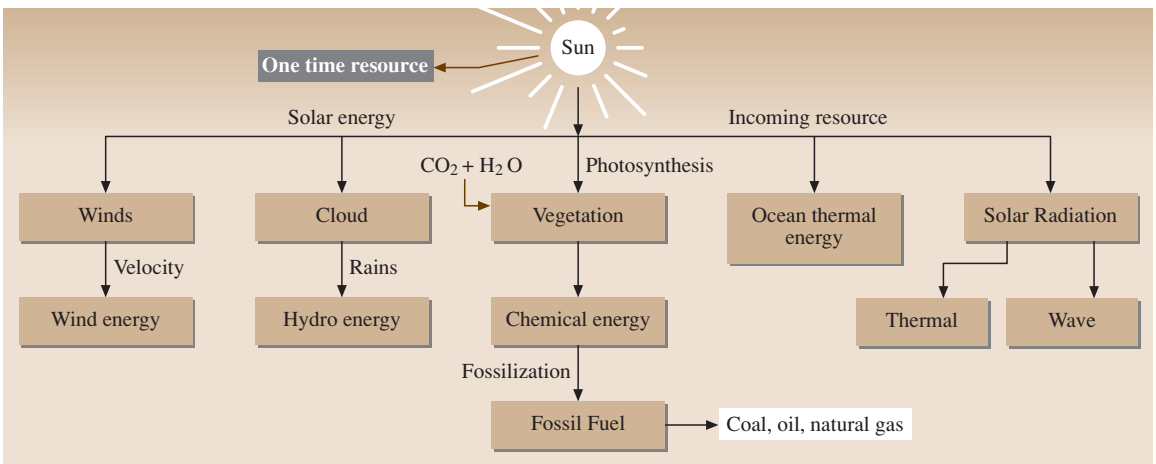

Fig. 16.2 Energy system diagram

16.5 Various Energy Systems and Their Conversion

Conversion of one form of energy into another form of energy is essential in order to utilize the maximum potential of energy resources. Efficient generation of electricity from various energy resources is one of the challenging tasks for the scientist. Efficient utilization of various sources of energy leads to a strong economy and promotes the wealth of the nation. Figures 16.3–16.5 depict various energy systems and their conversion process.

The sun heats our atmosphere unevenly, so some patches become warmer than others. These warm patches of air rise and other air blows in to replace them – and we feel a wind blowing. We can use the energy in the wind by building a tall tower, with a large propeller on the top.

The current global average conversion efficiency for coal-fired electricity generation is 34% and that for gas-fired electricity generation 37%. Modern coal-fired power plants are operating at a higher efficiency of 43–48 %.

16.5.1 Generation of Electrical Energy

Electric energy is the flow of electric power or charge. It is a secondary energy source, which means that we get it from the conversion of other sources of energy, such as coal, natural gas, oil, nuclear power, and other natural sources, which are called primary sources. The energy sources we use to make electricity can be renewable or nonrenewable, but electricity itself is either renew-

able or nonrenewable. Electricity generation from the combustion of fuel is reported under combustion-based power station.

16.5.2 Steam Power Cycle

The Rankine cycle is a thermodynamic cycle and is used in a variety of power plants. The simplest arrangement of the steam power plant is that without regeneration and reheat, as shown in Fig. 16.7. A simple Rankine cycle consists of four main components (steam generator, turbine, condenser, and pump). Additional components are sometimes added to enhance cycle performance and to improve efficiency. This cycle is named after William John Macquorn Rankine (1820–1872), who established it as the fundamental cycle for a steam power plant. In a simple steam power plant, which works on a Rankine cycle, heat is added reversibly at a constant pressure. The efficiency of the Rankine cycle is a function of the temperature of heat rejection and the mean temperature of heat addition. The higher the mean temperature of heat ad-

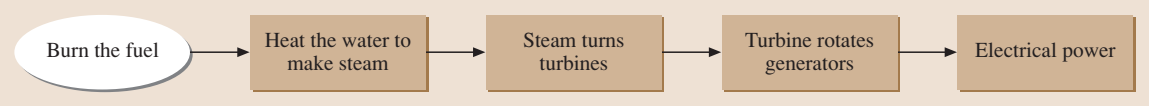

Fig. 16.3 Structure of energy systems – fossil sources

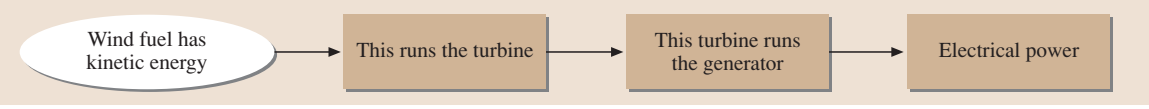

Fig. 16.6 Structure of energy systems – wind fuels

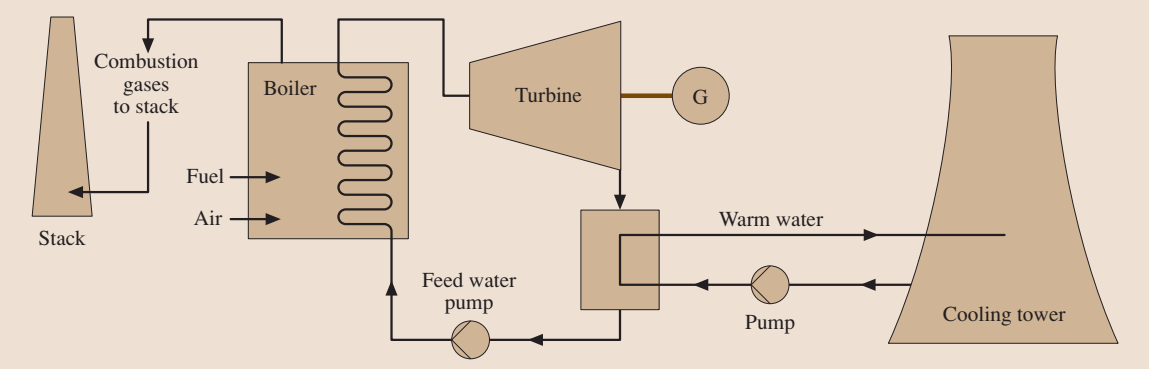

Fig. 16.7 Layout of a simple Rankine cycle power plant

dition the higher the efficiency. The working fluid in a Rankine cycle follows a closed loop and is reused constantly.

16.5.3 Process of the Rankine Cycle

There are four processes in the Rankine cycle, each changing the state of the working fluid. These states are identified in the T–S (temperature–entropy) diagram shown in Fig. 16.8.

Process 1–2. First the working fluid is pumped (isentropically) from low to high pressure by a pump. Pumping requires a power input (for example, mechanical or electrical).

Process 2–3. The high-pressure liquid enters a boiler, where it is heated at a constant pressure by an external heat source to become a superheated vapor. The common heat sources for power plant systems are coal, natural gas, and nuclear power.

Process 3–4. The superheated vapor expands through a turbine to generate power output; ideally this expansion is isentropic. This decreases the temperature and pressure of the vapor.

Process 4–1. The vapor then enters a condenser, where it is cooled to become a saturated liquid. This liquid then reenters the pump and the cycle repeats.

In order to improve coal-fired power plant efficiency, leading to a proportional reduction in coal consumption and carbon dioxide emissions, it is widely accepted that the domestic power industry must move from subcritical to supercritical steam cycles.

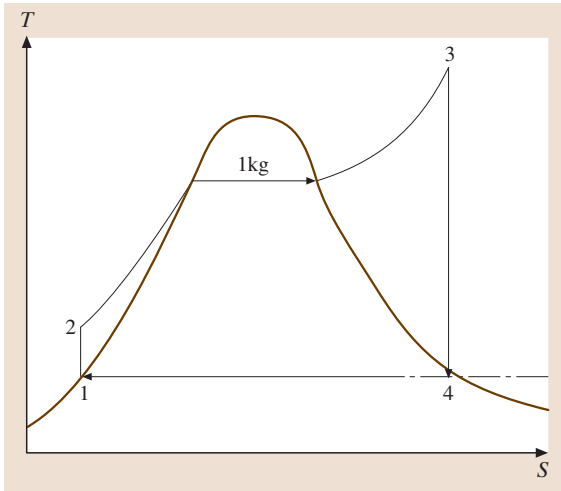

Fig. 16.8 T–S diagram of a simple Rankine cycle

Reaching 45% efficiency is possible with the help of a supercritical (SC) Rankine steam cycle employing a reheat and regeneration mode and operating at 250 bar and 540 °C. Today, ultra-supercritical steam (USC) parameters of 300 bars and 600/600 °C can be realized, resulting in 42% (HHV – higher heating value) efficiency for bituminous-coal-fired power plants [16.3].

The improved efficiency represents reductions of about 15% in all emissions including CO_2, compared to those from installed capacity. The challenges of coal-based power generation are environmental; the future technologies are near-zero emission and high-efficiency plants equipped to reduce CO_2 emission.

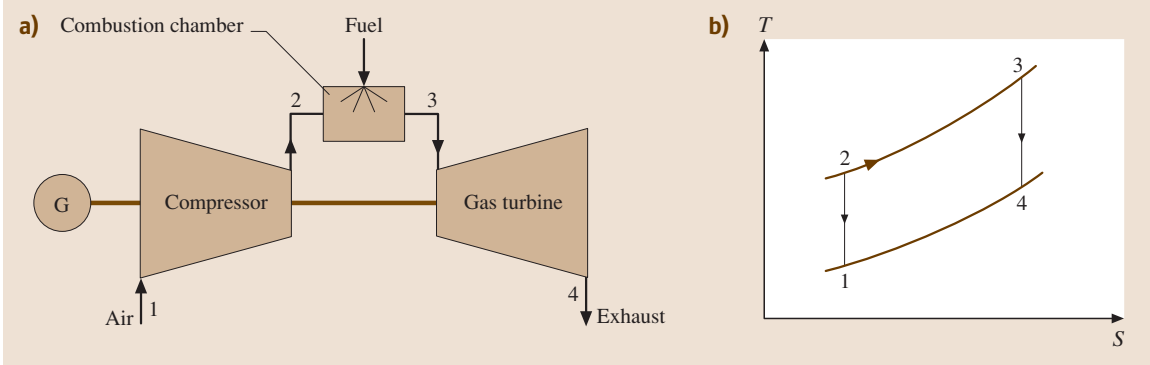

Fig. 16.9 Arrangement of an open-cycle gas turbine plant

16.6 Direct Combustion System

The economics of power generation by gas turbines is now quite attractive due to their low capital cost and high reliability and flexibility in operation. Another outstanding feature is their capability to start quickly and to use a wide variety of fuels from natural gas to residual oil or powdered coal.

16.6.1 Open-Cycle Gas Turbine Power Plant

The essential components of a gas turbine power plant are the compressor, combustion chamber, and the turbine. The air standard cycle of gas turbine power plant is the Brayton cycle shown in Fig. 16.9. It consists of two reversible adiabatic processes and two constant-pressure processes. Gas turbine plants can be operated either in an open or closed system configuration.

Analysis

1–2: Work input

$$w_{\text{comp}} = h_2 - h_1 = c_{\text{p}}(T_2 - T_1)\,, \tag{16.1}$$

2–3: Heat input

$$q_{\text{in}} = h_3 - h_2 = c_{\text{p}}(T_3 - T_2)\,, \tag{16.2}$$

3–4: Work output

$$w_{\text{tur}} = h_3 - h_4 = c_{\text{p}}(T_3 - T_4)\,, \tag{16.3}$$

4–1: Heat rejection

$$q_{\text{out}} = h_4 - h_1 = c_{\text{p}}(T_4 - T_1)\,. \tag{16.4}$$

Isentropic processes

$$\frac{p_2}{p_1} = \left(\frac{v_1}{v_2}\right)^{\gamma} = \left(\frac{T_2}{T_1}\right)^{\frac{\gamma}{\gamma-1}}\,, \tag{16.5}$$

$$\frac{p_3}{p_4} = \left(\frac{v_4}{v_3}\right)^{\gamma} = \left(\frac{T_3}{T_4}\right)^{\frac{\gamma}{\gamma-1}}\,. \tag{16.6}$$

Constant-pressure processes

$$p_3 = p_2 \quad \text{and} \quad p_4 = p_1\,; \tag{16.7}$$

$$r_{\text{p}} = \frac{p_2}{p_1} = \frac{p_3}{p_4} = \left(\frac{v_1}{v_2}\right)^{\gamma} = \left(\frac{v_4}{v_3}\right)^{\gamma} = \left(\frac{T_2}{T_1}\right)^{\frac{\gamma}{\gamma-1}} = \left(\frac{T_3}{T_4}\right)^{\frac{\gamma}{\gamma-1}}\,, \tag{16.8}$$

where r_{p} is the pressure ratio

$$T_2 = T_1(r_{\text{p}})^{\frac{\gamma-1}{\gamma}} = T_1\rho\,, \tag{16.9}$$

and

$$\rho = (r_{\text{p}})^{\frac{\gamma-1}{\gamma}}\,, \tag{16.10}$$

$$T_4 = \frac{T_3}{(r_{\text{p}})^{\frac{\gamma-1}{\gamma}}} = \frac{T_3}{\rho}\,, \tag{16.11}$$

$$\eta_{\text{th}} = \frac{w_{\text{net}}}{q_{\text{in}}} = \frac{c_{\text{p}}\left(\frac{T_3}{\rho} - T_1\right)}{c_{\text{p}}\,(T_3 - \rho T_1)} = \frac{1}{r_{\text{p}}^{\frac{\gamma}{\gamma-1}}}\,, \tag{16.12}$$

$$w_{\text{net}} = c_{\text{p}}\left[T_3\left(\frac{\rho-1}{\rho}\right) - T_1(\rho-1)\right]\,, \tag{16.13}$$

$$= c_{\text{p}}(\rho-1)\left(\frac{T_3}{\rho} - T_1\right)$$

$$= c_{\text{p}}\left(\frac{\rho-1}{\rho}\right)(T_3 - \rho T_1)\,. \tag{16.14}$$

The thermal efficiency can also be written as

$$\eta_{\text{th}} = \frac{1}{\rho} = \frac{1}{r_{\text{p}}^{\frac{\gamma}{\gamma-1}}}\,. \tag{16.15}$$

It may be noted that in a simple gas turbine cycle the cycle efficiency is a function of the pressure ratio only. The gas turbine inlet temperature is an important parameter of efficiency. The present state of the art temperature is 1570 K, but research on closed-cycle steam cooling of turbine blades, protective surface coating of combustor liners, and new ceramic structural parts of the turbine are areas of research that will lead to higher gas turbine inlet temperatures.

Merits and Demerits of the Brayton Cycle

1. Very compact, which is why it is used in aircraft.
2. It demands extremely high quality and costlier fuel.
3. The pressure of the exit gases should always be just above atmospheric pressure.
4. The compressor requires a large power input. In consumes more power than is produced from the steam turbine.
5. It has a lower cycle efficiency, due to the large exhaust loss.

16.7 Internal Combustion Engines

The internal combustion (IC) engine is one of the greatest inventions today. Internal combustion engines can be run by p.t.o., diesel, gasoline, methane, or natural gas. Internal combustion engines for power production are generally fueled by diesel.

Reciprocating engines have usually been employed for distributed power generation for the past few decades. Power generation from a diesel engine generator is the most cost-competitive technology to provide power to a small number of consumers. It is appropriate for an electrical load of about 0.01–50 MW.

Internal combustion engines have one or more cylinders in which the combustion of fuel takes place. The engine, which is connected to the shaft of the generator, provides the mechanical energy to drive the generator to produce electricity. The following are the benefits of IC engines for power production:

1. Easy to transport and install.
2. Like gas turbines, they are usually operated during periods of high demand for electricity.

16.8 Fuel Cells

A fuel cell is an electrochemical device that converts the chemical energy of the fuel directly into electrical energy. It consists of an electrolyte layer in contact with a porous anode and cathode on the sides. In a typical fuel cell gaseous fuels are fed continuously to the negative electrode and an oxidant is fed continuously to the positive electrode.

Electrochemical reactions take place at the electrodes to produce an electric current. In general, the oxidation of H_2, CO, CH_4, and higher hydrocarbons in fuel cells that produces power also produces rejected heat. This heat arises from two sources: when the entropy decreases, ΔS resulting from the overall oxidation reaction, accompanying the usual decrease in the number of moles of gases from reactants to products and due to the irreversible process occurring in the operation of the cell. Heat from these two sources must be rejected from the fuel cell in order to maintain the temperature at a desired level. In the case of hybridization, the efficiency is the ratio of the sum of stack electricity and the power generated by the bottoming cycle to the lower calorific value of the fuel consumed. This can be accomplished by three cycles, namely the regenerative Brayton cycle, the combined Brayton–Rankine cycle, and the steam-turbine-operated Rankine cycle.

The regenerative Brayton cycle in Fig. 16.10 shows a gas turbine compressor for the air flow to the cell. The flow then passes through a countercurrent recuperative heat exchanger to recover heat from the combustion product gases leaving the gas turbine. The air and the fuel streams then pass into the cathode and anode compartments of the fuel cell(s). The air and fuel streams

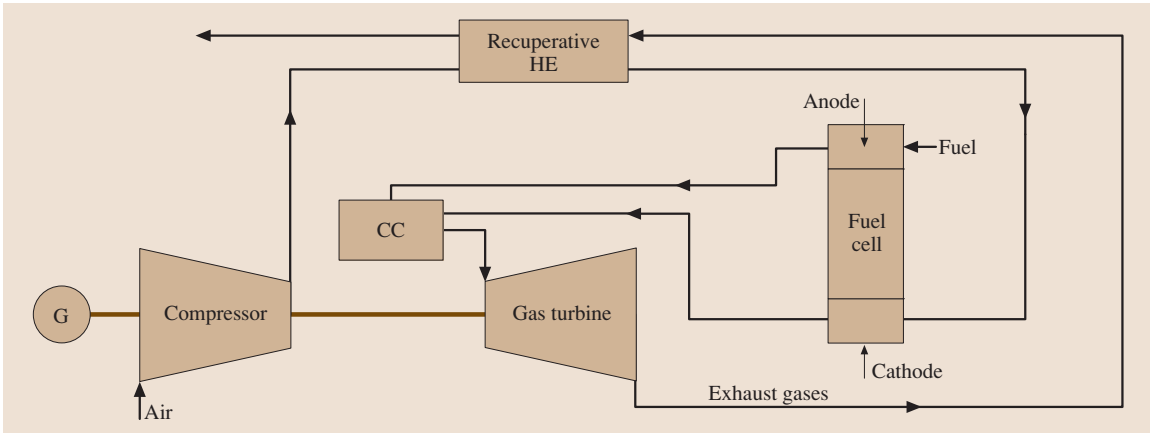

Fig. 16.10 Regenerative Brayton-cycle fuel-cell power system. (CC – combustion exchanger, HE – heat exchanger)

leaving the cell(s) enter the combustor, where they mix and the residual fuel burns. The combustion products enter the turbine, expand, and generate additional power. The turbine exhaust gases pass through the recuperative exchanger to the stack.

The overall solid oxide fuel cell reactions are

$$H_2 + \tfrac{1}{2}O_2 \rightarrow H_2O\,, \qquad \Delta H_{298} = -241\,\mathrm{kJ/mol}\,, \tag{16.16}$$

$$CO + \tfrac{1}{2}O_2 \rightarrow CO_2\,, \qquad \Delta H_{298} = -283\,\mathrm{kJ/mol}\,. \tag{16.17}$$

The ideal or equilibrium potential (E) for the above overall reactions can be calculated by the Nernst equation

$$E = E^0 + \frac{RT}{2F}\ln\left(\frac{P_{H_2}P_{O_2}^{1/2}}{P_{H_2O}}\right) \quad \text{and}$$

$$E = E^0 + \frac{RT}{2F}\ln\left(\frac{P_{CO}P_{O_2}^{1/2}}{P_{CO_2}}\right)\,. \tag{16.18}$$

Fuel cell power output

$$= \text{voltage (cell potential)} \times \text{current (load)}\,. \tag{16.19}$$

The total power and total efficiencies of the hybrid cycle are calculated as

$$P_{SOFC} = N_{cell}P_{cell}\eta_{DC/AC}\,, \tag{16.20}$$

$$P_{GT} = (P_{EXP} - P_{COMP})\eta_{GEN}\,, \tag{16.21}$$

$$P_{TOTAL} = P_{SOFC} + P_{GT} - P_{AUX}\,, \tag{16.22}$$

$$\eta_{ele} = \frac{P_{TOTAL}}{\sum N_c \mathrm{LHV}_c}\,, \tag{16.23}$$

where P_{SOFC} is the electrical power output from the fuel cell, P_{GT} is the power output from the gas turbine, P_{aux} is the power consumed by the auxiliary units, LHV_c is the lower heating value, and N_c is the number of cells.

The Siemens Westinghouse Power Corporation of Pittsburgh developed and fabricated the first advanced power plant to combine a solid oxide fuel cell and a gas turbine. The microturbine generator was manufactured by Northern Research and Engineering Corporation of Woburn. The factory acceptance test was completed in April 2000. Southern California Edison is operating the new hybrid plant at the National Fuel Cell Research Center at the University of California, Irvine. A year of testing in a commercial setting will be performed at this site. The system cycle is expected to generate electric power at 55% efficiency. The pressurized system will generate 220 kW of power and be operated at a pressure of 3 atm. The fuel cell is made up of 1152 individual tubular ceramic cells and generates about 200 kW of electricity. The microturbine generator will produce an additional 20 kW of electricity at full power. No sulfur dioxide pollutants will be released into the air. Nitrogen oxide emissions are likely to be less than 1 ppm. A 320 kW hybrid system is also in the planning stage. An initial commercial offering of a 1 MW fuel-cell microturbine power plant in late 2002 were the end results of this Department of Energy/Siemens Westinghouse partnership program. Global electricity generating capacity from fuel cells will grow from just 75 MW in 2001 to 15 000 MW by 2010. The cost of generating electricity (> $2000/kW) is very high for fuel cell, which restricts its wideusage.

16.9 Nuclear Power Stations

Due to the depleting nature of coal reserves, switching from coal to nuclear is mandatory today. In fact nuclear fuels have tremendous potential to release vast amount of energy from fission reactions. Uranium is one of the most important nuclear fuels used in nuclear power plants. When uranium is bombarded with neutrons, fission reactions take place, releasing neutrons and tremendous amounts of energy. In 1942 Enrico Fermi used uranium to produce the first controlled chain reaction. The fission of uranium atoms in the reactor imparts the heat to produce steam for the generation

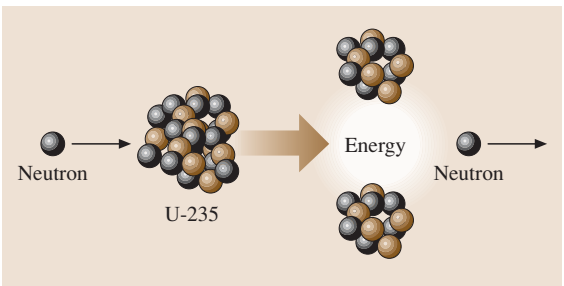

Fig. 16.11 Fission of a uranium 235 nucleus

electricity. When one pound of pure uranium is completely fissioned, it creates as much energy as burning of 1500 short tons of coal.

16.9.1 Basic Principles of Nuclear Energy

The powerful theory used to estimate the amount of energy released in a fission process is Albert Einstein's theory of relativity. Einstein's theory of relativity states that,

$$E = mc^2 , \tag{16.24}$$

where E is the energy in a substance, which equals the mass (m) of that substance multiplied by the speed of light squared (c^2). Nowadays most nuclear reactors are of fission type. In nuclear fission, the nuclei of atoms are split, causing energy to be released. The element uranium is the main fuel used in nuclear fission to produce energy since it has many useful properties: uranium nuclei can easily be split by shooting neutrons at them, and multiple neutrons released during this process are used to split other uranium, nuclei as shown in Fig. 16.11. This phenomenon is known as a chain reaction.

16.9.2 Types of Nuclear Power Plants

Nuclear power plants are classified according to the type of reactor used.

Fission Reactors

Fission power reactors generate heat by the nuclear fission of fissile isotopes of uranium and plutonium.

Various types of nuclear reactors are used in practice for power plants, which may be categorized into three classes:

- *Thermal reactors* use a neutron moderator to slow down or *moderate* the rate of production of fast neutrons by fission, to increase the probability that they will produce fission and thus sustain the chain reaction.
- *Fast reactors* sustain the chain reaction without the need for a neutron moderator.
- *Subcritical reactors* use an outside source of neutrons.
- Light-water reactor (LWR):
  - Pressurized-water reactor (PWR)
  - Boiling-water reactor (BWR)
- Graphite-moderated reactor:
  - Magnox
  - Advanced gas-cooled reactor (AGR)
  - Chernobyl type
  - Pebble-bed reactor (PBMR)
- Heavy-water moderated reactor:
  - CANDU (CANadian Deuterium Uranium)

16.10 Combined Power Station

When two cycles are combined, the cycle operated at the higher temperature is called the *topping cycle*. The waste heat it produces is then used in a second process that operates at a lower temperature level and is therefore called the *bottoming cycle* [16.4]. A combined cycle system is a sandwich of two different cycles,

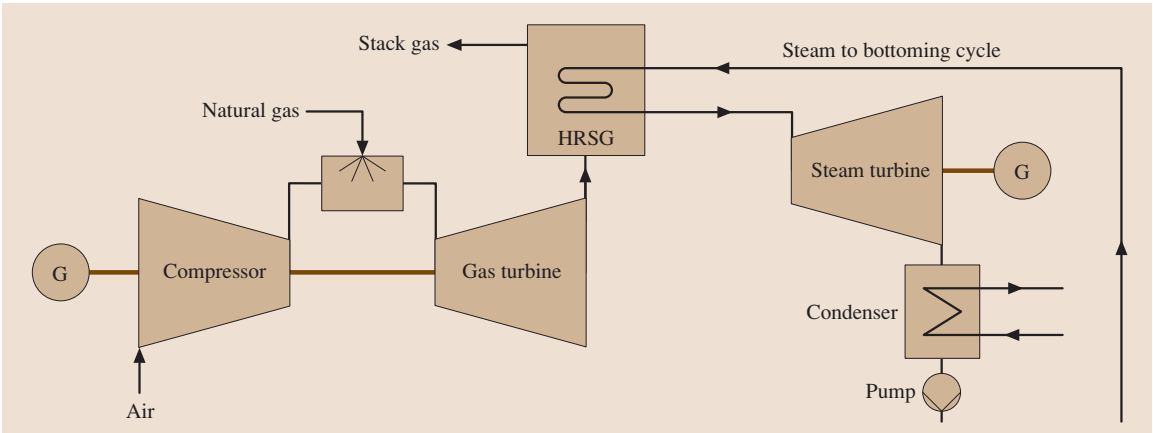

Fig. 16.12 Schematic diagram of a combined-cycle power plant

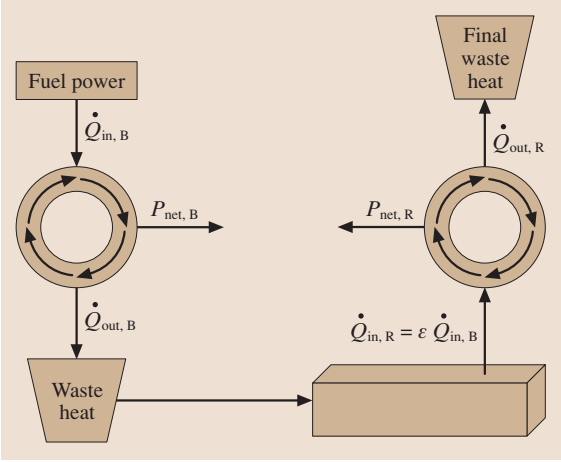

Fig. 16.13 Analysis of the combination of two different cycles

normally gas turbine and steam turbine cycles. The combination of two different cycles with different working media is interesting because the advantages of one complement the other [16.5].

The simplest form of combined cycle power plant, as shown in Fig. 16.12, is a single-pressure system. The major components present in the cycle is a single-pressure heat recovery steam generator (HRSG), a steam turbine, a water-cooled condenser, and a deaerater. The air is compressed inside the compressor and is supplied to the combustion chamber. The fuel (natural gas) from the main supply line is compressed in gas compressors and injected into the combustion chamber. The air and fuel mix together and then the combustion products leave the combustion chamber.

The combustion products from the combustion chamber enter the gas turbine and there expand to a low pressure and hence power is produced. The exhaust gas leaving the gas turbine is then supplied to the heat-recovery steam generator.

In the HRSG water flows in the direction opposite to the exhaust gas leaving the gas turbine and hence heat transfer takes place between the two fluids. The water absorbs heat from the exhaust gas, turns into steam, is superheated, and is then supplied to the steam turbine.

16.10.1 Thermodynamic Analysis of the Combined Cycle System

From Fig. 16.13 the net power output of the Brayton cycle is

$$P_{\text{net,B}} = \eta_{\text{B}}\,\dot{Q}_{\text{in,B}}\,, \tag{16.25}$$

where η_{B} is the Brayton efficiency.

The rate of heat rejected in the Brayton cycle is

$$\dot{Q}_{\text{out,B}} = (1-\eta_{\text{B}})\dot{Q}_{\text{in,B}}\,. \tag{16.26}$$

The rate of heat input to the Rankine cycle is

$$\dot{Q}_{\text{in,R}} = \varepsilon\,\dot{Q}_{\text{out,B}} = \varepsilon(1-\eta_{\text{B}})\dot{Q}_{\text{in,B}}\,, \tag{16.27}$$

where ε is the effectiveness.

The net power output of the Rankine cycle is

$$P_{\text{net,R}} = \eta_{\text{R}}\,\dot{Q}_{\text{in,R}} = \eta_{\text{R}}\varepsilon(1-\eta_{\text{B}})\dot{Q}_{\text{in,B}}\,, \tag{16.28}$$

where η_{R} is the Rankine efficiency.

The net power output of the combined cycle is

$$P_{\text{tot}} = P_{\text{net,B}} + P_{\text{net,R}}\,, \tag{16.29}$$

$$P_{\text{tot}} = \eta_{\text{B}}\,\dot{Q}_{\text{in,B}} + \eta_{\text{R}}\varepsilon(1-\eta_{\text{B}})\dot{Q}_{\text{in,B}}\,. \tag{16.30}$$

Overall Efficiency of the Combined Cycle Power Plant

The overall efficiency is defined as the ratio between the total power output to the heat added to the system

$$\eta_{\text{ov}} = \frac{P_{\text{tot}}}{\dot{Q}_{\text{in,B}}} \tag{16.31}$$

$$\eta_{\text{ov}} = \frac{\eta_{\text{B}}\,\dot{Q}_{\text{in,B}} + \eta_{\text{R}}\varepsilon(1-\eta_{\text{B}})\dot{Q}_{\text{in,B}}}{\dot{Q}_{\text{in,B}}} \tag{16.32}$$

$$\eta_{\text{ov}} = \eta_{\text{B}} + \eta_{\text{R}}\varepsilon(1-\eta_{\text{B}})\,. \tag{16.33}$$

16.11 Integrated Gasification Combined Cycle (IGCC) System

16.11.1 Introduction

IGCC technology is a promising technology which includes the benefit of gasification. A variety of fuel such as bituminous coal, sub-bituminous coal, lignite, petroleum coke, heavy oil, orimulsion, and biomass can provide the input to the IGCC cycle. Figure 16.14 shows the layout of integrated gasification combined cycle. Any grade of coal is gasified under pressure in the gasifier.

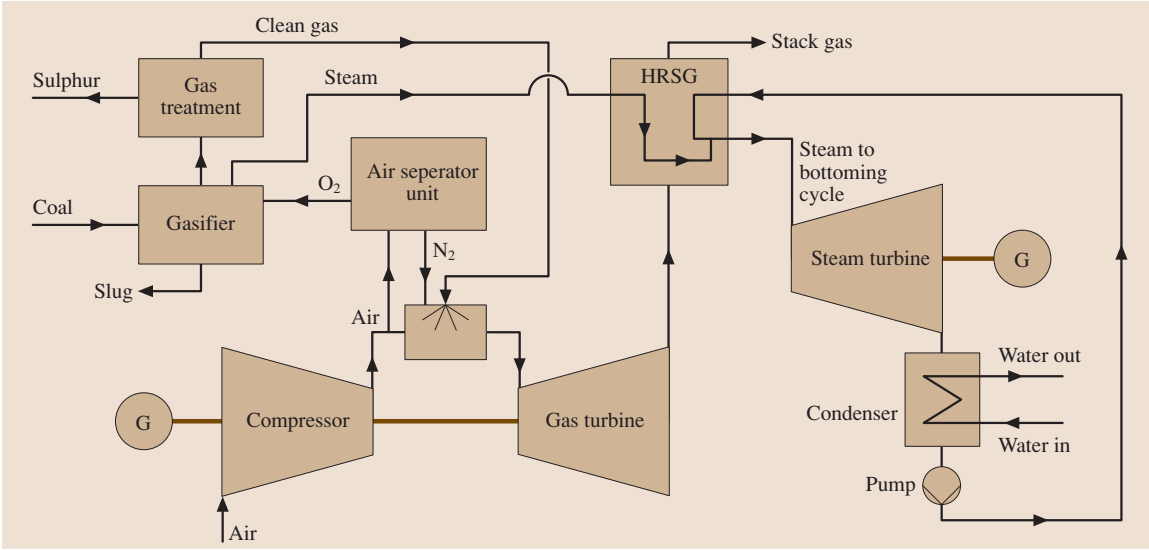

Fig. 16.14 Layout of an integrated gasification combined-cycle power plant

Syngas from the gasifier is cleaned of its hydrogen sulfide, ammonia, and particulate matter and is fed into a gas turbine where it is mixed inside the combustion chamber with hot pressurized air from the compressor. The final hot combustion products drive the gas turbine. The hot combustion gases from the gas turbine are used to produce steam in the steam generator. The steam drives the steam turbine, which produces 30–40% of the total electricity output. An air separation unit is also employed in modern IGCC power plants. Nitrogen and oxygen are completely separated in the air separator, from which pure oxygen is fed into the gasifier to reduce carbon dioxide emissions and the inert gas nitrogen is very well utilized in the gas turbine.

The technology makes use of the thermodynamic advantages provided by combining two different cycles: a gas turbine cycle and steam turbine cycle. Cleaning the gas before combustion provides benefits over the treatment of flue gases: a much smaller quantity of gas has to be treated and in addition the composition of the coal gas is such that it allows easier purification. The purification process could possibly be extended and could also permit the elimination of exhaust carbon dioxide. Hence, this technology has been proposed as the basis for a low-CO_2-emission coal power plant with CO_2 capture. Ample gasification processes have to be selected and the integration and optimization of all the processes are crucial for the overall efficiency. Coal gas clean up is another critical issue.

16.11.2 Environmental Benefits

1. Coal that contains a higher sulfur content can be very well utilized in IGCC plant. During the coal gasification process the sulfur in the coal appears as hydrogen sulphide; capturing hydrogen sulphide is not a tedious task. In some IGCC plants the sulfur can be extracted in a form that can be sold commercially.
2. Likewise, nitrogen typically exits as ammonia and can be scrubbed from the coal gas by processes that produce fertilizers or other ammonia-based chemicals.
3. If oxygen is used in a coal gasifier instead of air, carbon dioxide is emitted as a concentrated gas stream. In this form, it can be captured more easily and at lower costs for ultimate disposition in various sequestration approaches.

16.11.3 Efficiency Benefits

Efficiency gain is another benefit of IGCC plants. The fuel efficiency of IGCC power plant can be boosted to 50% or more. Future insights that integrate a fuel cell could achieve even higher efficiencies, maybe in the 60% range, which is nearly twice the value of today's typical coal-fired power plants. Higher efficiencies translate into more economical electric power and potential savings for ratepayers. A more efficient plant also uses less fuel to generate power, meaning that

less carbon dioxide is produced. IGCC plants with the flexibility to produce chemicals such as ammonia and hydrogen along with electricity make this a promising technology for future generations.

16.11.4 The Science of Coal Gasification

Coal gasification involves the chemical reaction of coal, steam, and air or oxygen at high temperatures to produce a mixture of hydrocarbon gases, typically carbon monoxide, carbon dioxide, and methane as well as hydrogen sulfide.

16.11.5 Chemical Reactions

Coal combustion, which is the exothermic reaction of coal with oxygen or air to produce carbon dioxide and water, is a fundamental part of coal gasification, using 20–40% of the oxygen or air required for complete combustion.

The purpose of this partial combustion is to supply the energy necessary to complete the gasification of the coal particles.

$$\mathrm{C(s)} + \tfrac{1}{2}\mathrm{O_2} \rightarrow \mathrm{CO\ (partial\ combustion)}\,,$$
$$\Delta H_\mathrm{R} = -1110.5\,\mathrm{MJ/kmol}\,, \qquad (16.34)$$

where ΔH_R is the standard heat of reaction at 298 K and atmospheric pressure

This partial combustion reaction is exothermic, that is, it liberates heat, as signified by the negative sign.

Furthermore the reaction of carbon does not stop at CO_2, but any remaining oxygen rapidly reacts with CO in the gas phase to produce CO_2

$$\mathrm{CO} + \tfrac{1}{2}\mathrm{O_2} \rightarrow \mathrm{CO_2}\,,$$
$$\Delta H_\mathrm{R} = -283.1\,\mathrm{MJ/kmol}\,. \qquad (16.35)$$

The solid carbonaceous material that is not combusted by oxygen reacts endothermically with carbon dioxide, hydrogen, and methane

$$\mathrm{C} + \mathrm{CO_2} \rightarrow 2\mathrm{CO}\,,$$
$$\Delta H_\mathrm{R} = +172.0\,\mathrm{MJ/kmol}\,. \qquad (16.36)$$

This reaction is called the Boudouard reaction.

In order to control the high temperatures resulting from the C(s)-O_2 reactions, and to increase the heating value of the product gas through the production of hydrogen, steam is often added as a reactant.

$$\mathrm{C(s)} + \mathrm{H_2O(g)} \rightarrow \mathrm{CO} + \mathrm{H_2}\,,$$
$$\Delta H_\mathrm{R} = +131.4\,\mathrm{MJ/kmol}\,. \qquad (16.37)$$

In a coal–steam or oxygen–steam, the homogeneous water-gas shift reaction is also important:

$$\mathrm{CO} + \mathrm{H_2O(g)} \rightarrow \mathrm{CO_2} + \mathrm{H_2}\,,$$
$$\Delta H_\mathrm{R} = -41.0\,\mathrm{MJ/kmol}\,. \qquad (16.38)$$

Hydrogen is added as a reactant in order to increase the quantity of methane. Water gas from which the CO_2 has been removed is called *synthesis gas*. Synthesis gas can also be used to produce methane, or synthetic natural gas (SNG)

$$\mathrm{CO(g)} + 3\mathrm{H_2(g)} \rightarrow \mathrm{CH_4(g)} + \mathrm{H_2O(g)}\,, \qquad (16.39)$$
$$2\mathrm{CO(g)} + 2\mathrm{H_2(g)} \rightarrow \mathrm{CH_4(g)} + \mathrm{CO_2(g)}\,. \qquad (16.40)$$

In fuel-rich combustion, the sulfur in the coal is released mainly as hydrogen sulfide with a small amount of carbonyl sulfide and the fuel-bound nitrogen is released as elemental nitrogen, ammonia, and hydrogen cyanide.

In order to capture the sulfur, lime stone or dolomite may be fed to the gasifier

$$\mathrm{CaO} + \mathrm{H_2S} \rightarrow \mathrm{CaS} + \mathrm{H_2O}\,. \qquad (16.41)$$

16.11.6 Optimal Coal Gasifiers

Gasifiers convert carbonaceous feedstock into gaseous products at high temperature and elevated pressure in the presence of oxygen and steam. Partial oxidation of the feedstock provides the heat. At operating conditions, chemical reactions occur that produce synthesis gas or *syngas*, a mixture of predominantly CO and H_2.

16.11.7 Classification of Gasifiers

A wide variety of gasifier designs has been developed for different applications and types of fuel used. The important parameters used for selecting the type of gasifiers are temperature, pressure, reactant gases, and the method of contacting. The different types of gasifier used in combined cycle technology are:

1. The entrained-flow (downflow) gasifier
2. The E-GAS entrained flow (up flow) gasifier
3. The Shell entrained flow (up flow) gasifier
4. The fluidized-bed gasifier
5. The transport reactor gasifier
6. The Lurgi dry ash gasifier
7. The British Gas/Lurgi fixed-bed gasifier
8. The Prenflo entrained bed gasifier

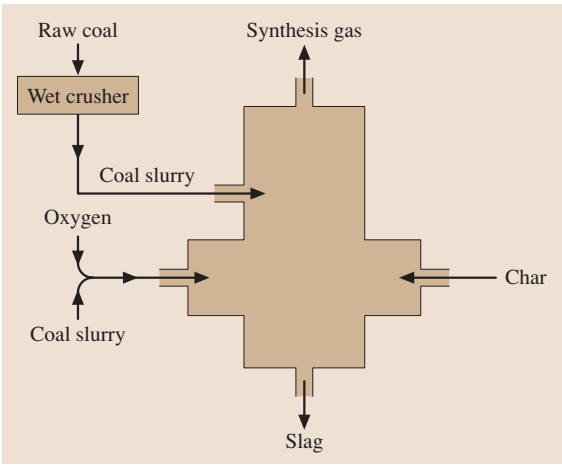

Fig. 16.15 E-GAS entrained-flow system◀

16.11.8 E-GAS Entrained Flow

Figure 16.15 shows the arrangement of the E-GAS entrained-flow gasifier. The gasification reaction occurs in two regions of the gasifier, normally called the primary and secondary. The raw feed coal is crushed in the wet crusher to produce slurries and is fed to the gasifier from the bottom portion normally called the first stage or the primary region of the gasifier. In this region exothermic gasification/oxidation reactions take place at a temperature of 1300–1400 °C, so great care has to be taken for the design. This region is normally lined with special slag-resistant refractory. There are two opposed horizontal burners with a horizontal cylinder provided in this region. Oxygen is used to gasify the slurry fed to the first stage of the gasifier. Usually 80% of the coal slurry is fed into this region. The remaining 20% of the coal slurry is injected into the hot raw gas coming out from the first stage.

The second stage contains a vertical cylinder that is perpendicular to the first stage. The endothermic gasification/devolatilization reactions in this stage reduce the final gas temperature and add some hydrocarbons to the product gas. Char is produced in the second stage. The hot gas leaving the gasifier is cooled in a fire-tube product gas cooler, generating saturated steam that is sent to the steam turbine.

16.12 Magnetohydrodynamic (MHD) Power Generation

16.12.1 Principle of MHD

The underlying principle of MHD power generation is elegantly simple. An electrically conducting fluid is driven by a primary energy source (e.g., the combustion of coal or a gas) through a magnetic field, resulting in the establishment of an electromotive force within the conductor in accordance with the principle established by Faraday [16.6].

Furthermore, if the conductor is an electrically conducting gas, it will expand, and hence the MHD system constitutes a heat engine concerning an expansion from high to low pressure in a manner similar to that of a gas turbine. Unlike gas turbine which involves surface interaction, the MHD system, however, involves a volume interaction between a gas and the magnetic field through which it is passing.

16.12.2 General Characteristics

The MHD generator can properly be viewed as an electromagnetic turbine because its output is obtained from the conducting gas–magnetic field interaction directly in electrical form rather than in mechanical form. Electrical conduction in gases occurs when electrons are available to be organized into an electric current in response to an applied or induced electric field. The electrons may be either injected or generated internally, and, because of the electrostatic forces involved, they require the presence of corresponding positive charge from ions to maintain electrical neutrality. An electrically conducting gas consists in general of electrons, ions to balance the electric charge, and neutral atoms or molecules; such a gas is termed a plasma [16.7].

16.12.3 The Production of Plasma

In MHD generators, electrons to support the flow of current can be obtained by two different methods: thermal and nonequilibrium ionization.

16.12.4 Thermal Ionization

Plasma is obtained by heating the gas to a sufficiently high temperature to yield electrons through ionization.

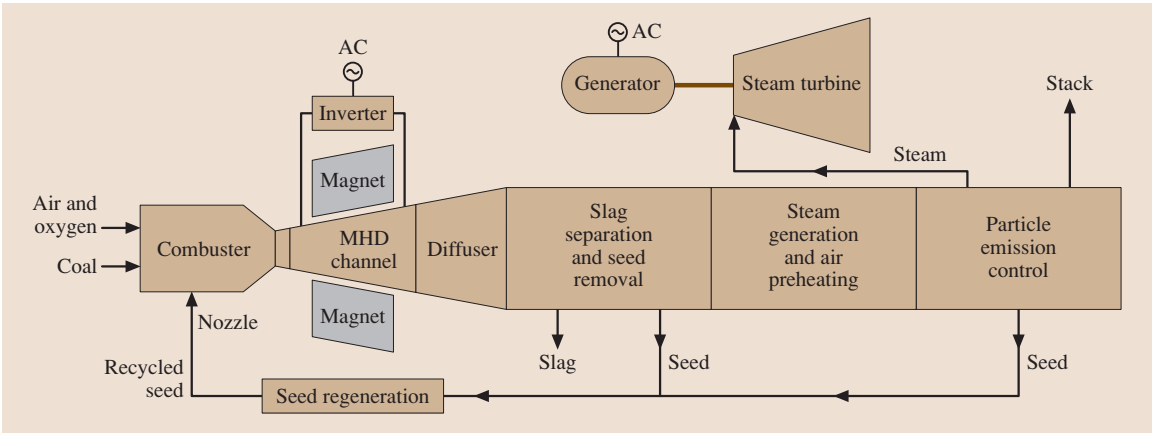

Fig. 16.16 Schematic view of an MHD steam power plant

16.12.5 Nonequilibrium Ionization

Sufficiently strong electric fields are induced in a manner similar to that in gas discharge devices. In either case, the mechanism of energy transfer from the flowing fluid to the electrical output can be thought of as a coupling of the electron-containing gas to the ions through electromagnetic forces. The ions in turn are embedded in the background of an atomic or molecular gas and lack mobility by virtue of their being coupled to the molecules or ions through collision processes described by kinetic behavior.

16.12.6 MHD Steam Power Plant

A schematic diagram of an MHD steam power plant is shown in Fig. 16.16. The product gas with a high electrical conductivity formed by burning the coal in the combustor is mixed with potassium carbonate (called seed) to increase its conductivity. The ionized gas then flows through a strong magnetic field, inducing an electric field and setting up a potential difference between the walls of the duct. Then using a solid-state inverter, the direct current (DC) generated is converted to alternating current (AC).

After flowing through the magnetic field, the hot gasses are then used to generate steam and turn a turbine as in a conventional plant. As the heat is transferred, slag is removed for disposal and the seed is captured for recycling. One considerable drawback is the need to use expensive superconducting magnets that must be cooled to −269 °C (4 K) to generate the necessary magnetic fields. About 50% of efficiency can be achieved if the MHD generator is operated in tandem with a conventional plant.

16.13 Total-Energy Systems for Heat and Power Generation

16.13.1 Cogeneration

A plant producing both electrical power and process heat simultaneously is called a cogeneration plant. The generation process can be any amalgamation of two different forms of useful energy (electricity and heat). Loss of energy in the condenser is very well utilized to obtain the required amount of heat, as the efficiency of a cogeneration system is higher than a conventional system operating in condensing mode. The heat obtained from a cogeneration plant is used for space heating of buildings, drying, to produce hot water or steam, or in various industrial processes.

The different types of cogeneration technologies are:

1. Steam turbine (ST) cogeneration system
2. Gas turbine (GT) cogeneration system
3. Combined cycle gas turbine (CCGT) cogeneration system
4. Internal combustion engine cogeneration system

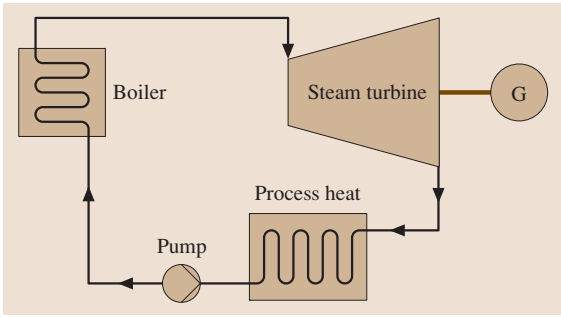

Fig. 16.17 Layout of a back-pressure turbine

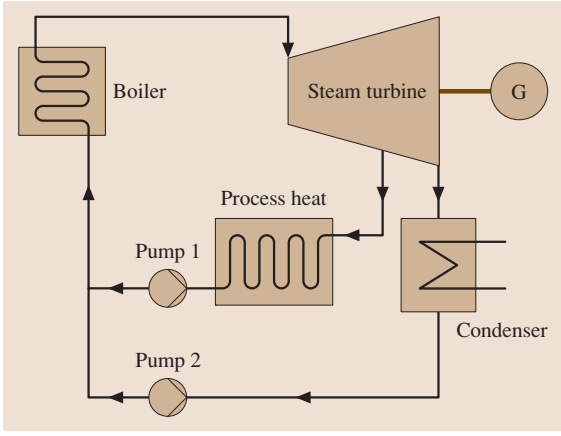

Fig. 16.18 Extraction condensing turbine

Steam Turbine Cogeneration System

Figure 16.17 depicts the layout of a cogeneration with a back pressure turbine. This signifies generation of electricity and heat by means of steam, generated in boilers by burning a suitable fuel (fossil or nonfossil, e.g., biomass). The steam is sent to the back-pressure extraction turbine, where it is expanded until its designed back pressure. The steam turbine coupled with electric generators drives the steam turbine and produces electricity. Normally in cogeneration the required amount of heat is obtained by energy from the outlet of the steam turbine, from the back-pressure outlet or from the extractions of the steam turbine depicted in Figs. 16.17 and 16.18. The required thermal energy is delivered in the form of steam at a pressure corresponding to the design or with the required temperature in accord with the thermal energy level.

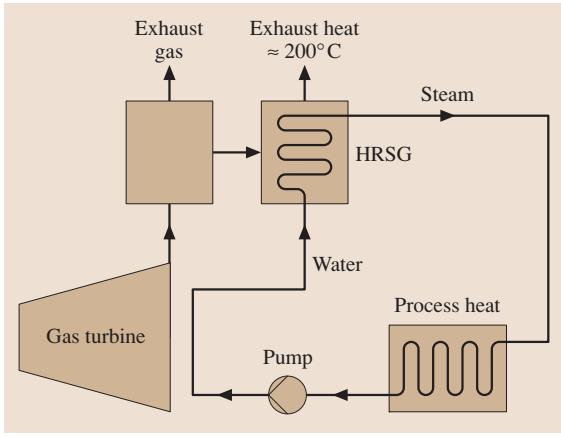

Fig. 16.20 Layout of an internal combustion engine cogeneration system

Gas Turbine Cogeneration System

In this design, a combination of gas and steam turbines is installed to convert energy from fuel to mechanical energy to drive electric generators.

Figure 16.19 represents the layout of a gas turbine cogeneration system. Hot gases from the gas turbine are

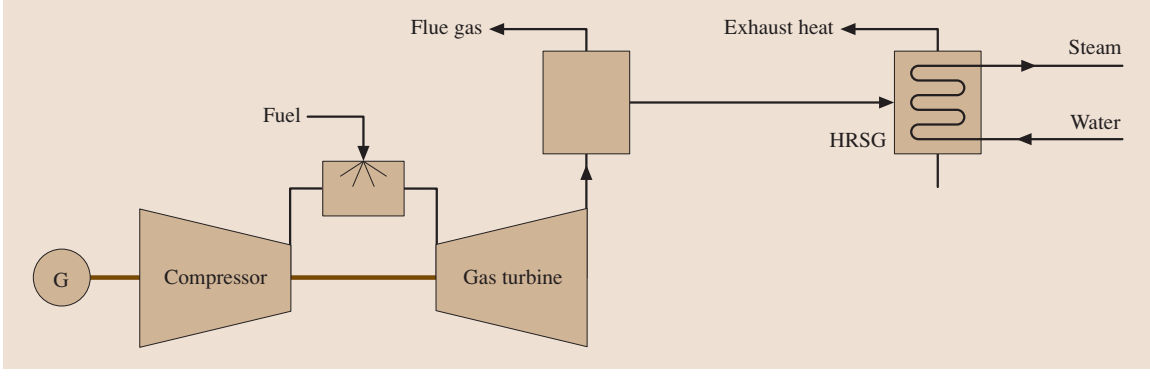

Fig. 16.19 Layout of a gas turbine cogeneration system

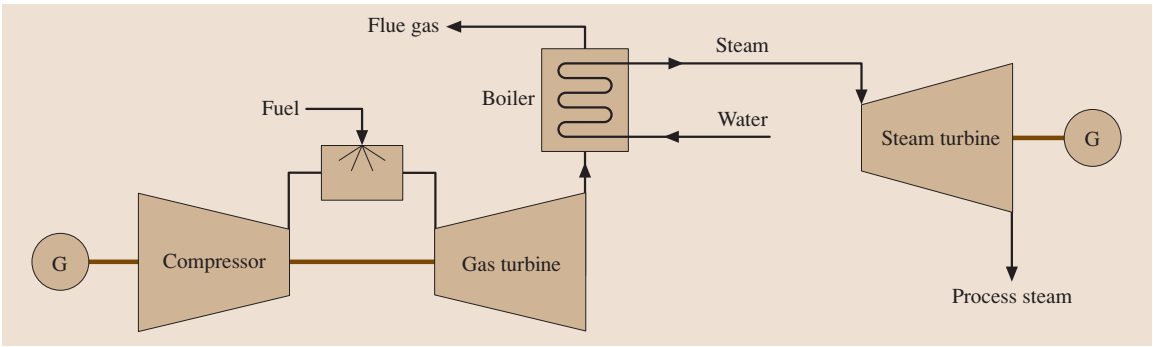

Fig. 16.21 Layout of a combined-cycle cogeneration system

used to generate steam for the steam turbine. Heat energy of the steam escaping from the turbine is used to provide heat. Mechanical energy (gas turbine and steam turbine) is converted into electrical energy with the help of a generator. The net efficiency of the plant is more than 50%.

Internal Combustion Engine Cogeneration System

Combined heat and power (CHP) systems are also available to serve smaller-sized facilities. In this type of facility, these smaller *modular* cogeneration units can generate 20–650 kW, and produce hot water from engine waste heat. Figure 16.20 represents the layout of an internal combustion engine cogeneration system. The generator converts mechanical work produced at the engine shaft into electrical energy. Heat resulting from combustion during power generation is used for process heat supply or heating purposes. Exhaust gases and the engine cooling water function as heat sources.

Combined Cycle Cogeneration System

Figure 16.21 represents the layout of a combined cycle cogeneration system. The combined cycle cogeneration system consists of a gas-turbine-driven generator package, a heat recovery steam generator closely matched to the process steam conditions, and a steam turbine matched to the HRSG's output and connected to the generator.

The advantages of this design are:

1. High thermal efficiency
2. Operating flexibility
3. Low installation cost

16.14 Transformation of Regenerative Energies

16.14.1 Wind Energy Power Plant

Wind is essentially created by solar heating of the atmosphere. Wind as a power source is attractive because it is plentiful, inexhaustible, and nonpolluting. Furthermore, it does not impose an extra heat burden on the environment [16.8]. Unfortunately, it is nonsteady and unreliable. Control equipment has been devised to start the wind power plant whenever the wind speed reaches 30 km/h. Methods have also been found to generate constant-frequency power with varying wind speeds and consequently varying speeds of windmill propellers. Wind power may prove practical for small power needs in isolated sites, but for maximum flexibility, it should be used in conjunction with other methods of power generation to ensure continuity [16.9]:

1. Small generators (0.5–10 kW) for isolated single premises
2. Medium generators (10–100 kW) for communities
3. Large generators (1.5 MW) for connection to the grid

Figure 16.22 depicts the arrangement of a wind turbine. The wind power is a measure of the energy available in the wind and is a function of the cube (the third power) of the wind speed. If the wind speed is doubled, the power in the wind increases by a factor of eight, so small differences in wind speed lead to large differences in electric power. This example points out that minor differences in wind speed due to either site selection or measurement errors can have a major bearing on a decision to invest in a wind turbine. For this

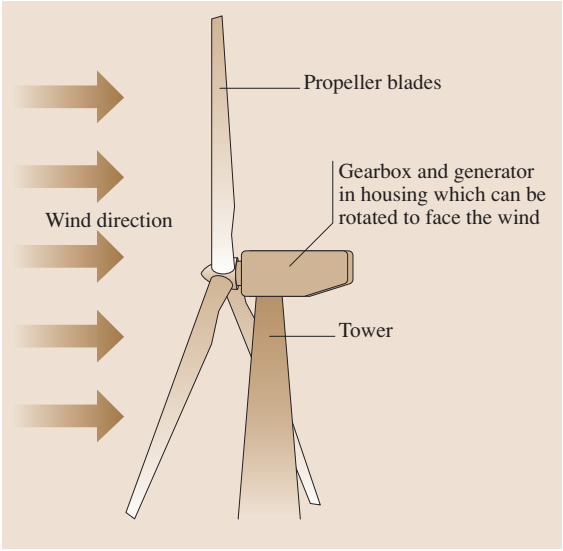

Fig. 16.22 Schematic view of the conversion of wind energy into electrical power▶

reason, a thorough and accurate wind study is imperative before buying a wind turbine.

The theoretical power in a wind stream is given by

$$P = 0.5\rho A V^3 \quad \text{(W)}\,, \tag{16.42}$$

where ρ is the density of air (1201 g/m^3 at normal temperature and pressure (NTP), V is the mean air velocity (m/s), and A is the swept area (m^2).

This equation states that the power is equal to one-half of the air density times the rotor area, times the cube of the wind speed. Moreover the air density varies due to the following features:

1. Elevation
2. Temperature
3. Weather fronts

16.15 Solar Power Stations

The sun acts as an atomic furnace as it converts mass into a huge amount of energy, according to Einstein's mass–energy relation $E = mc^2$. Every second it converts over 657 million tons of hydrogen into 653 million tons of helium, producing energy by nuclear fusion. The remaining 4 million tons of mass is discharged into space as energy. The Earth accepts only about one two-billionths of this. The radiation energy from the sun is massive, within 15 min the sun radiates energy equivalent to the amount of energy mankind consumes during a whole year. It is imperative to utilize this energy radiated by the sun, in order to fulfill our energy requirement.

16.15.1 Significant Features of Solar Energy

Ultimately solar energy is free and results in no hazard to the environment. In sunny countries, solar power can be used where there is no easy way to supply electricity to a remote place. It is also convenient for low-power devices such as solar-powered garden lights and battery chargers. There are various ways to produce electricity from the energy obtained from the sun.

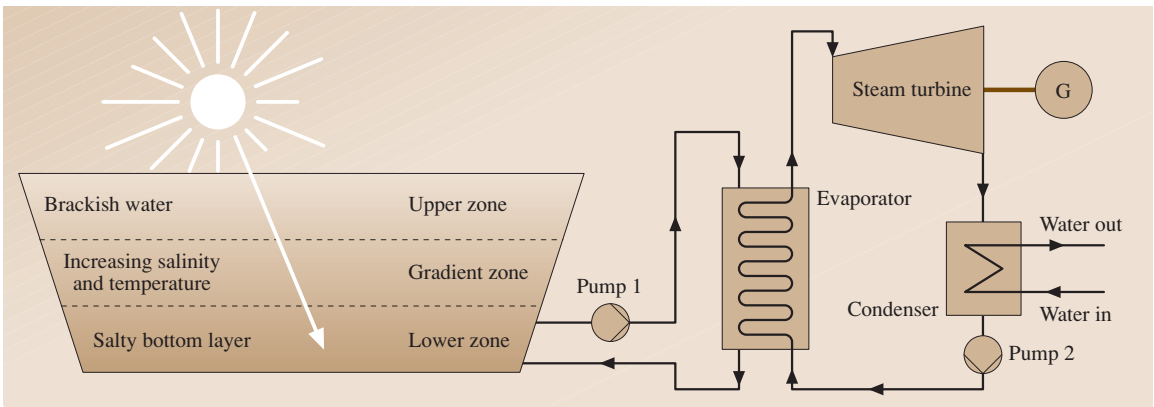

Fig. 16.23 Schematic of a solar pond

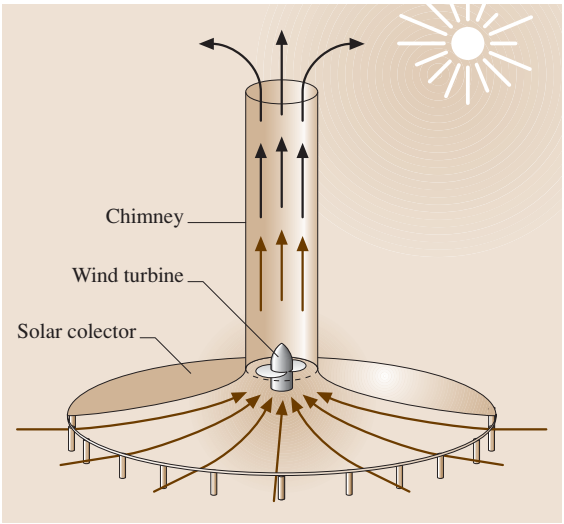

Fig. 16.24 Arrangement of a solar chimney

16.15.2 Solar Cells or Photovoltaic Cells

A solar panel is made up of the natural element silicon, which becomes charged electrically when subjected to sunlight. Sunlight is composed of packets of energy called photons. These photons contain various amounts of energy corresponding to the different wavelengths of light. The solar cell is made up of a material with well-defined possible energy levels for electrons. When a photon is absorbed in the active material, the energy of the photon is transferred to an electron, which becomes excited from a low to a higher energy level. The asymmetric structure of the solar cell ensures that this electron escapes from its normal position, carrying away the extra energy. This electron leaves the cell through a metal contact and becomes part of the current in an electrical circuit.

16.15.3 Solar Pond

A solar pond is a relatively low-tech, low-cost approach to harvest solar energy. A solar pond consists of three layers of water with different salt concentrations, as shown in the Fig. 16.23. A low-salt-content salt layer and an intermediate layer with a salt gradient, which creates a density gradient that averts heat exchange by natural convection in the water. The bottom layer with a higher salt content reaches a temperature of around 90 °C. The heat energy from the salty bottom layer can be used to generate electricity.

Normally an organic fluid with lower boiling point is used to convert this low-grade energy into electricity. The hot brine is pumped from the salty bottom layer and is sent into the evaporator, where it transfers heat to the organic fluid and the properly utilized brine is again sent to the salty bottom layer. The organic fluid in vapor form at the exit of the evaporator is used to rotate the turbine and generator.

The exhaust from the turbine is condensed in the condenser and then pumped back to the evaporator and hence the cycle is closed. The efficiency of the overall system entirely depends on the salinity and purity of the pond, and normally it is quite difficult to maintain salinity and dirt-free condition.

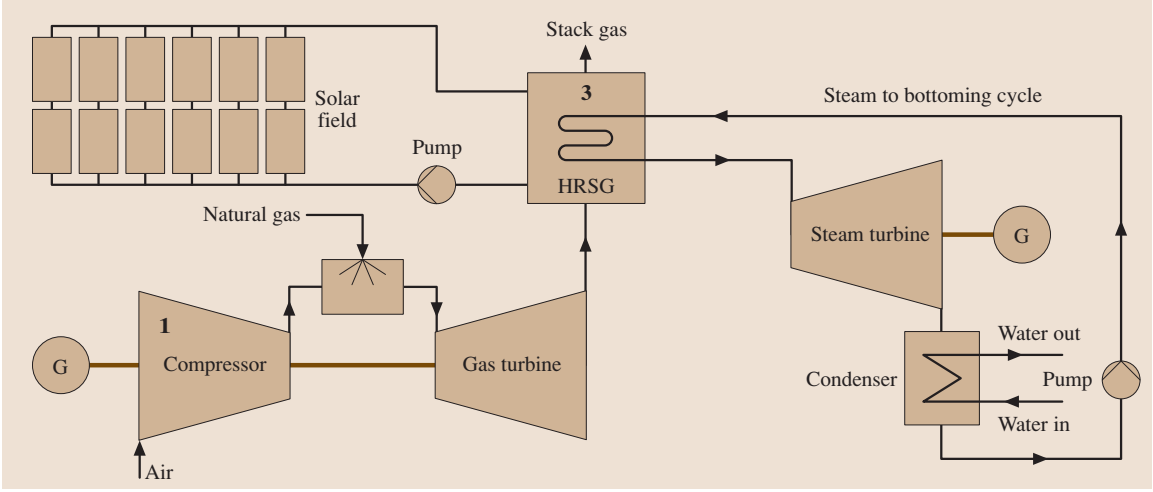

Fig. 16.25 Layout of an integrated solar combined cycle using a solar field

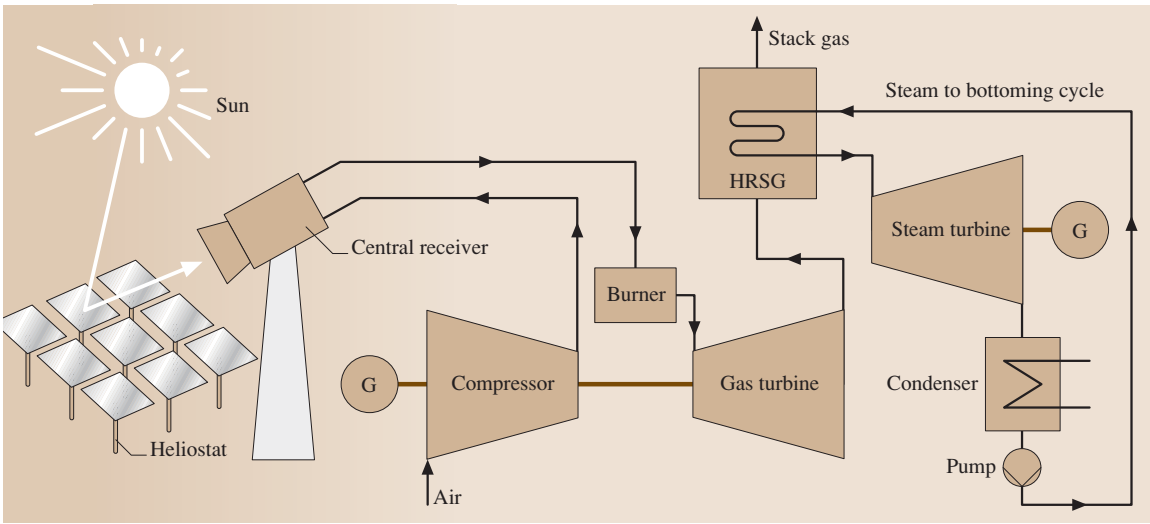

Fig. 16.26 Layout of integrated solar combined system using heliostats

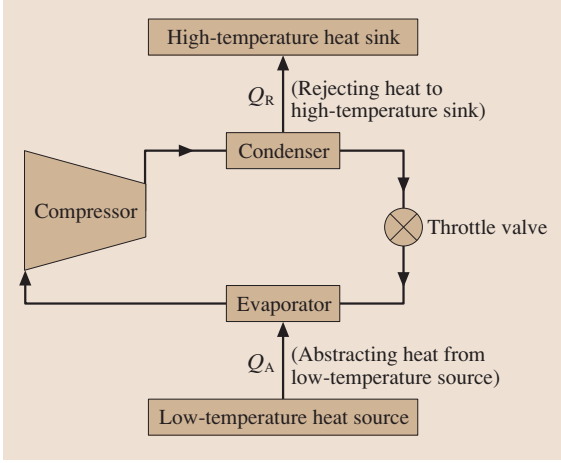

Fig. 16.27 Layout of a heat pump

16.15.4 Solar Chimney

Solar chimney technology is an innovative cost-effective technique to harness energy from the sun. A solar chimney consists of a glass collector, a wind turbine, an electrical generator, and a chimney. The glass collector is situated at the bottom and extends to a height of 2–7 m above the ground, as shown in the Fig. 16.24. The chimney is located at the center and its height varies from 500 to 1000 m. The conversion efficiency depends on the chimney height, the collector area, and the intensity of solar radiation.

The working principle of a solar chimney is quite simple: the air trapped inside the glass collector is heated by the radiation from the sun and becomes less dense, ascending the chimney. The rising hot air turns the wind turbine, which generates electricity.

16.15.5 Integrated Solar Combined Cycle Power System

Solar energy from a parabolic trough integrated in a combined cycle leads to high efficiency and low emission. Figure 16.25 shows the layout of this integrated solar combined cycle system. The heat from the parabolic trough collector can be directly utilized in the heat-recovery steam generator in addition to the heat supplied from the gas turbine exhaust. This integration seeks to achieve efficient operation even though solar energy intensity varies according to weather and time of day.

Sun-tracking concentrating mirrors called *heliostats* collect the sunlight and concentrate it onto a central receiver located at the top of a high tower, as shown in the Fig. 16.26. The receiver converts the radiative solar energy to thermal energy by heating air to the temperature required for direct feeding of the gas turbine.

Other possibilities for the exploitation of this energy can be endothermic chemical processes, or direct use of thermal energy for process heating. Central receiver technology is a promising alternative technology [16.10] overcoming the disadvantages of the trough technology.

16.16 Heat Pump

A reversed Carnot cycle can be used as heat pump. If the aim is to heat a body or space, the heat is rejected at a high temperature to the body or space and the heat is absorbed at a lower temperature from the ambient air or circulating water. Thus heat is drawn from the atmospheric air and pumped to the space to be heated. Such a cycle is called a heat pump cycle (Fig. 16.27) and the coefficient of performance (COP) for a Carnot reversed cycle heat pump is given by

$$\mathrm{COP}_{\text{Carnot heat pump}} = \frac{\text{Heat rejected}}{\text{Work done}} ,$$

$$\mathrm{COP}_{\text{Carnot heat pump}} = \frac{T_2}{T_2 - T_1} ,$$

where T_1 and T_2 are temperatures of source and sink.

The efficiency of this device to transfer heat Q_R to a high-temperature body is

$$\text{Efficiency} = \frac{\text{Energy effect sought}}{\text{Energy input}} .$$

16.17 Energy Storage and Distribution

Energy storage plays an important role in the competent management of energy resources. The demand for electricity fluctuates with time, which affects the economics of power plants that are normally designed for higher capacity.

The ultimate aim of an energy storage device is to reduce the economic losses due to fluctuating demand. When the demand is lower than the capacity, energy is stored. When the demand is higher than the capacity, the stored energy is released. This will provide savings in operating cost and ensure complete customer satisfaction, which can improve the status of the organization in the international market. Finally, energy storage is commonly used in stand-alone applications, where it can serve as an uninterruptible power supply (UPS) unit. The most important energy storage technologies are:

1. Pumped hydro power
2. Compressed energy storage
3. Flywheels
4. Electrochemical storage devices
5. Thermal energy storage devices
6. Secondary battery energy storage

16.17.1 Pumped Hydro Power

Pumped hydro facilities consist of two large reservoirs, one located at the base level and the other located at a different elevation. In pumped hydro, surplus power is utilized to pump the water from the lower reservoir to the upper reservoir, where it can be stored as potential energy. During periods of higher demand, water is sent back into the lower reservoir, passing through hydraulic turbines that generate electrical power [16.11]. The only drawback in pumped hydro power devices is that their construction cost is very high.

The combined efficiency of a pumped hydro system is given by

$$\eta_{\text{comb. effic.}} = \frac{\text{Total energy output}}{\text{Total energy input during a charge–discharge cycle}} . \tag{16.43}$$

16.17.2 Compressed Air Energy Storage

Excess energy is used to compress air and store it an airtight underground storage cavern. The stored energy is then released during periods of peak demand by expansion of the air through an air turbine. Three types of reservoirs can be used to store compressed air: salt caverns, aquifers, and hard rock caverns. When air is compressed for storage, its temperature increases according to

$$T_2 = T_1 \left(\frac{p_2}{p_1}\right)^{\frac{n-1}{n}} , \tag{16.44}$$

where n is the polytropic index, and P_1, T_1 and P_2, T_2 are the pressures and temperatures before and after compression.

Various studies have concluded that compressed air energy storage is competitive with combustion turbines and combined-cycle units, even without taking into account its unique benefits in terms of energy storage [16.12].

The layout of compressed energy storage device is shown in the Fig. 16.28. The heat of compres-

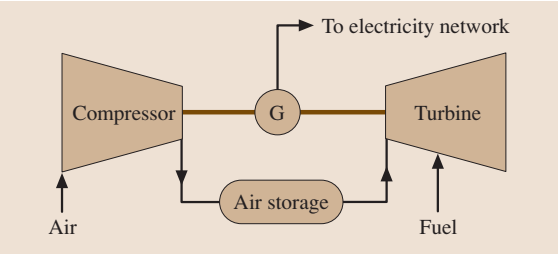

Fig. 16.28 Layout of compressed air storage

sion may be retained in the compressed air. This is called adiabatic storage and results in high storage efficiency, since more energy is recovered by expansion.

16.17.3 Energy Storage by Flywheels

Flywheel energy storage is a promising technology for providing intermediate energy storage. A flywheel storage device consists of a flywheel that rotates at a very high velocity and an integrated electrical apparatus that can operate either as a motor to turn the flywheel and store energy or as a generator to produce electrical power on demand using the energy stored in the flywheel. The use of magnetic bearings and a vacuum chamber helps reduce energy losses.

In a flywheel, energy storage is in the form of mechanical kinetic energy. The rotating mass stores the energy input so that the rotation can be maintained at a fairly constant rate. There are two main sources of losses in the flywheel: windage and bearing.

The energy stored in flywheel is

$$\mathrm{KE}_{\mathrm{disc}} = \frac{1}{4} M r^2 \omega^2 \,, \tag{16.45}$$

where M is the mass of the flywheel, and r is the radius of the flywheel.

In order to achieve high energy density, the rotation speed ω must be very high.

16.17.4 Electrochemical Energy Storage

Electrochemical energy storage is one of the recent technologies, which can be classified into three categories: primary batteries, secondary batteries, and fuel cells. These devices convert stored chemical energy into electrical energy. Primary and secondary batteries utilize the chemicals built into them, whereas fuel cells use chemically bonded energy supplied from the outside in the form of synthetic fuel [16.13].

16.17.5 Thermal Energy Storage

Thermal energy storage is ideally suited for applications such as space heating, where a low quantity of heat is required. The two distinct thermal energy storage mechanisms are sensible heat storage and latent heat storage. In sensible heat storage, energy can be stored as sensible heat by virtue of a rise in temperature of the storage medium.

16.17.6 Secondary Batteries

Large-scale battery use is almost unfeasible and their use is limited to battery-powered vehicles and storage for local fluctuating energy sources such as windmills or solar. The most widely used battery is the lead-acid battery, invented by Plante in 1859. The sodium-sulphur battery (200 W h/kg) and other combinations of materials are also being developed to obtain more output and storage per unit weight [16.9].

16.18 Furnaces

The furnace is the heart of a steam generation system. It is an enclosed chamber in which heat is produced by burning fuel, to heat water in the case of a steam generation system. Its dimensions and geometry are adapted to the amount of heat release, type of fuel, and to the method of firing so as to promote complete burning of the combustible and suitable disposal of the resulting ash. A furnace can provide combustion of fuel in solid, liquid or gaseous form.

Based upon the type of fuel used furnace are classified into:

1. Solid-fuel furnaces
2. Liquid-fuel furnaces
3. Gas-fuel furnaces

16.18.1 Combustion

Combustion or burning is a chemical process, an exothermic reaction between a substance (the fuel) and

a gas (the oxidizer), usually O_2, to release heat. The presence of CO_2 in the product gas signifies complete combustion whereas CO signifies incomplete combustion.

The basic chemical equations for complete combustion are

$$C + O_2 \rightarrow CO_2 \,, \tag{16.46}$$

$$2H_2 + O_2 \rightarrow 2H_2O \,. \tag{16.47}$$

When the amount of oxygen supplied is insufficient for complete combustion then carbon will be burned incompletely with the formation of carbon monoxide

$$2C + O_2 \rightarrow 2CO \,. \tag{16.48}$$

The most important parameter to estimate the effectiveness of combustion is called the combustion efficiency, which depends on the following parameters:

1. Air–fuel ratio
2. Fuel–air mixing
3. Flame temperature
4. Flame shape
5. Fuel residence time
6. Degree of atomization (for liquid fuel)
7. Degree of turbulence

The theoretical air–fuel ratio for complete combustion is known as the stoichiometric ratio. In practice every oxygen molecule does not come into contact with a fuel molecule. In order to ensure complete combustion some amount of air is used to compensate this shortage of oxygen molecules, normally called *excess air*, and attain complete combustion. Turbulence enhances the proper mixing of fuel and oxygen and hence the combustion efficiency.

16.18.2 Ideal Combustion

The generalized ideal combustion equation can be written as

$$C_X H_Y S_Z O_K + \left(X + \frac{Y}{4} + Z + \frac{K}{2}\right) O_2 + mH_2O \rightarrow PCO_2 + QH_2O + GSO_2 \,. \tag{16.49}$$

The generalized combustion equation can be written

$$C_X H_Y S_Z O_K + \left(X + \frac{Y}{4} + Z + \frac{K}{2}\right) O_2 + 3.76\left(X + \frac{Y}{4} + Z + \frac{K}{2}\right) N_2 + mH_2O \rightarrow PCO_2 + QH_2O + RN_2 + GSO_2 \,. \tag{16.50}$$

The air–fuel ratio can be written

$$\frac{A}{F} = \frac{m_{\text{air}}}{m_{\text{f}}} \,. \tag{16.51}$$

16.18.3 Theoretical Dry Air–Fuel Ratio

1 kmole of oxygen and 3.76 mole of nitrogen generate a mixture of 4.76 mole of air.

The molecular weight of air is therefore

$$\frac{32 + 3.76 \times 28}{4.76} = 28.84 \,, \tag{16.52}$$

$$\left(\frac{A}{F}\right)_{\text{TD}} = \frac{m_{\text{air}}}{m_{\text{f}}} = \frac{4.76\left(X + \frac{Y}{4} + Z - \frac{K}{2}\right) 28.84}{100} \,. \tag{16.53}$$

16.18.4 Theoretical Wet-Air–Fuel Ratio

Ambient air is always humid in nature so the calculation of the theoretical wet-air–fuel ratio depends on the relative humidity. The specific humidity of air, w (kg) of moisture per kg of dry air.

Relative humidity

$$\phi = \frac{p_{\text{vapor,act}}}{p_{\text{vapor,sat}}} \,. \tag{16.54}$$

Amount of moisture in ambient air

$$n = \frac{4.76\,(X + Y/4 + Z - K/2)\,28.84w}{18} \,. \tag{16.55}$$

Theoretical wet-air–fuel ratio

$$\left(\frac{A}{F}\right)_{\text{TW}} = \frac{m_{\text{wet,air}}}{m_{\text{f}}} = \frac{\left[4.76\left(X + \frac{Y}{4} + Z - \frac{K}{2}\right)\right](28.84 + w18)}{100} \,. \tag{16.56}$$

16.18.5 Pressure Conditions

Not all boiler furnaces are airtight, especially stokers (boilers that burn solid fuels). Flue gases may escape into the plant area if the furnace pressure is greater than the atmospheric pressure. Other furnace designs may require draft and furnace pressure control. Typically, the furnace pressure is controlled using a balance draft system. The induced draft fan is modulated to maintain the

furnace at a slight negative pressure. Furnace pressure measurement and induced fan control is required. The location of the furnace pressure transmitter is important because the pressure is not uniform within the furnace. If the combustion airflow rate measurement is available, furnace pressure control can be more effective.

16.18.6 Emission

The combustion of fuel finally leads to the emission of various gases and particulate matter. The amount and chemical components of these emissions depend on the fuel type, boiler type and size, and the firing method. Different forms of emissions are described below.

16.18.7 Particulate Emissions

The particulates present in the stack gases depend primarily on the combustion efficiency and on the amount of ash contained in the fuel. All fuels except natural gas contain some quantity of ash or noncombustible material, which forms the majority of these particulates [16.14, 15].

16.18.8 Nitrogen Oxide Emission

The level of nitrogen oxides (NO_x) present in the stack gas depends on many variables; the furnace heat rate levels, temperature, and excess air are the major variables that affect NO_x emission levels. NO_x is one of the contributors to acid rain and ozone formation, visibility degradation, and human health concerns. Combustion of any fossil fuel generates some level of NO_x due to the high temperature and availability of oxygen and nitrogen from both the air and fuel. Based on the method of formation, NO_x can be classified as thermal NO_x and fuel NO_x.

16.18.9 Thermal NO_x

High-temperature oxidation (above 1200 °C) initiates the formation of NO_x, normally called thermal NO_x. The nitrogen and oxygen in the air dissociate at higher combustion temperatures and lead to the formation of NO_x. Thermal NO_x formation is typically controlled by reducing the peak and average flame temperature. Apart from a higher temperature, the formation of NO_x is also due to longer residence time and oxygen concentration. Three possible reactions for the formation of NO_x during combustion are [16.15]

$$N_2 + O \rightarrow NO + N\,, \tag{16.57}$$

$$N + O_2 \rightarrow NO + O\,, \tag{16.58}$$

$$N + OH \rightarrow NO + H\,. \tag{16.59}$$

16.18.10 Fuel NO_x

Fuel NO_x refers to the formation of chemically bound nitrogen in the fuel during combustion. The fuel–air ratio is one of the deciding factors for the formation of fuel NO_x. Conversion of fuel-bound nitrogen to NO_x is strongly dependent on the fuel–air ratio but is relatively independent of the combustion-zone temperature. The formation of NO_x happens at two levels, one is during oxidation of volatile nitrogen and another is from the char during combustion.

16.18.11 Sulfur Dioxide Emission

SO_2 is an acidic gas formed by the combustion of sulfur in the fuel with oxygen. Dilute sulfuric acid is a major constituent of acid rain. An aqueous solution of sulfurous acid (SO_3) is formed when sulphur dioxide combines with water. This can easily oxidize in the atmosphere to form sulfuric acid (H_2SO_4).

16.18.12 Solid-Fuel Furnaces

Furnaces that use solid fuels for combustion are normally called solid fuel furnaces. Fuels include, coal, coke, and firewood (wood chips and pellets).

16.18.13 Stokers and Grates

There are various ways to introduce coal into the furnace. Stokers play a vital role in distributing coal into the furnace. Stokers are normally differentiated on the basis of how the coal is introduced into the fire. Different types of stokers are:

1. Traveling-grate stoker
2. Chain-grate stoker
3. Spreader stoker
4. Vibrating stoker
5. Underfeed stoker

Traveling-grate stokers have been in use for the past 50 years and are the most popular way to burn coal in stokers for boilers. In addition to coal, traveling-grate

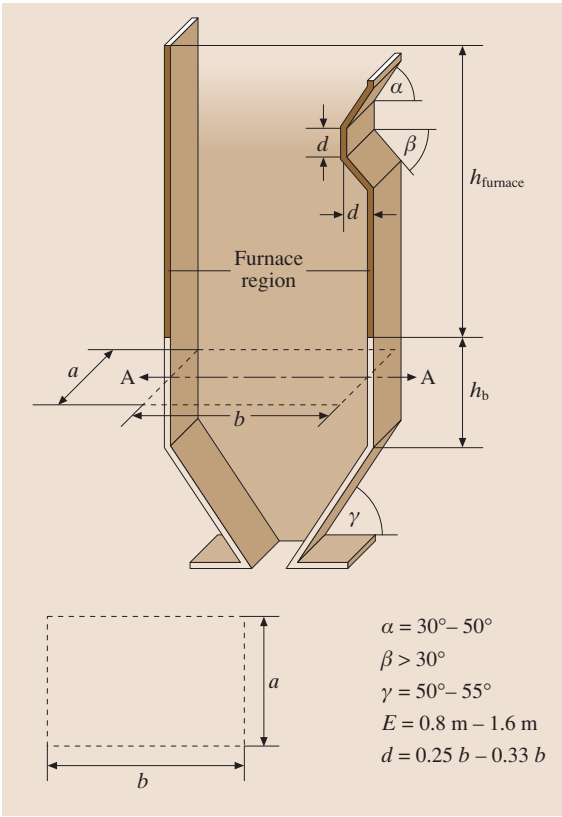

Fig. 16.29 Basic furnace geometry

stokers can handle a wide variety of waste fuels. Underfeed stokers are only used for small plants, and mainly for steam production rather than power generation. An underfeed stoker pushes the coal up into the furnace from below the grate.

Chain and traveling grate furnaces have similar characteristics. Coal lumps are fed continuously on to a moving grate or chain. Air is drawn through the grate and through the bed of coal on top. As the coal enters, it is heated by radiation from the refractory. Moisture and volatile matter are driven off. The chain/grate moves the coal slowly into the region in which ignition is established, and the temperature in the coal bed rises. The carbon gradually burns off, leaving ash which drops off at the end into a receptacle, from which it is removed for disposal. The ash formed may have a carbon content as high as 4–5 %.

In the spreader stoker arrangement, a high-speed rotor throws the coal into the furnace over a moving grate to promote fuel distribution.

16.18.14 Pulverized-Fuel Furnaces

The furnace is the most important part of a boiler. Its primary function is to provide sufficient space for fuel particles to burn completely and to cool the flue gas to a temperature at which the convective heating surfaces can be operated safely. Structurally the boiler furnace consists of the combustion space surrounded by water walls. The principle of combustion in pulverized-fuel boilers is that coal ground into a fine powder is mixed with air and transported into a combustion chamber where it is burnt in a flame similar to the flame of a liquid or gaseous fuel.

The furnace is designed to perform two functions simultaneously, namely:

- The release of the chemical energy of fuel by combustion: the first task of combustion technology is to burn the fuel efficiently and steadily, to consume controlled excess air (as little as possible).
- To generate a flame with a controlled shape that will generate the lowest amount of pollutants and ensure the transfer of heat from the furnace to the working fluid inside the water walls. The important task of furnace heat removal is to produce a controlled furnace exit gas temperature (FEGT). The FEGT is an important aspect of boiler safety.

The combustion gases leave the furnace at a safe temperature which will not cause clinkering to the subsequent heating surface.

A furnace can be characterized geometrically by its linear dimensions: the front width a, the depth b, and height h_f as mentioned in Fig. 16.29 which are estimated according to the rated fuel consumption and the thermal, physical, and chemical properties of the fuel to be used.

The furnace height should be sufficiently high that the flame should not heat the superheater tubes. Furnace width and depth are two of the most important parameters for design. The minimum value of furnace depth depends on the capacity of the boiler and types of fuel burnt.

The following factors influence the width and depth of the furnace:

1. The arrangement of burners
2. The heat release rate per unit furnace area
3. The power output of each burner
4. The flame length

Depending upon the condition of the ash leaving the bottom of the furnace, pulverized furnaces can be classified into two types:

1. Dry-bottom furnaces
2. Wet-bottom furnaces

16.18.15 Dry-Bottom Furnace

Dry bottom means that the boiler has a furnace bottom temperature below the ash melting point. In this furnace design ash or slag is removed in the dry state. In the dry-bottom type, ash falling down from the boiler furnace is conveyed by a continuously moving scraper chain conveyor to the clinker grinder, which is conveyed to the slurry sump through sloping trenches with the help of a high-pressure water jet. The furnace hopper dimension is one of the most important parameters for the effective removal of dry ash from the furnace. Normally the walls of the hopper are inclined at an angle of 48–60°.

16.18.16 Wet-Bottom Furnace

In a wet-bottom furnace ash or slag is removed in the wet state. In this design the hopper is filled with water and ash falling down is quenched and removed after a predetermined time with the help of a jet pumping system and conveyed to the slurry sump. This type of hopper is known as a water-impounded bottom ash hopper. There are two types of wet-bottom boilers: the slag-tap boiler and the cyclone boiler. The slag-tap boiler burns pulverized coal and the cyclone boiler burns crushed coal. In each type, the bottom ash is kept in a molten state and tapped off as a liquid. Both boiler types have a solid base with an orifice that can be opened to permit the molten ash that has collected at the base to flow into the ash hopper below. The ash hopper in wet-bottom furnaces contains quenching water. When the molten slag comes into contact with the quenching water, it fractures instantly, crystallizes, and forms pellets.

16.19 Fluidized-Bed Combustion System

Fluidized-bed combustion (FBC) technology is a very appropriate technology for efficient solid-fuel combustion. The velocity at which the bed behaves like a fluid is called fluidization velocity. At this point the pressure drop across the bed is equal to the weight of the particles per unit cross section of the bed. Increasing the air velocity imparts turbulent motion, which helps ensure proper mixing of the gas and particles.

Solid coal is crushed in the crusher to the required size, normally a mean particle diameter of around 0.5–12 mm, and fed into the fluidized bed, where it mixes with gas and inert materials and undergoes various reactions such as drying, devolatilization, combustion of volatiles, and the combustion of residual tar. During drying all the moisture present in the coal will be removed and the volatile matter is gradually released as the temperature increases; moreover the release of volatile matter is directly proportion to the temperature and inversely proportional to the gas pressure. After the volatile is released, combustion of the volatiles takes place, and finally burning of char takes place depending on the coal type, fluidization system, and char diameter.

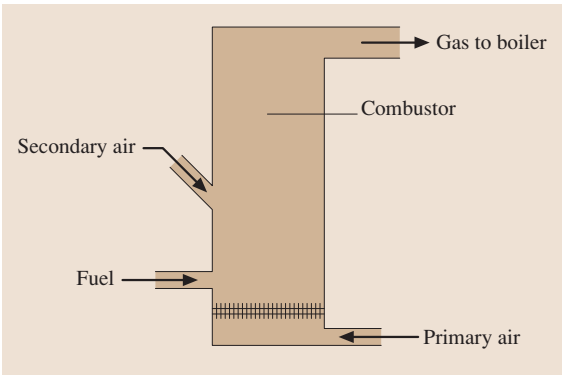

Fig. 16.30 Bubbling fluidized-bed combustion

Fluidization technique results in a vast improvement in combustion efficiency of high-moisture-content fuels, and is adaptable to a variety of waste-type fuels. The scrubbing action of the bed material on the fuel particle enhances the combustion process by shredding away the carbon dioxide and char layers that normally form around the fuel particle. FBC reduces the amount of sulfur emitted in the form of SO_x emissions. Limestone is used to precipitate out sulfate during combustion. FBC boilers can burn fuels other than coal, and the lower temperatures of combustion (800 °C) have other added benefits as well. FBC

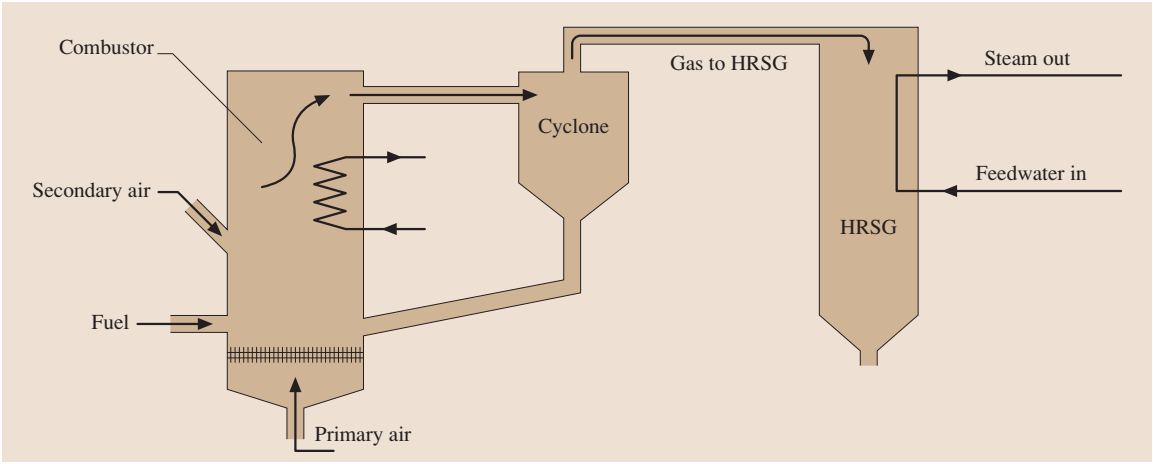

Fig. 16.31 Circulating fluidized-bed combustion

in boilers at atmospheric pressure can be particularly useful for high-ash coals, and/or those with variable characteristics.

Features of Fluidized-Bed Combustion Systems

Emissions from fluidized-bed combustor are always lower than conventional combustion technologies for the following reasons:

- Low combustion temperatures and low excess air within the fluidized bed reduces the formation of NO_x.
- High combustion efficiency results in flue gases that contain low amounts of CO.
- Emission such as SO_x may be abated within the fluidized-bed system by injecting limestone into the bed and ammonia into the vapor space.
- Fluidized-bed combustion is an environmentally favorable, proven technology for the disposal of solid wastes and the generation of energy.

16.19.1 Bubbling Fluidized-Bed Combustion

Bubbling beds use a low fluidizing velocity, so that the particles are held mainly in a bed with a definable surface. Inert materials are often used to improve the bed stability, together with limestone for SO_2 absorption. In-bed tubes are used to control the bed temperature and generate steam.

16.19.2 Circulating Fluidized-Bed Combustion

Generally circulating fluidized-bed combustion uses a boiler and a high-temperature cyclone. The gas velocity is as high as 4–8 m/s. Coarse fluidizing medium and char in the flue gas are collected by the high-temperature cyclone, and are recycled to the boiler as shown in Fig. 16.31. Air is introduced into the bed in two regions. About 40–70% of the air is injected through the nozzle grate at the bottom of the bed, normally called the primary air, and the remaining air, called the secondary air, is injected through nozzles on the side walls of the fluidized bed. The combustion proceeds in two zones: a primary reducing zone in the lower section of the combustor and an oxidizing zone in the upper part of the combustor where complete combustion is achieved through the use of excess air. This staged combustion, at controlled low temperatures, effectively suppresses NO_x formation. To increase the thermal efficiency, a preheater for fluidizing air and combustion air, and a boiler feedwater heater are installed.

16.20 Liquid-Fuel Furnace

Liquid fuels such as gasoline, kerosene, and diesel fuel are used directly for combustion in a liquid-fuel-fired furnace. Two major categories of fuel oil are burned by combustion sources: distillate oil and residual oil. Distillate oils are commonly used in domestic and small commercial applications, and include kerosene and diesel oil. Residual oil is mainly used in utility and large commercial application.

16.20.1 Special Characteristics

1. Due to the finer atomization (mean particle size 20 mm in the cause of fuel oil) better combustion takes place, resulting in a reduction in excess air requirement from 31% to 6%.
2. Liquid fuels having higher calorific value when compared to solid fuels.
3. These fuels occupy less space during storage.
4. These furnaces have practically no ash formation.

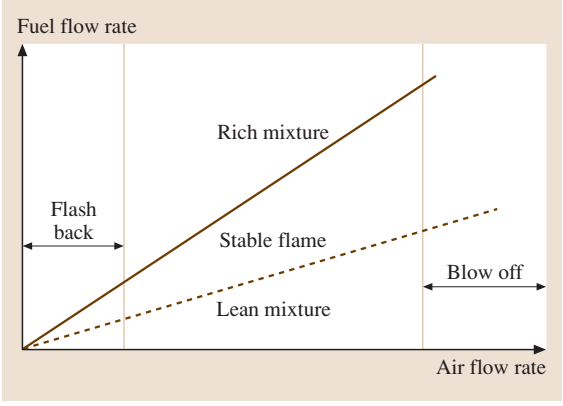

Fig. 16.32 Stability and flammability limits

5. The furnaces are easy to light up and shut down.
6. The furnaces have higher efficiency.
7. The fuel consumption rate can be controlled easily.

16.21 Burners

In order to achieve efficient combustion proper mixing of air and fuel is always necessary. The fuel must be evenly dispersed in the combustion airstream such that the fuel and air can make intimate contact. Failure to achieve this results in unburnt or partially burnt fuel. It is very important to design a component to achieve this task and provide better combustion efficiency. The burner is the apparatus for burning fuels continuously and more securely. The burner design attempts to achieve this using a variety of techniques. Important design criteria of burners are the burning rate, burning velocity, flashback, and the quenching diameter. Among these, the burning velocity is the deciding factor for the performance of the burner. It is defined as the relative velocity of the flame front to the unburned gases which is propagating normal to the flame front. These design parameters are related as follows

$$\text{burning velocity} > \text{flow velocity: flashback limit},$$
$$\text{burning velocity} < \text{flow velocity: blow-off limit},$$
$$\text{burning velocity} = \text{flow velocity: stable flame}.$$

The graph between the fuel flow rate and the airflow rate describes the mixing conditions, as shown in Fig. 16.32. The amount of air inflow affects the heat of the flame, and can be controlled by adjusting the slot openings. Stoichiometric calculation of the designed fuel determines the amount of air required, the fuel gas produced, and the heat released per unit weight of fuel burnt.

Minimum Air Required per Kilogram of Solid or Liquid Fuel Burnt

If a known mass of fuel consists of fractions of carbon, hydrogen, oxygen, and sulphur, then the minimum air required to burn the fuel is calculated as

For carbon requirement

$$= \text{mass of carbon (kg)} \times \left(\frac{8}{3\,\text{kg}}\right) \text{ of oxygen.}$$

For hydrogen

$$= \text{mass of hydrogen (kg)} \times 8\,\text{kg of oxygen.}$$

For sulphur

$$= \text{mass of sulphur} \times 1\,\text{kg of oxygen}.$$

Therefore, the amount of oxygen required for complete combustion of 1 kg of fuel is given by

$$\tfrac{8}{3}\text{C} + 8\text{H}_2 + \text{S} - \text{O}_2$$
$$= \tfrac{8}{3}\text{C} + 8\left(\text{H}_2 - \frac{\text{O}_2}{8}\right) + \text{S}$$

and atmospheric air contains 23 wt % of oxygen. Therefore, the minimum amount of air required per kilogram of fuel is

$$\frac{100}{23}\left(\frac{8}{3}\mathrm{C}+8\mathrm{H_2}+\mathrm{S}-\mathrm{O_2}\right)$$
$$=11.6\mathrm{C}+34.8\left(\mathrm{H_2}-\frac{\mathrm{O_2}}{8}\right)+4.35\mathrm{S}\,.$$

This is the theoretical amount of air required. The quantity of air in excess of this theoretical minimum that is actually required for complete combustion of the solid and liquid fuels is called the excess air.

16.21.1 Various Types of Burners

Burners can be classified in a number of ways: principle of operation (swirl type, parallel, or direct flow type), fuel (gaseous-fuel burners, liquid-fuel burners, and solid-fuel burners), and geometry (orifice burners, nozzle burners, flat flame burners, and burners with different shapes of openings).

16.21.2 Liquid-Fuel Burners

Fuel oil is the commonly used liquid fuel in the burners. An oil supply pump is provided to supply oil from the tank to the burner. To facilitate the fuel vaporization oil burners are designed to increase the contact surface area of the oil with air. To facilitate this, oil is atomized before entering the combustion chamber. It is difficult to atomize the fuel at ambient temperature so it has to be heated. this is achieved by single unit heating loops and a centralized heating system. A liquid fuel burner consists of a fuel supply line with a fuel atomizer, a concentric primary air supply with an air bag, and a secondary air supply with a vane control valve.

An oil burner is a mechanical device that combines fuel oil with appropriate amounts of air before delivering the mixture to the point of ignition in a combustion chamber. It is essential for the efficiency of the combustion process that the oil–air mixture is well homogenized and with as few pure droplets of fuel oil as possible. Fuel oil burners either vaporize or atomize the fuel oil.

Fuel oil burners can in general categorized into:

- Gun-type (atomizing) burners (pressure gun)
- Pot-type (vaporizing) burners
- Rotary-type fuel oil burners

16.21.3 Gun-Type Burners (Pressure Gun)

A gun-type burner atomizes the fuel oil by forcing the oil through a nozzle and spraying it into a gun-like airflow atomic nozzle. The liquid forms microscopic particles or globules that are well mixed and partly evaporated before being ignited in the combustion chamber. A residential gun-type burner normally requires a 551–896 kPa oil pressure. Commercial and industrial burners require 689–2068 kPa. The gun type is very flexible and can be used within a large range of

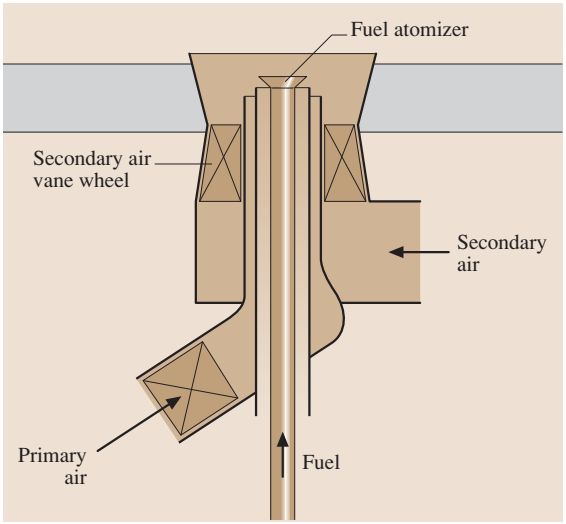

Fig. 16.33 Liquid-fuel burner arrangement

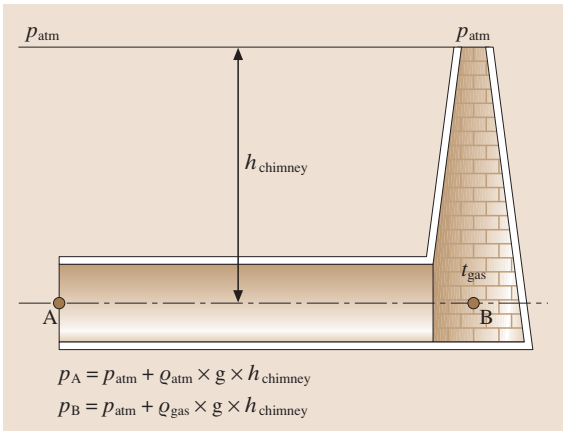

Fig. 16.34 Natural draught produced by a chimney

applications, from relative small residential heaters to larger industrial heating applications.

16.21.4 Pot-Type Burners

In a pot-type fuel burner the fuel evaporates into the combustion air. They are in general:

- Natural draft burners
- Forced draft burners
- Sleeve burners

In atmospheric pot-type heaters gravity causes the oil to flow to the burner. The natural draft burner relies on the natural draft in the chimney for air supply. The forced draft burner relies on a mechanical fan and/or the chimney for air supply. The perforated sleeve burner is only used in small applications. The pot-type burner is the most inexpensive of the fuel oil burners and has the lowest operating cost. A disadvantage of the pot-type is its limited capacity. This type is in general most suitable for smaller applications.

16.22 General Furnace Accessories

16.22.1 Fans

A fan moves a quantity of air or gas by adding sufficient energy to the stream to initiate motion and overcome resistance to flow. It helps to supply air for combustion, drying coal, and recirculation of gas.

16.22.2 Forced Draft Fan

The forced draft fan supplies combustion air and is important because it ensures adequate air–fuel mixing and keeps the flame away from the nozzle. The furnace operates under pressure and flue gases are exhausted by forced draft convection. The airflow rate is typically controlled with air dampers. Some applications use fan speed control.

16.22.3 Induced Draft Fan

The induced draft fan exhausts flue gases from the furnace and induces combustion air into the furnace by having the furnace operate under negative pressure. An induced draft fan can handle higher-temperature gas, which may contain corrosive ash.

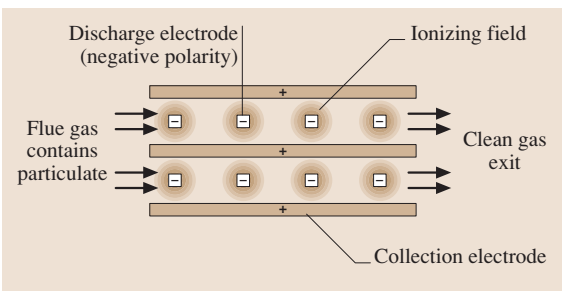

Fig. 16.35 Electrostatic precipitator (ESP), schematic diagram (top view)

16.22.4 Balanced Draft (BD)

The balanced draft design uses both forced draft and induced draft fans. It is used when the furnace design requires draft and furnace pressure control. Balance draft furnaces are typically operated at a slightly negative pressure, but they can also operate at slightly positive pressure. A furnace pressure measurement and induced fan control are required.

16.22.5 Primary Air Fans

In a coal-fired boiler, primary fans are used to supply the air needed to dry the coal and transport it to the boiler. Primary fans are usually located before or after the preheater.

16.22.6 Stacks

Stacks are used to create the required pressure differential for the flow of air and flue gas.

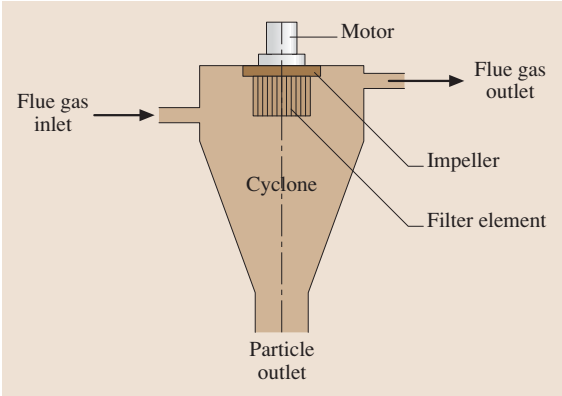

Fig. 16.36 Arrangement of a cyclone

The draft is the difference between the atmospheric pressure and the static pressure of the combustion gases in a furnace gas passage. In a coal-fired power plant tow methods are used to create a draught in the furnace:

1. A natural draft, or
2. A mechanical draft

16.22.7 Natural Draft

Natural draft establishes furnace breathing by continuous exhalation of flue gas and continuous inhalation of fresh air (Fig. 16.37). The tall chimney creates the natural draught by the temperature difference between the hot gases in the chimney and the cold atmospheric air outside the chimney.

The advantages of this method are:

- No external power is required.
- Air pollution is less since gases are discharged at a high level.
- No maintenance cost.
- Capital cost is less than artificial draught.

The draught or pressure difference produced is given by

$$\Delta p_{\mathrm{nd}} = \pm(\rho_{\mathrm{a}} - \rho_{\mathrm{g}})gH\,, \tag{16.60}$$

where Δp_{nd} is the head of natural draft (Pa), ρ_{a} is the ambient air density (kg/m^3), ρ_{g} is the gas density in the flue (kg/m^3), and H is the height difference between the beginning and the end of the section (m).

The flue gas density ρ_{g} is calculated as

$$\rho_{\mathrm{g}} = \rho_{\mathrm{g}}^{0}\frac{273}{273+T_{\mathrm{g}}}\,, \tag{16.61}$$

where T_{g} is the gas temperature (°C), ρ_{g} is the gas density in the flue under standard atmospheric conditions (1 atm) kg/m^3

$$\rho_{\mathrm{g}}^{0} = \frac{1-0.01A+1.302\alpha V^{0}}{V_{\mathrm{g}}}\,, \tag{16.62}$$

where α^0 is the excess air ratio in the flue gas, V^0 is the theoretical air requirement for unit weight of fuel (N m^3/kg), V_{g} is flue gas produced per unit weight of fuel (N m^3/kg $\approx \alpha V^0$), and A is the percentage ash content of the fuel.

The stack provides two functions:

1. Assisting the fan in overcoming pressure losses
2. Helping disperse the gas effluent

The amount of flow is limited by the strength of the draft. The pressure variation inside the chimney differs from atmospheric pressure. The variation of chimney pressure depends on the temperature variation along the chimney, which itself depends on the rate of cooling of hot gas due to natural convection.

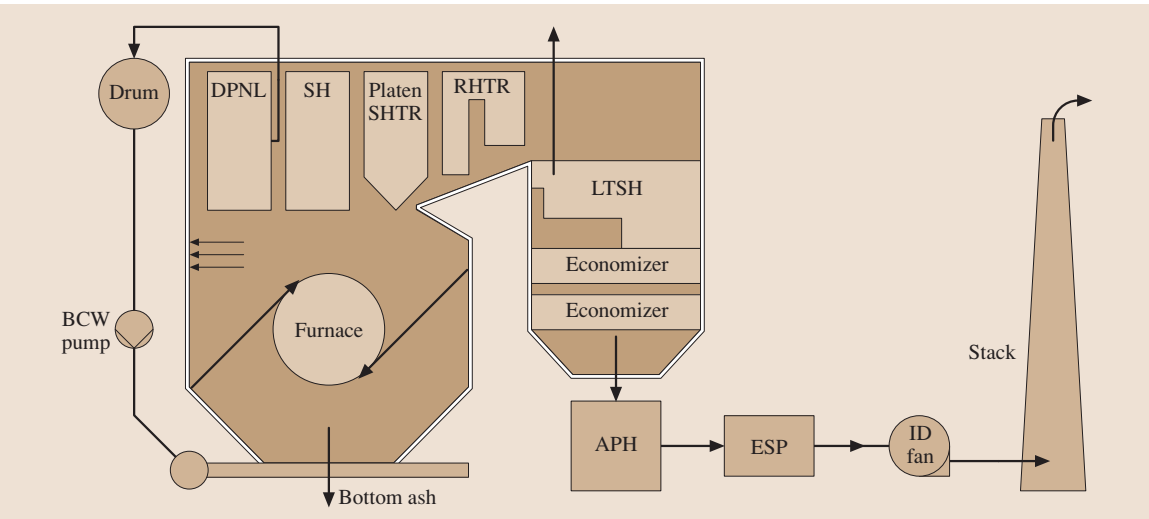

Fig. 16.37 Thermal structure of a boiler furnace (APH – air preheater, EPS – electrostatic precipitator, ID fan – induced draft fan, LTSH – latent superheater, platen SHTR – platen superheater, RHTR – reheater,SH – superheater)

16.22.8 Artificial Draught

In modern power plants, the draught should be flexible to meet the needs of fluctuating loads and it be independent of atmospheric conditions. To achieve this, the aid of draft fans becomes mandatory; by employing the fans, the height of the chimney can also be reduced. There are two types of fans used for producing mechanical draught:

1. Forced draught (FD)
2. Induced draught (ID)

16.22.9 Forced Draught

In this system, the blower (forced draft fan) is located at the base of the boiler near the grate. Air is forced into the furnace by the forced fan and the flue gases are forced to chimney through the economizer and air preheater.

Advantages of the Forced Draught System

- Since the fan handles cold air, the fan size and the power required are lower.
- No need for water-cooled bearings because the air being handled is cold.
- The pressure throughout the system is above atmospheric pressure so that air leakage into the furnace is reduced.

16.22.10 Induced Draught

In an induced draught system, a blower (induced draft fan) is placed near (or) at the base of the chimney. The fan sucks the flue gas from the furnace, creating a partial vacuum inside the furnace. Thus atmospheric air is induced to flow through the furnace to aid the combustion of fuel. The flue gases drawn by the fan passes through the chimney to the atmosphere.

16.22.11 Balanced Draught

In the induced draught system, when the furnace is opened for firing, cold air enters the furnace and dilates the combustion. In the forced draught system, when the furnace is opened for firing, the high-pressure air will try to blow out suddenly and the furnace may stop. Hence the furnace cannot be opened for firing and inspection in both systems. Balanced draught, which is a combination of induced and forced draught, is used to overcome these difficulties.

16.23 Environmental Control Technology

There are many technologies that can be used in industry to reduce the emissions of pollutants to the atmosphere, and these can be applied before, during, or after combustion.

16.23.1 Particulate Emission Control

There are several types of equipment available to control particulate matter from the flue gas which includes:

1. Electrostatic precipitators
2. Fabric filters
3. Mechanical collectors
4. Venturi scrubbers

16.23.2 Electrostatic Precipitators

When the ash particles present in the flue gas pass through the electrostatic precipitators (ESP) at a certain velocity, they become charged electrically and are attracted towards the collecting plate, which is normally positively charged.

Figure 16.35 shows a schematic diagram of ESP. The particulate-laden gas, normally laden with flyash, is sent through pipes with negatively charged plates which give the particles a negative charge. The particles are then routed past positively charged plates, or grounded plates, which attract the newly negatively charged ash particles. The particles stick to the positive plates until they are collected. The air that leaves the plates is then clean of harmful pollutants. Velocity is one of the important factors that affect the performance of an electrostatic precipitator. A lower velocity allows more time to collect the ash particles.

16.23.3 Fabric Filters

Fabric filters are used to remove particles from the gas stream. They are made up of woven or felted material. Fabric filters are generally in the form of a cylindrical bag. Fabric filters generally operate in a temperature range of 120–180 °C. The choice between ESP and fabric filtration generally depends on coal type, plant size, and boiler type and configuration. The two fundamen-

tal parameters in sizing and operating bag houses are the air-to-cloth (A/C) ratio (m/s) and the pressure drop (mm water gauge, Pascal or in H_2O). In operation, dust-laden gas flows through the filters, which remove the dust particles from the gas stream.

The most important factors that affect the performance of fabric filters are:

1. Flue gas temperature
2. Dew point and moisture content
3. Particle size distribution
4. Chemical composition of the fly ash

Fabric filters are classified into three types:

1. Pulse jet fabric filters
2. Reverse-air fabric filters
3. Shake-deflate filters

16.23.4 Pulse Jet Fabric Filters

Pulse jet fabric filters use high-pressure air to clean the filter bags, and are provided in standard configurations that are capable of treating gas flow rates up to about 300 000 ACFM (actual cubic feet per minute). Custom-designed units can handle larger flow rates.

16.23.5 Shake-Deflate Filters

This kind of filters collect the dust inside the bags as in the reverse-air design. To clean the bags, the top ends are shaken by a driver linkage.

16.23.6 Reverse-Air Fabric Filter

The reverse-air fabric filter is a customized design for utility boilers and industrial applications where large volumes of process gas flow (250 000 ACFM and more) must be cleaned. The systems consist of 6–24 structural compartments. Compartments are available with nominal 20 or 30 cm diameter bags with typical bag lengths of 7.31–11 m.

16.23.7 Mechanical Collectors

Mechanical dust collectors are often called cyclones. Cyclones are used to remove dust and fibrous material either as the first stage of a scrubber or fabric filter system. Although cyclones are an established form of dust collector, care and application knowledge are required to ensure correct sizing. The arrangement of a cyclone separator is shown in Fig. 16.36. The basic principle is the centrifugal force created by spinning a gas stream, which is used to separate the particles from the gas. In a conventional cyclone, the gas enters a cylinder tangentially, where it spins in a vortex as it proceeds down the cylinder. A cone section causes the vortex diameter to decrease until the gas reverses on itself and spins up the center to the outlet pipe or vortex finder. A cone causes flow reversal to occur sooner and makes the cyclone more compact. Dust particles are centrifuged toward the wall and collected by inertial impingement.

The collected dust flows down in the gas boundary layer to the cone apex where it is discharged through an airlock or into a dust hopper serving one or more parallel cyclone.

16.23.8 NO_x Control

It is very important to control the level of NO_x emitted from power plants. NO_2 from the exhaust reacts with sunlight and hydrocarbons to produce photochemical smog and acid rain constituents. The following techniques are used to reduce the level of NO_x formation in current practices:

- Low excess air operation
- Off-stoichiometric combustion, combustion modification
- Flue gas recirculation and treatment

Low Excess Air Operation

This technique involves a reduction in the total quantity of air used in the combustion process. By using less oxygen, the amount of NO_x produced is reduced.

Off-Stoichiometric Combustion

This technique involves the mixing of the fuel and air in a way that reduces the peak gas temperatures and peak oxygen concentrations. Advanced low-nitrogen-oxide burners can reduce emissions by up to 30%. Such burners can be installed in either new or existing combustion plants. For a low-NO_x burner, sudden heating up and temperature rise is important. In this case the high-temperature zone is very close to the burner compared with a conventional burner, so the pulverized coal is heated very rapidly in order to increase the fractional volatile and nitrogen release according to quantity introduced. Also, the recirculation flow near the center of the burner is important, because hot gas returning to the burner creates a very high-temperature region at this point. Altogether, the modified shape of the flow divider

and the pulverized fuel nozzle, together with an optimized strength of swirl in the air flow, produce a strong internal recirculation and NO_x reducing zone in the CI-a burner, with longer residence time in this region and reduced unburnt matter. So the result is a reduction of 50% in unburnt carbon and, at the same time, a significant reduction of at least 10% in NO_x production.

Over Fire Air (OFA)

This technique keeps the mixture fuel rich and completes the combustion process using air injection nozzles.

Combustion Modifications

Flue Gas Recirculation. A second method is to add some of the flue gas with the combustion air at the burner, normally known as flue gas recirculation. This increases the gas weight which must be heated by the chemical energy in the fuel, thereby reducing the flame temperature.

Flue Gas Treatment

Selective Noncatalytic Reduction Systems (SNCR). This technique involves the injection of ammonia (NH_3) or urea into the hot gas zone where reactions leading to reduction of nitrogen oxides can occur. The reactions are completed within the boiler, and no waste products are generated. There is a risk of ammonia (NH_3) being emitted into the atmosphere if temperatures are too low, however. SCNR systems are capable of reducing nitrogen oxides by 20–60%. The reactions are

$$4NH_3 + 4NO + O_2 \rightarrow 4N_2 + 6H_2O\,,$$
$$4NH_3 + 5O_2 \rightarrow 4NO + 6H_2O\,.$$

Flue Gas Desulphurization.

Precombustion Sulphur Control Technology. Removing the sulphur before burning is one of the challenging options. There are a verity of techniques available to reduce the sulphur, including coal scrubbing and oil desulphurization.

Another removal process is to change the design of the boiler and to install pressurized fluidized-bed combustors (FBC), which remove sulphur from the coal during the burning process.

Another process that removes sulphur dioxide from coal during combustion is the integrated gasification combined cycle. Coal is gasified under pressure with a mixture of air and steam which results in the formation of gas which can then be burned to produce electricity.

Post-Combustion Sulphur Control Technology. One of the post-combustion sulphur control methods (removing sulphur after burning) is flue gas desulphurization (FGD). In FGD processes, waste gases are scrubbed with a chemical absorbent such as limestone to remove sulphur dioxide. There are many different FGD processes, the main ones being the limestone–gypsum process and the Wellman–Lord regenerative process. Limestone–gypsum FGD involves mixing limestone and water with the flue gases to produce slurry which absorbs the sulphur dioxide. The slurry is then oxidized to calcium sulphate (gypsum) which can then be used in the building trade. FGD technologies can be classified into six main categories: wet scrubbers, spray dry scrubbers, sorbent injection processes, dry scrubbers, regenerable processes, and combined SO_2/NO_x removal processes.

16.24 Steam Generators

The steam generator is one of the main components in modern coal fired-power plants. Its concept, design, and integration into the overall plant considerably influence costs, operating behavior, and availability of the power plant. The thermal structure of the boiler furnace is shown in Fig. 16.37. Within the steam generator, fuel and air are forced into the furnace by the burner, where burning produces heat; from there fuel gas travels throughout the boiler, the feedwater absorbs the heat, and eventually absorbs enough energy to change into vapor. Boiler makers have developed various designs to extract the most energy from fuel and to maximize its transfer to the water.

Water enters the boiler, preheated, at the top as shown in the Fig. 16.37. The hot water naturally circulates through the tubes down to the lower area where it is hot. The water heats up and flows back to the steam drum, where the steam collects. Not all of the water is turned to steam, so the process starts again. Water keeps on circulating until it becomes steam. Meanwhile, the control system measures the temperature of the steam drum, along with numerous other readings, to determine if it should keep the burner burning, or shut it down. Sensors also control the amount of water entering the boiler, known as the feedwater. A steam generator is normally equipped with

basic component like a furnace, economizer, reheater, superheater, evaporator, air preheater, and auxiliary devices.

16.24.1 Types of Steam Generators

The classification of boilers depends on various phenomena, such as furnace position, the type of fuels used, tube contents, circulation etc.

16.24.2 Boiler Safety

Boiler safety is one of the prime aspects while operating the boiler. Operating the pressure above the design pressure is extremely dangerous, so proper control of the pressure inside the steam generator is very important. Though boilers are usually equipped with a pressure-relief valve, if the boiler fails to contain the expansion pressure, the steam energy is released instantly. This combination of exploding metal and superheated steam can be extremely dangerous.

The concentration of solids in the boiler should be measured and the boiler blow-down at such intervals as necessary to maintain established limits. Blow-down valves are placed at the lowest point of the boiler for the purpose of blowing sediment or scale from the boiler. They should be maintained in good working order and have to be opened and closed carefully when used.

Boilers should always be brought online slowly and cold water should never be injected into a hot system as sudden changes in temperature can warp or rupture the boiler. Because many boilers are fired by natural gas, diesel or fuel oil, special precautions need to be taken. Boiler operators should ensure that the fuel system, including valves, lines, and tanks, is operating properly with no leaks. The low-water cutoff is the most important electrical/mechanical device on a boiler for maintaining a safe water level. If a low-water condition develops, it could very well result in an overheating and explosion of the boiler. The low-water cutoff should be tested at least weekly.

To prevent furnace explosions, it is imperative that boiler operators purge the boiler before ignition of the burner. Workers should check the fuel-to-air ratio, the condition of the draft, and the flame to make sure that it is not too high and not smoky. Ventilation systems should also be inspected and maintained to make sure that combustion gases do not build up in the boiler room.

16.24.3 Boiler Water Treatment

Efficient performance of the boiler depends upon the quality of the water. The treatment of the boiler feedwater is required to prevent excessive fouling of the heat transfer equipment and the erosion of turbine blades.

The common impurities present in the raw water are:

1. Dissolved solids – calcium, magnesium
2. Suspended solids – mineral matter
3. Dissolved gases – oxygen and carbon dioxide
4. Scum-forming substances – carbonate, chlorate, and sulphate

In the steam boiler industry, high-purity feedwater is required to ensure proper operation of steam generation systems. High-purity feedwater reduces the use of boiler chemicals due to less frequent blow-down requirements. This lower blow-down frequency also results in lower fuel costs.

The boiler system loses water through steam and water leaks. Additional water called *make-up water* is added to the boiler to replace these losses. The amount of make-up water and the level of naturally occurring impurities in this water will determine the type of water treatment required. Boiler heating systems that have very few leaks require a simple water treatment program.

All water contains dissolved minerals and these minerals, if allowed to reach high enough levels in the boiler water, will come out of solutions and form as a hard shell on the hot surfaces of the boiler. This hard shell is called *scale* and is often found on the outside of the fire tubes or the inside of water tubes. Scale insulates the heating surfaces, reducing the ability of the fire tubes to transfer heat from the hot combustion to the boiler water. High stack temperatures or ruptured tubes are common problems related to scale build up. Boiler water also contains dissolved gases such as oxygen or carbon dioxide. These gases, in the presence of water and metal, can cause corrosion. Corrosion eats away the metal, affecting the durability of the boiler.

For boiler feedwater treatment, depending on its requirements, a number of processes can be utilized including chemical treatment/lime softening, dual-media filtration, carbon adsorption, conventional reverse osmosis membranes, and final ion-exchange resin polishing. Various methods of pretreatment of water are discussed below.

Lime Soda Process

Calcium and magnesium salts are removed using lime and soda ash. The chemical reactions during this process are

$$\begin{aligned} Ca(HCO_3)_2 + Ca(OH)_2 &= 2CaCO_3 + 2H_2O\,, \\ MgCl_2 + Ca(OH)_2 &= Mg(OH)_2 + CaCl_2\,, \\ MgSO_4 + Ca(OH)_2 &= Mg(OH)_2 + CaSO_4\,, \\ CaSO_4 + Na_2CO_3 &= CaCO_3 + Na_2SO_4\,, \\ CaCl_2 + Na_2CO_3 &= CaCO_3 + 2NaCl\,. \end{aligned}$$

Insoluble components such as calcium carbonate and magnesium hydroxide settle at the bottom.

Deaeration

The feedwater from the condenser contains dissolved gases such as O_2 and CO_2. Oxygen is found in feedwater with a relatively high partial pressure, so, it requires a near saturation temperature to be disassociated from the water. Oxygen in combination with water will attack iron and cause corrosion. This reaction occurs in two steps

$$Fe^{2+} + 2OH^- = Fe(OH)_2\,.$$

Then,

$$\underset{\substack{\text{Soluble}\\\text{ferrous}\\\text{hydroxide}}}{4Fe(OH)_2} + \underset{\substack{\text{Dissolved}\\\text{oxygen}}}{O_2} + \underset{\text{Water}}{2H_2O} = \underset{\substack{\text{Insoluble}\\\text{ferric}\\\text{hydroxide}}}{4Fe(OH)_3}$$

A deaerator is an open-type feedwater heater, in which the steam that is bled from the turbine is mixed directly with water. When the water temperature increases, the dissolved gases reduce.

16.24.4 Shell-Type Steam Generator

This is a cylindrical boiler where the shell axis is vertical to the firing floor. Originally it consisted of a chamber at the lower end of the shell, which contained the combustion appliance. The gases rose vertically through a flue surrounded by water. Large-diameter (100 mm) cross tubes were fitted across this flue to help extract heat from the gases, which then proceeded to the chimney. Later versions had the vertical flue replaced by one or two banks of small-bore tubes running horizontally before the gases discharged to the chimney. The steam was contained in a hemispherical chamber forming the top of the shell.

The present vertical boiler is generally used for heat recovery from exhaust gases from power generation or marine applications. The gases pass through small-bore vertical tube banks. The same shell may also contain an independently fired section to produce steam at such times that there is insufficient or no exhaust gas available.

In relation to the thermal capacity generated, a shell-type boiler has much higher water contents than a water tube boiler. Therefore, a shell-type boiler is more robust towards load fluctuations or load demands that temporarily exceed the rated boiler capacity.

Shell-type boilers are fire-tube boilers, because the products of combustion pass through the boiler tubes. Lancashire and Cornish are examples of shell-type boilers.

16.24.5 Natural Circulation Boiler

The distinct features of natural circulation boiler are that natural circulation occurs due to the density difference between the fluids in the down comer and riser or is caused by convection currents that result from the uneven heating of the water contained in the boiler. The natural circulation has been largely used in boilers up to 140 bar. Based upon the position and geometry natural circulation boilers are classified into two types:

1. Vertical-tube type
2. Sloped-tube type

Figure 16.39 shows a typical water-tube natural circulation waste heat boiler with steam drum and down comer and riser pipes. Feedwater enters the drum from an economizer. This mixes with the steam/water mixture inside the drum. Down comers carry the resultant cool water to the bottom of the evaporator tubes while external risers carry the water–steam mixture to the steam drum. The heat transfer tubes also act as risers, generating steam.

The natural circulation is maintained due to the static head difference and natural convection due to the density differential between the mean down comer density and mean riser density. The down comers are located outside the furnace and away from the heat of combustion. They serve as pathways for the downward flow of relatively cool water.

The circulation ratio is defined as the ratio of the mass of steam–water mixture to steam generation. The natural circulation largely depends upon the

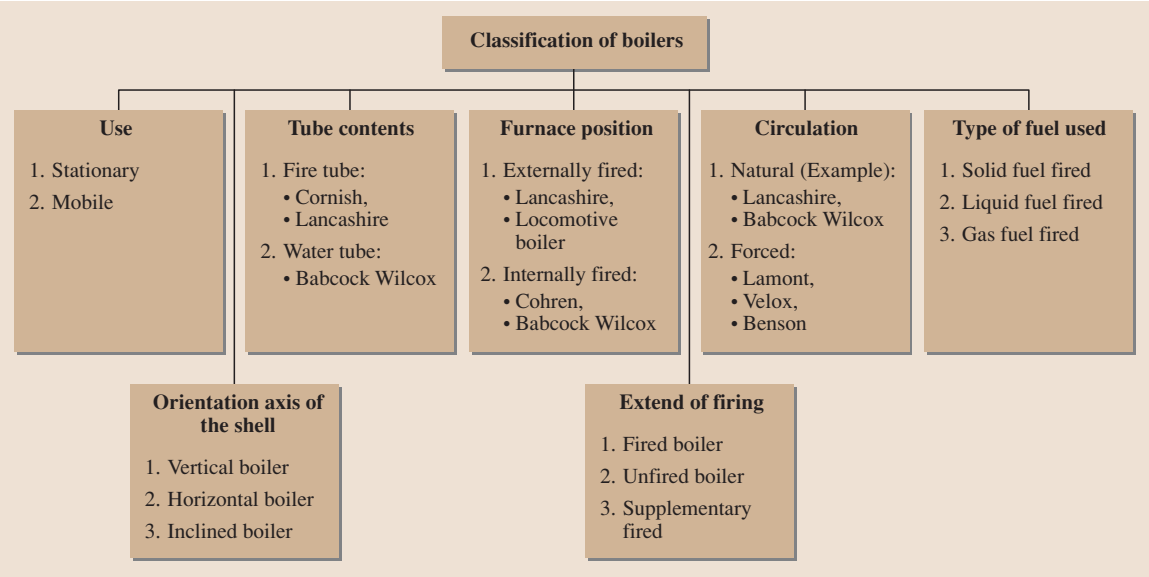

Fig. 16.38 Classification of boilers

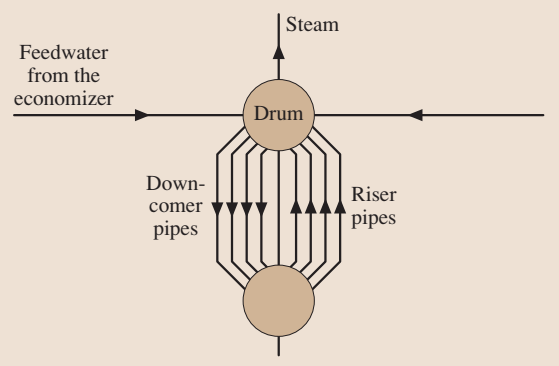

Fig. 16.39 Natural-circulation-type water tube boiler

height of the riser and the down comer, and the mean density of the fluids. The main feature of natural circulation boilers is the absence of water circulation pumps.

16.24.6 Forced Circulation Boiler

Modern boilers use the principle of forced circulation. When the boiler pressure is very high, the difference between the densities of water and the saturated steam decreases and hence less circulation occurs. The difference between the lower drum and steam drum must be increased in order to obtain the same output under higher-pressure condition. This can be achieved by means of forced circulation. The example of a forced circulation boiler is the Lamont boiler. The operation is basically similar to that of natural circulation unit, with a pump being used below the down comer for circulating water through the risers.

Normally forced circulation boilers are used if the pressure is very high. If the pressure is very high, the density difference between liquid/water and liquid mixture is very less, so, there abstract the problem of free flow like in natural circulation.

A once-through boiler is a forced circulation boiler. Once-through boilers have been favored in many countries for more than 30 years. They can be used up to a pressure of more than 30 MPa without any change in the process engineering. In the once-through boiler, subcooled water, supplied by a feedwater pump at the inlet of the tubes, is heated, evaporated, and superheated in the long evaporation tubes to produce superheated steam at a prescribed pressure and temperature at the outlet of the tubes.

A principle advantage of the once-through boiler is that it does not require circulating pumps or drums. The energy required for circulation is provided by the feed pump. Since the state of the superheated steam at the outlet is determined by the total amount of heat input, independent of the heat the heat flux distribution along the tube at a defined mass flow rate, the once-through boiler is a fairly simple device to obtain superheated steam of a prescribed state at any partial load.

16.24.7 Boiling Water Reactors

The fission zone is contained in a reactor pressure vessel, at a pressure of about 70 bar (7 MPa). At the temperature reached (approximately 290 °C), the water starts to boil and the resulting steam is produced directly in the reactor pressure vessel. After the separation of the steam and water in the upper part of the reactor pressure vessel, the steam is routed directly to a turbine driving an alternator. The steam coming out of the turbine is converted back into water by a condenser after having delivered a large amount of its energy to the turbine. It is then fed back into the primary cooling circuit where it absorbs new heat in the fission zone. Since the steam produced in the fission zone is slightly radioactive, mainly due to short-lived activation products, the turbine is housed in the same reinforced building as the reactor.

16.25 Parts and Components of Steam Generator

16.25.1 Superheaters

One of the most important accessories of a boiler is a superheater, which affects improvement and economy in the following ways. The steam that is produced in the boiler has a certain percentage moisture content. Due to the high velocities of the steam inside a turbine, the moisture content of the steam can erode the turbine blades. A superheater is utilized to remove the moisture content in the steam by raising the temperature while keeping the pressure constant. Steam that undergoes this process is referred to as superheated steam. Superheating improves the turbine internal efficiency and hence the lifetime of the turbine. The degree of superheating is a term which is used to describe the temperature difference between the raised temperature and the temperature at constant pressure.

A superheater therefore:

1. Increases the capacity of the plant
2. Reduces corrosion of the steam turbine
3. Reduces steam consumption of the steam turbine

Depending upon the way heat is transferred, superheaters are classified into three types:

1. Radiant superheaters
2. Convective superheaters
3. Combined radiative and convective superheaters

Convective superheaters are normally called primary superheaters and are located near the convective zone of the furnace, whereas radiant and combined superheaters are termed secondary superheaters.

Flow Arrangements of the Different Types of Superheater

The saturated steam from the drum is sent into the convective superheaters. After the convective superheater the steam is passed into the radiant superheater, where the heat is absorbed purely by means of radiation. Steam leaving the radiant superheater is sent into the desuperheater, where highly pure water is sprayed directly into the steam. The temperature of the steam leaving the pendent superheater should not exceed the rated value.

Superheaters are often divided into more than one stage such as:

1. A platen superheater
2. A pendent superheater
3. A horizontal superheater
4. A radiant superheaters

16.25.2 Radiant Superheater

Radiant superheaters receive energy primarily by thermal radiation from the furnace with little energy from convective heat transfer. Radiant superheaters are located at the furnace exit or turning section. The radiant superheater absorbs more enthalpy at partial loads when compared to the convective type. At lower loads the flow distribution inside the superheater tubes is less uniform. The radiant superheater outlet temperature decreases with increasing boiler output. At higher loads the mass flow rate of the combustion gas is high, because of increased amount of fuel and air for combustion. The convective heat transfer coefficient increases both inside and outside the tubes. Thus the steam receives more heat transfer per unit mass flow rate, and its temperature increases with load. The surface area required to transfer a given amount of energy will be lower due to the higher log mean temperature difference and higher heat transfer coefficient. Hence their cost may be lower in spite of the better grade of materials required.

16.25.3 Convective Heat Transfer

A convective superheater is located in a low-gas-temperature region ranging from 423 to 813 K lower, depending on the degree of superheating required. Since it is shielded by several rows of screen tubes, the gas is well mixed and cooled before it encounters the superheater and hence the performance can be predicted more accurately. Due to the Lower log mean temperature difference and lower heat transfer coefficient, the surface area required will be greater and the device hence could therefore be more expensive than the radiant design.

16.25.4 Pendent Superheater

Pendent superheaters receive heat by both convection and radiation, they are normally hung from the top as shown in the Fig. 16.40, usually located in the crossover duct between the furnace and the back pass.

The outside tube diameters of the pendent superheaters normally falls in the range 32–51 mm and the tube thickness is usually in the range 3–7 mm.

16.25.5 Platen Superheater

These devices are made from flat panels of tubes located in the upper part of the furnace, where the gas temperature is high. The tubes of the platen superheater receive very high radiation as well as a heavy dust burden, so ultimate care should be taken while designing platen superheaters. The arrangement of platen superheater is shown in Fig. 16.41.

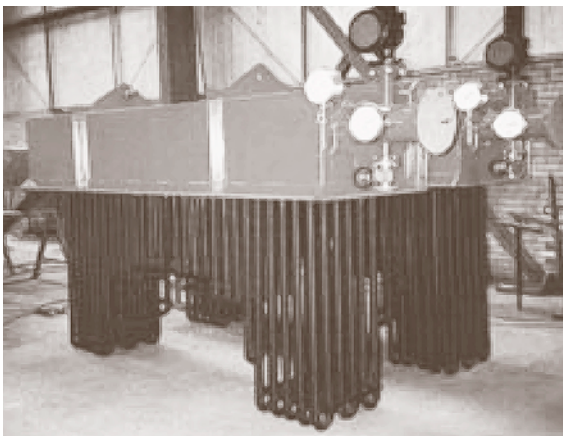

Fig. 16.40 Arrangement of a pendent superheater

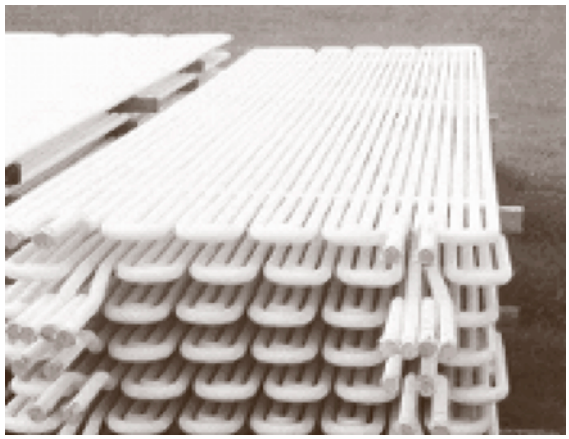

Fig. 16.41 Arrangement of a platen superheater

The mass flow velocity of steam in the platen superheater is normally in the range 800–1000 kg/(m^2 s). The outer diameter of the platen superheater tubes is in the range 32–42 mm. The number of parallel tubes in a platen is generally 15–35, depending on the design steam velocity.

16.25.6 Reheaters

The design considerations for reheaters are similar to those for superheaters. The reheater is usually located above the primary or convective superheater in the convective zone of utility boilers. A schematic view of a convective reheater is shown in Fig. 16.43. The pressure drop inside the reheater tubes has an important adverse effect on the efficiency of the turbine. The pressure drop through the reheater should be kept as low as possible. The tube diameter of the reheater is normally 42–60 mm and the overall heat transfer coefficient is 90–110 W/(m^2 K).

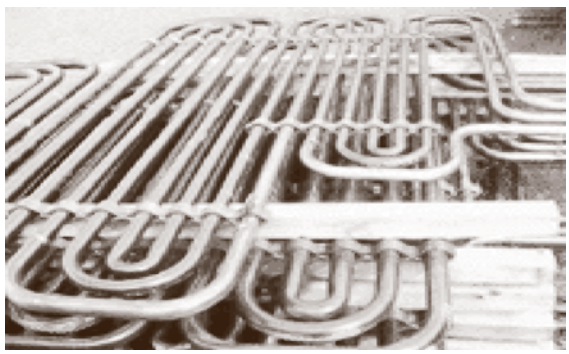

Fig. 16.42 Schematic view of convective reheaters

16.25.7 Economizers

The feedwater from the first high-pressure heater passing through a heat exchanger and heats up to the saturation temperature corresponding to the boiler pressure. This heat exchanger is normally called the economizer; it extracts waste heat from hot stack gases to heat the feedwater to the desired saturation temperature, hence the energy input to the boiler increases and the efficiency as well as economy of the power plant increase. The economizer is generally placed between the convective superheater and the air preheater.

Economizers are designed for downward flow of gas and upward flow of water, consisting of more than 250–300 coils in a staggered arrangement in a single bank. Figure 16.43 depicts the arrangement of the economizer.

Water enters from a lower header and flows through horizontal tubes that comprise the heating surface. Return bends at the ends of the tubing provide continuous tube elements whose upper ends connect to the outlet headers, which are in turn connected to the boiler drum by means of piping. Modern power plants use steel-tube-type economizers. The outside diameter of the economizer tubes is normally in the range 25–75 mm and the tube thickness is 3–5 mm; providing an extended surface over the economizer will enhance the heat transfer rate.

16.25.8 Feedwater Heaters

Feedwater heaters are used to raise the temperature of the water or to increase the mean temperature of heat addition in the cycle before it enters the boiler. The feedwater heater utilizes the steam which is extracted along the turbine expansion line for water heating. Feedwater heaters are used in a regenerative feedwater cycle to increase thermal efficiency and thus provide fuel savings.

Feedwater heaters are normally classified into two types

1. Open feedwater heaters
2. Closed feedwater heaters

Closed Feedwater Heaters

A closed feedwater heater is a shell-and-tube heat exchanger that warms feedwater by means of superheated steam or dry saturated or wet steam. Normally water flows inside the pipe and steam flows on the shell side. The arrangement of a closed feedwater heater in a typical steam turbine power plant is shown in Fig. 16.44.

According to the method of releasing the drain, closed feedwater arrangements are further classified into two types:

1. Drain cascaded forward
2. Drain cascaded backward

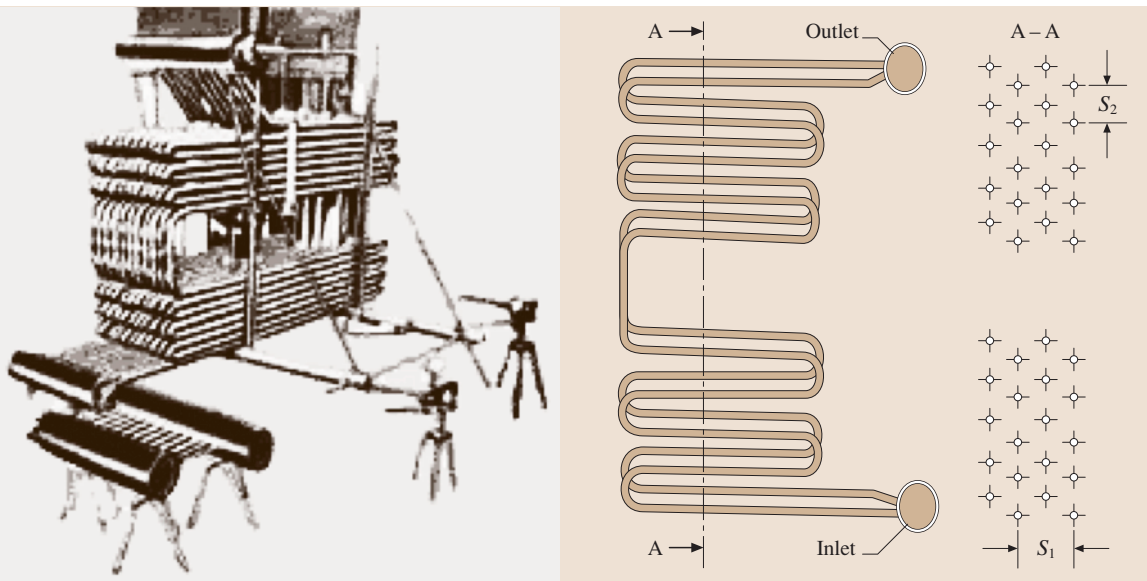

Fig. 16.43 Arrangement of an economizer

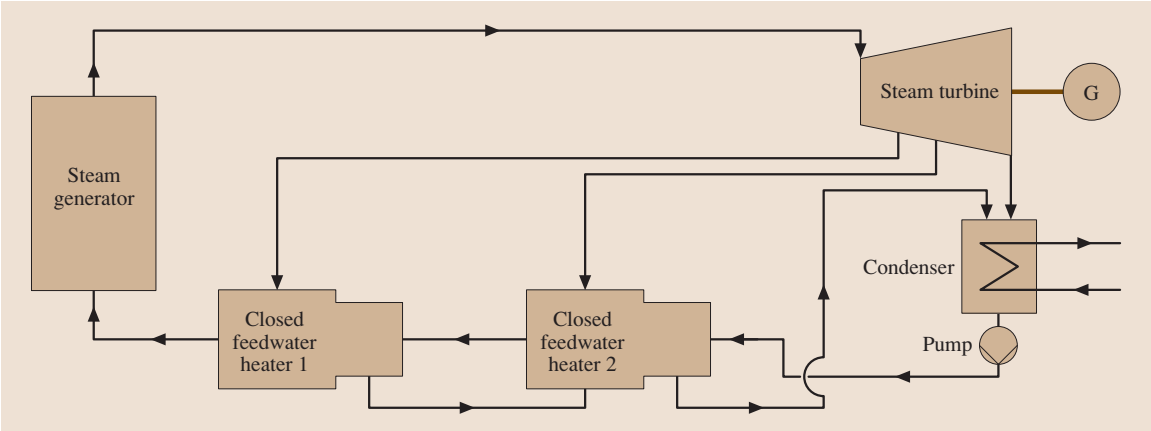

Fig. 16.44 Steam turbine regenerative cycle with closed feedwater heater (drains cascaded backward)

In the drain cascaded forward type the drain from the feedwater heater is mixed with the drain from the preceding feedwater heater. The reverse happens in the drain cascaded backward type, as shown in Fig. 16.44. Based on the state of the steam or level of turbine extraction feedwater heaters are further classified as high-, intermediate-, and low-pressure feedwater heaters. Modern power plants employing regeneration normally employ more than six feedwater heaters. There should always be one deaerator along with open feedwater heater. The purpose of the deaerator is to remove the dissolved oxygen presence in the system. High-pressure (HP) feedwater heaters utilize steam from the HP turbine and hence are called high-pressure feedwater heaters. A high-pressure closed feedwater heater has three zones, namely the desuperheating zone, the condensing zone, and the drain cooling zone. During the design of such a heat exchanger each zone is consider as a separate heat exchanger and the corresponding heat transfer coefficients and pressure drops are evaluated separately. The temperature duty diagram for a three-zone feedwater heater or high-pressure closed feedwater heater is shown in Fig. 16.45.

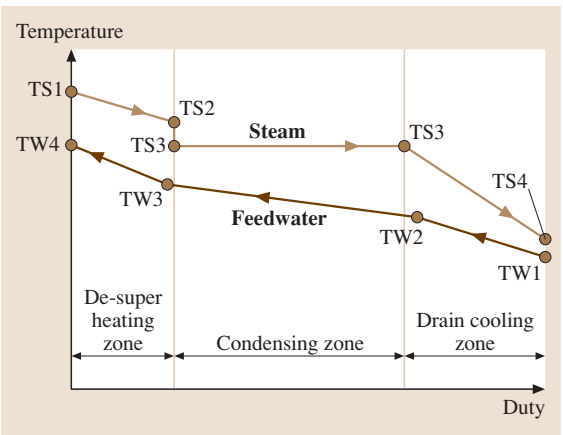

Fig. 16.45 Temperature–duty diagram for a three-zone feedwater heater

Open Feedwater Heaters

In open feedwater heaters, heat transfer takes place by direct mixing of steam and water. Normally open feedwater heaters are more efficient than closed feedwater heaters. Though the efficiency of open feedwater heater is higher, closed feedwater is normally used for modern power plants utilizing a large number of feedwater heaters to avoid a large number of pumps at each entrance and exit of the heater.

16.25.9 Air Preheaters

The flue gas leaving the chimney is normally in the range 280–480 °C. Leaving the flue to the atmosphere at this high temperature causes high energy losses. Air heaters are used to utilize this hot flue gas to heat the air required for combustion, and lead to an improvement in combustion efficiency. Since this is a gas-to-gas heat exchanger, its heat transfer surface area is extremely large. Recuperative and regenerative heaters are two different air preheaters normally employed in power plants.

16.25.10 Recuperative Air Preheater

A recuperative air preheater is nothing but a shell-and-tube heat exchanger in which hot flue gas flows inside

the tubes and air flows outside. Since this is a gas-to-gas heat exchanger it requires a huge heat transfer surface area and hence larger size.

16.25.11 Rotary or Regenerative Air Preheater

Rotary preheaters works on the counterflow principle, and consist of a rotor and housing. The rotor is normally divided into 12–24 radial divisions of heat transfer elements and is made up of steel sheets. The rotor is driven by an electric motor and is coupled with worm-gear drive that helps to reduce the speed of the rotor device to 2–6 rpm. During the rotation through the flue gas side the heat transfer element absorbs heat which is later given off during the rotation through the air section. Based on the number of sections rotary preheaters are further classified into three types: bisector, trisector, and quadsector types. Trisector-type air preheaters are divided into three sections: one for the flue gas, one for the primary, and one for the secondary section. In the quadsector type, the secondary air section is divided into two sections, taking up primary air. Control of the leakage of air into the flue gases is very important to avoid energy loss in the system. Various types of sealing systems are normally employed:

1. Radial sealing system
2. Axial sealing system
3. Circumferential sealing system
4. Shaft sealing system

16.26 Energy Balance Analysis of a Furnace/Combustion System

16.26.1 Performance Analysis of a Furnace

The following procedures should be adopted to carry out the performance analysis of the furnace:

1. Obtain the ultimate fuel analysis
2. Compute the equivalent chemical formula
3. Select the recommended exhaust gas composition
4. Write and balance the combustion equation

$$\begin{aligned}&\mathrm{C}_X\mathrm{H}_Y\mathrm{S}_Z\mathrm{O}_K + \varepsilon 4.76\left(X+\frac{Y}{4}+Z-\frac{K}{2}\right)\text{ air}\\&\quad+\text{moisture in air}+\text{ash moisture in fuel}\\&\rightarrow P\mathrm{CO}_2+Q\mathrm{H}_2\mathrm{O}+R\mathrm{SO}_2+T\mathrm{N}_2+U\mathrm{O}_2\\&\quad+V\mathrm{CO}+W\mathrm{C}+\text{ash}\,.\end{aligned}$$

Dry Exhaust Gases.

$$P\mathrm{CO}_2+R\mathrm{SO}_2+T\mathrm{N}_2+U\mathrm{O}_2+V\mathrm{CO}\quad\text{(kmol)}\,.$$

1. Carry out first law analysis to calculate the theoretical combustion temperature.
2. Calculate the total number of moles of wet exhaust gas for 100 kg of fuel

$$n_{\text{ex.gas}} = P+Q+R+T+U+V\,.$$

3. $100\,\text{CV of fuel} = n_{\text{ex.gas}}c_{\text{p}_{\text{exhaust gas}}}(T_{\text{th}}-T_{\text{atm}})\,.$
4. Calculate the total heat transfer area of the furnace A_{furnace}.

16.26.2 Analysis

$$\begin{aligned}&\mathrm{C}_X\mathrm{H}_Y\mathrm{S}_Z\mathrm{O}_K + \varepsilon 4.76\left(X+\frac{Y}{4}+Z-\frac{K}{2}\right)\text{ air}\\&\quad+\text{moisture in air}+\text{ash moisture in fuel}\\&\rightarrow P\mathrm{CO}_2+Q\mathrm{H}_2\mathrm{O}+R\mathrm{SO}_2+T\mathrm{N}_2+U\mathrm{O}_2\\&\quad+V\mathrm{CO}+W\mathrm{C}+\text{ash}\,.\end{aligned}$$

Dry exhaust gases

$$P\mathrm{CO}_2+R\mathrm{SO}_2+T\mathrm{N}_2+U\mathrm{O}_2+V\mathrm{CO}\quad\text{(kmol)}\,.$$

The volume of gases is directly proportional to the number of moles

Volume fraction = mole fraction

Volume fraction of CO_2

$$x_1 = P\frac{100}{(P+R+T+U+V)}\,.$$

Volume fraction of CO

$$x_2 = V\mathrm{CO}\frac{100}{(P+R+T+U+V)}\,.$$

Volume fraction of SO_2

$$x_3 = R\frac{100}{(P+R+T+U+V)}\,.$$

Volume fraction of O_2

$$x_4 = U\frac{100}{(P+R+T+U+V)} .$$

Volume fraction of N_2

$$x_5 = T\frac{100}{(P+R+T+U+V)} .$$

These are dry gas volume fractions. Emission measurement devices only indicate dry gas volume fractions.

Measurements

Volume flow rate of air, volume flow rate of exhaust are obtained from exhaust gas analysis

$$x_1 + x_2 + x_3 + x_4 + x_5 = 100 \text{ or } 1 .$$

Ultimate Analysis of Coal

$$n\mathrm{C}_X\mathrm{H}_Y\mathrm{S}_Z\mathrm{O}_K + \varepsilon n 4.76\left(X + \frac{Y}{4} + Z - \frac{K}{2}\right) \text{ air}$$
$$+ \text{moisture in air} + \text{ash and moisture in fuel}$$
$$\rightarrow x_1\mathrm{CO}_2 + x_6\mathrm{H}_2\mathrm{O} + x_3\mathrm{SO}_2 + x_5\mathrm{N}_2 + x_4\mathrm{O}_2$$
$$+ x_2\mathrm{CO} + x_7\mathrm{C} + \text{ash} ,$$

where x_1, x_2, x_3, x_4, and x_5 are dry volume fractions or percentages.

Conservation Species. Conservation of carbon

$$nX = x_1 + x_2 + x_7 .$$

Conservation of hydrogen

$$nY = 2x_6 .$$

Conservation of oxygen

$$nK + 2n\varepsilon\left(X + \frac{Y}{4} + Z - \frac{K}{2}\right)$$
$$= 2x_1 + x_2 + 2x_3 + 2x_4 + x_6 .$$

Conservation of nitrogen

$$\varepsilon n 3.76\left(X + \frac{Y}{4} + Z - \frac{K}{2}\right) = x_5 .$$

Conservation of sulfur

$$nZ = x_3 .$$

By rearranging the terms, we obtain

$$\mathrm{C}_X\mathrm{H}_Y\mathrm{S}_Z\mathrm{O}_K + \varepsilon 4.76\left(X + \frac{Y}{4} + Z - \frac{K}{2}\right) \text{ air}$$
$$+ \text{moisture in air} + \text{ash moisture in fuel}$$
$$\rightarrow P\mathrm{CO}_2 + Q\mathrm{H}_2\mathrm{O} + R\mathrm{SO}_2 + T\mathrm{N}_2 + U\mathrm{O}_2$$
$$+ V\mathrm{CO} + W\mathrm{C} + \text{ash} .$$

16.26.3 First Law Analysis of Combustion

$$\mathrm{C}_X\mathrm{H}_Y\mathrm{S}_Z\mathrm{O}_K + \varepsilon 4.76\left(X + \frac{Y}{4} + Z - \frac{K}{2}\right) \text{ air}$$
$$+ \text{moisture in air} + \text{ash} + \text{moisture in fuel}$$
$$\rightarrow P\mathrm{CO}_2 + Q\mathrm{H}_2\mathrm{O} + R\mathrm{SO}_2 + T\mathrm{N}_2 + U\mathrm{O}_2$$
$$+ V\mathrm{CO} + W\mathrm{C} + \text{ash} ,$$

$$\sum Q_{\mathrm{CV}} + n_{\mathrm{air}}h_{\mathrm{f,air}} + n_{\mathrm{fuel}}h_{\mathrm{f,fuel}}$$
$$= \sum_{i=1}^{n} n_i h_{\mathrm{f,fluegas},i} + \sum W_{\mathrm{CV}} . \qquad (16.63)$$

Furnace characterization criteria

$$A_{\mathrm{furnace}} = \frac{Gm_{\mathrm{f}}c_{\mathrm{P}}}{T_{\mathrm{th}}^3}\left[\frac{1}{m}\left(\frac{T_{\mathrm{th}}}{T_{\mathrm{out}}} - 1\right)\right]^{1/0.6} , \qquad (16.64)$$

where G is the furnace quality factor, M is the temperature field coefficient, T_{th} is the theoretical combustion temperature, A_{furnace} is the total surface area of the furnace, and m_{f} is the mass flow rate of fuel.

16.26.4 Boiler Fuel Consumption and Efficiency Calculation

For any fuel there is a minimum quantity of oxygen required for complete combustion. The amount of air that contains this minimum quantity of oxygen is called the *theoretical air*; it is the measure of capability of the boiler to transfer heat liberated in the furnace to water and steam. The boiler efficiency may be expressed in any one of the following methods.

16.26.5 Various Energy Losses in a Steam Generator

1. Heat loss from the furnace surface area
2. Unburned carbon loss
3. Incomplete combustion loss
4. Loss due to hot ash
5. Loss due to moisture in the air
6. Loss due to moisture in the fuel
7. Loss due to combustion-generated moisture
8. Dry exhaust gas losses

The pictorial representation of the Shanky diagram, as shown in Fig. 16.47, represents the various energy losses that take place in a steam generator.

The first law analysis steam generator in steady state steady flow (SSSF) mode in molar form (see Fig. 16.48)

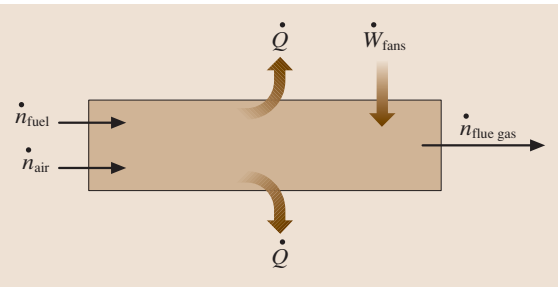

Fig. 16.46 Energy balance diagram

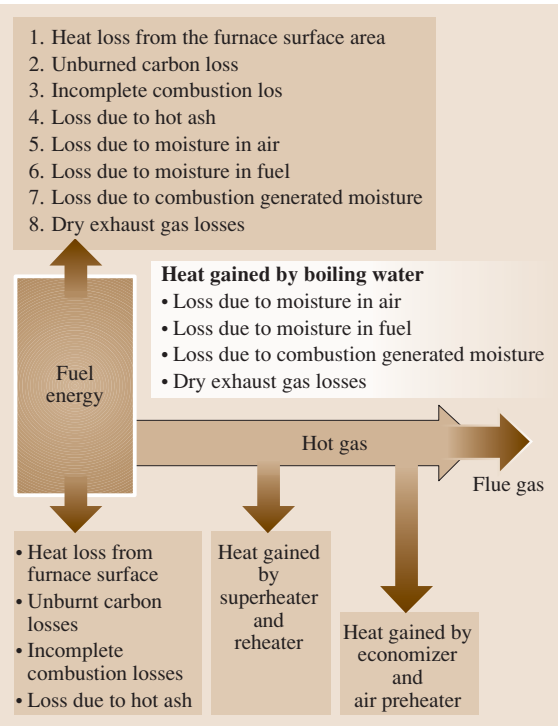

Fig. 16.47 Shanky diagram showing various losses in the steam generator

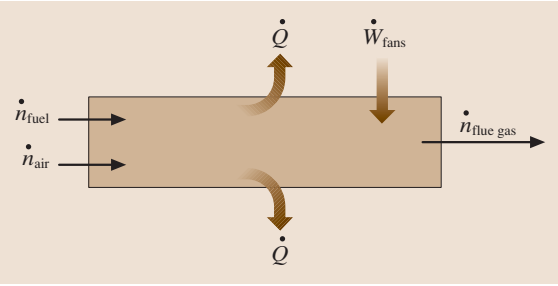

Fig. 16.48 Furnace energy balance

yields

$$\sum \dot{Q} + \dot{n}_{\text{air}} h_{\text{air}} + \dot{n}_{\text{fuel}} h_{\text{fuel}} = \sum \dot{n}_{\text{fluegas}} h_{\text{fluegas}} + \sum \dot{w} \, .$$

Dry Exhaust Gas Losses (DEGL)

For 100 kg of fuel

$$Q_{\text{DEGL}} = \Delta n_{\text{fluegas}} \Delta h_{\text{fluegas}} \, ,$$

$$Q_{\text{DEGL}} = n_{\text{CO}_2} \Delta h_{\text{CO}_2} + n_{\text{CO}} \Delta h_{\text{CO}} + n_{\text{O}_2} \Delta h_{\text{O}_2} + n_{\text{N}_2} \Delta h_{\text{N}_2} + n_{\text{SO}_2} \Delta h_{\text{SO}_2} \text{ kJ} \, ,$$

$$Q_{\text{DEGL}} = P \Delta h_{\text{CO}_2} + R \Delta h_{\text{SO}_2} + T \Delta h_{\text{N}_2} + U \Delta h_{\text{O}_2} + v \Delta h_{\text{CO}} \text{ kJ} \, .$$

Alternate method. The total number of moles of dry exhaust gas $n_{\text{ex.gas}} = P + R + T + U + V$ is

$$Q_{\text{DEGL}} = n_{\text{ex.gas}} C_{\text{p,ex.gas}} (T_{\text{ex.gas}} - T_{\text{atm}}) \, .$$

Accurate calculation of the gas enthalpy gives, for any gas

$$\mathrm{d}h = c_{\text{p}} \, \mathrm{d}T \, ,$$

$$\Delta h = \int_{\text{ambient}}^{\text{SG}_{\text{exit}}} \mathrm{d}h = \int_{T_{\text{amb}}}^{T_{\text{exit}}} c_{\text{p}}(T) \, \mathrm{d}T \, . \qquad (16.65)$$

Unburnt Carbon Loss (UCL)

For 100 kg of fuel

$$Q_{\text{UCL}} = \text{MC } W \text{ calorific value of carbon} \quad \text{(kJ)} \, ,$$

$$Q_{\text{UCL}} = 12 W \, 33\,820 \text{ kJ} \, , \qquad (16.66)$$

where MC is the molecular weight of carbon.

Incomplete Combustion Loss (ICL)

For 100 kg of fuel

$$Q_{\text{ICL}} = \text{MCO} VCV \text{ of CO} \quad \text{(kJ)} \, ,$$

$$Q_{\text{ICL}} = 28 V \, 23\,717 \text{ kJ} \, . \qquad (16.67)$$

Losses due to Moisture in the Combustion Air (MCAL)

$$Q_{\text{MCAL}} = e 4.76 \left(X + \frac{Y}{2} + Z - \frac{K}{2} \right) \times 29.9 w c_{\text{steam}} (T_{\text{g}} - 25) \quad \text{(kJ)} \, , \qquad (16.68)$$

where w is the absolute or specific humidity (kg of moisture per kg of dry air), c_{steam} is the specific heat

of steam at constant pressure (1.88 kJ/(kg K)), and T_g is the temperature of exhaust gas.

Losses due to Moisture in Fuel and Combustion Generated Moisture

For 100 kg of fuel

$$Q_{ML} = (M + 9Y)[2442 + c_{steam}(T_g - 25)] \quad \text{(kJ)}\,, \tag{16.69}$$

where M is the percentage moisture content in the fuel and Y is the combustible hydrogen atoms in the fuel.

Losses due to Hot Ash or Slag (ASL)

For 100 kg of fuel

$$Q_{ASL} = A c_{p,as} T_{ash}\,, \tag{16.70}$$

where $c_{p,ash}$ is the specific heat of ash (0.55–0.6 kJ/(kg, K)), T_{ash} is the temperature of the ash or slag, and T_{ash} varies from 300 to 800 °C.

Radiation and Unaccounted-for Losses (RUL)

This calculation captures losses due to radiation and incomplete combustion resulting in hydrogen and hydrocarbons in the flue gases. While the radiation and unaccounted loss is relatively small, it is difficult to determine accurately. In practice, this loss is 3–5%.

$$Q_{RCL} = A_s(h_s)(T_{surface} - T_{amb}) \quad \text{(kW)}\,, \tag{16.71}$$

where A_s is the total surface area (m^2), and h_s is the surface heat transfer coefficient.

16.27 Performance of Steam Generator

16.27.1 Boiler Efficiency

This is the measure of the capability of the boiler to transfer heat liberated in the furnace into water and steam. The boiler efficiency may be expressed in any of the following methods

$$\eta_{boiler} = \frac{\text{mass flow rate of steam} \times (\text{steam heat} - \text{feedwater heat})}{\text{fuel mass} \times \text{heating value of fuel}}$$

or

$$\eta_{boiler} = \frac{(\text{HHV} - \text{total loss})}{\text{HHV}}\,, \tag{16.72}$$

where HHV is the higher heating value of the fuel.

16.28 Furnace Design

There are two aspects of furnace design. The first is concerned with the generation of the heat; the second part involves the absorption of the heat in the furnace. The amount of fuel can be burned in the given furnace volume, liberating the required amount of heat.

The heat release rate and furnace gas temperature are two of the important parameters used for the design of the size of the furnace. The heat release rate is expressed on three different bases: furnace volume (q_v), furnace cross-sectional area, and water wall area in the burner region (q_b).

The important thermal characteristic of the furnace for design analysis are:

- Heat release rate per unit cross-sectional area
- Heat release rate per unit volume
- Heat release rate per unit wall area of the burner region

16.28.1 Heat Release Rate per Unit Volume q_v

The amount of heat generated by the combustion of fuel in a unit effective volume of the furnace is given by

$$q_v = \frac{m_f \times \text{LHV}}{V_{furnace}} \quad \text{(kW/m}^3\text{)}\,, \tag{16.73}$$

where m_f is the designed fuel consumption rate (kg/s), LHV is the lower heating value of the fuel (kJ/kg), V_f is the volume of the furnace ($a \times b \times h_f$), and h_f is the height of the furnace.

The value of q_v depends on the coal type and type of furnace.

The volumetric heat release rate also depends on the ash characteristic, firing method, and the arrangement of the burners. The proper selection of the volumetric flow

rate in accord with the heat release rate will ensure that fuel particles are substantially burned.

16.28.2 Heat Release Rate per Unit Wall Area of the Burner Region

One of the most important regions in the furnace is the burner region. The heat release rate in the burner region is calculated on the basis of the water wall in this region. The heat release rate per unit wall area of the furnace depends on the following parameters [16.16]:

1. Ash characteristic
2. Fuel ignition characteristics
3. Firing method
4. Arrangement of burners

The heat release rate per unit wall area of the burner region my be written

$$q_b = \frac{m_f \mathrm{LHV}}{2(a+b)h_b} \quad (\mathrm{kW/m^2}) , \tag{16.74}$$

where a and b are the width and depth of the furnace, respectively, and h_b is the distance between the top edge of the uppermost burner and the lower edge of the lowest burner.

16.28.3 Heat Release Rate per Unit Cross-Sectional Area

This is the amount of heat released per unit cross section of the furnace. It is given by

$$q_f = \frac{m_f \mathrm{LHV}}{A_{\mathrm{furnace}}} \quad (\mathrm{kW/m^2}) , \tag{16.75}$$

where A_{furnace} is the cross-sectional area of the furnace in $\mathrm{m^2}$.

16.28.4 Furnace Exit Gas Temperature

The furnace exit gas temperature is an important design parameter. It determines the rate of heat absorption by the radiant heating surface in the furnace and that by the convective heating surface of the furnace. The optimum value of the furnace exit gas temperature is 1200–1400 °C.

16.28.5 Example Problem

An optimal operation test on a model steam generator gives the following information:

- Ultimate analysis: C: 63.4%, H: 5.7%, O: 16.8%, N: 10%, ash: 8.9%, moisture: 13%
- HHV of coal: 33 318 kJ/kg
- Combustible solid refuse: 7.5%
- Dry exhaust gas analysis: CO_2: 15.4%, CO: 0.5%, O_2: 2.8%, N_2: 81.3%
- Ambient conditions: 50 °C and 100 kPa
- Temperature of air entering the furnace: 235 °C

Design a PC (pulverized coal) furnace for a steam generator with a thermal capacity of 1000 MW with the following characteristics:

- Steam generator efficiency of 0.86
- Furnace quality factor of 0.406×10^8
- Temperature field coefficient of $M = 0.405$
- Thermal capacity of the gas of $c_p = 1.17\,\mathrm{kJ/(kg\,K)}$

A furnace can be characterized geometrically by its linear dimensions: front width a, the depth b, and the height h_f (Fig. 16.29), which are estimated according to the rated fuel consumption and the thermal, physical, and chemical properties of the fuel to be used.

Flow Rate of Fuel

$$\begin{aligned} Q_{\mathrm{boiler}} &= m_{\mathrm{coal}} \mathrm{HHV} \eta_{\mathrm{SG}} , \\ 1\,000\,000 &= m_{\mathrm{coal}} 33\,318 \eta_{\mathrm{SG}} , \\ m_{\mathrm{coal}} &= 34.899\,\mathrm{kg/s} ; \\ \mathrm{LHV} &= \mathrm{HHV} - \frac{m_{\mathrm{H_2O}}}{\mathrm{kg\ of\ fuel}} 2442 , \\ \mathrm{LHV} &= 323\,827\,\mathrm{kJ/kg} . \end{aligned}$$

Here, η_{SG} is the efficiency of the steam generator.

Heat Release Rate per Unit Volume

$$q_v = \frac{m_f \mathrm{LHV}}{V_f} \quad (\mathrm{kW/m^3}) . \tag{16.76}$$

The large content of H and O is largely volatile matter and hence the given composition is bituminous. For bituminous coal the range of value of q_v is $0.14–0.20\,\mathrm{MW/m^3}$ [16.16].

Substituting the values of q_v, m_f, and LHV (Table 16.1) we find the volume of the furnace to be

$$V = 7532.05\,\mathrm{m^3} .$$

Heat Release Rate per Unit Cross-Sectional Area

This is the amount of heat released per unit cross section of the furnace. It is given by

$$q_a = \frac{m_f \mathrm{LHV}}{A_{\mathrm{grade}}} \quad (\mathrm{kW/m^2}) , \tag{16.77}$$

Table 16.1 Typical values of the volumetric heat release (q_v) in MW/m^3

Coal type	Dry-bottom furnace q_v (MW/m^3)	Wet (slagging) bottom furnace q_v (MW/m^3)		
		Open furnace	Half-open furnace	Slagging pool
Anthracite	0.110–0.140	≤ 0.145	≤ 0.169	0.523–0.598
Semi-anthracite	0.116–0.163	0.151–0.186	0.163–0.198	0.523–0.698
Bituminous	0.14–0.20	–	–	–
Oil	0.23–0.35	–	–	–
Lignite	0.09–0.15	≤ 0.186	≤ 0.198	0.523–0.640
Gas	0.35	–	–	–

Table 16.2 Upper limits of q_a for tangentially fired furnaces

Boiler capacity (t/h)	Upper limit of q_a (MW/m^2)		
	ST[a] ≤ 1300 °C	ST = 1300 °C	ST ≥ 1300 °C
130	2.13	2.56	2.59
220	2.79	3.37	3.91
420	3.65	4.49	5.12
500	3.91	4.65	5.44
1000	4.42	5.12	6.16
1500	4.77	5.45	6.63

[a] ST = softening temperature of ash (°C)

where A_{grade} is the cross-sectional area of the grade in m^2

$$A_{\text{grade}} = ab = \frac{m_f \text{LHV}}{q_a} \quad (\text{kW/m}^2)\,. \tag{16.78}$$

Substitute the value of q_a, m_f, and LHV (Table 16.2) in (16.78) we find the grade area $ab = 441.46\,\text{m}^2$.

Heat Release Rate per Unit Wall Area of the Burner Region

The heat release rate per unit wall area of the burner region may be written

$$q_b = \frac{m_f \text{LHV}}{2(a+b)h_b} \quad (\text{kW/m}^2)\,. \tag{16.79}$$

The recommended value of the burner region heat release rate was taken as

$$h_b = 1\,\text{MW/m}^3\,.$$

$$2(a+b)h_b = 1129.80\,\text{m}^2\,.$$

Based on Tables 16.1 and 16.3, corresponding to the boiler capacity, the minimum width was chosen as $b_{\min} = 6\,\text{m}$ and $h_{\text{furnace,min}} = 11\,\text{m}$.

Based on the above constraints suitable values for a and b are

$$a = 20.62\,\text{m}\,,$$

$$b = 21.4\,\text{m}\,,$$

$$h_b = \frac{1129.8}{2(21.4+20.62)} = 13.44\,\text{m}\,.$$

The volume of the furnace region (Fig. 16.29) is therefore

$$V_{\text{furnace}} = h_{\text{furnace}}ab - \frac{a}{2}(d+d+d\tan\beta+d\tan\alpha)d\,, \tag{16.80}$$

$$V_{\text{furnace}} = h_{\text{furnace}}ab - \frac{ad}{2}(2d+d\tan\beta+d\tan\alpha)\,, \tag{16.81}$$

$$V_{\text{furnace}} = h_{\text{furnace}}ab - \frac{ad^2}{2}(2+\tan\beta+\tan\alpha)\,. \tag{16.82}$$

Substituting the values of a, b, α, β, and V_{furnace} into (16.82) yields

$$h_{\text{furnace}} = 19.33\,\text{m}\,.$$

To find the height of the hopper we insert the data into

$$h_h = \left(\frac{b-e}{2}\right)\tan\gamma = 14.56\,\text{m}\,. \tag{16.83}$$

From the geometry we calculate the total surface area as

$$\begin{aligned} &a(h_f+h_b)+a(h_f+h_b-d-d\tan\alpha-d\tan\beta \\ &\quad +d\sec\alpha+d\sec\beta)+2b(h_f+h_b) \\ &\quad -d(d+d+d\tan\alpha+d\tan\beta)+2\left[\frac{1}{2}h_h(b+e)\right] \\ &\quad +2ah_h\,\text{cos ec}\,\gamma\,. \end{aligned} \tag{16.84}$$

Table 16.3 Lower limit of h_{furnace} (m)

Boiler capacity (t/h)	65–75	130	220	420	670
Anthracite	8	11	13	17	18
Bituminous	7	9	12	14	17

Substituting all the values into (16.84), the surface area of the furnace is calculated to be 3793.98 m^2.

Adiabatic Flame Temperature

Ultimate Analysis.

$$\text{C}: \quad \frac{64.4}{12} = 5.283$$

$$\text{H}: \quad 5.7 - \frac{13}{9} = 4.255$$

$$\text{O}: \quad \frac{16.8}{16} - \left[\left(\frac{8}{9}\right)\left(\frac{13}{16}\right)\right] = 0.327$$

$$\text{N}: \quad \frac{1}{14} = 0.071$$

$$\text{Ash} \quad = 8.9$$

$$\text{Moisture} \quad = \frac{13}{18}$$

$$\text{C}_X\text{H}_Y\text{S}_Z\text{O}_K + \left(X + \frac{Y}{4} + Z - \frac{K}{2}\right)\text{O}_2$$
$$\rightarrow 15.4\text{CO}_2 + 0.5\text{H}_2\text{O} + 2.8\text{O}_2 + 81.3\text{N}_2 + Z\text{H}_2\text{O}$$

For 100 kg of fuel

$$\text{C}_{5.28}\text{H}_{4.25}\text{O}_{0.327} + 4.76 \cdot 1.162 \cdot 6.152\text{air}$$
$$\rightarrow 5.11\text{CO}_2 + 0.166\text{H}_2\text{O} + 0.933\text{O}_2$$
$$+ 27.1\text{N}_2 + 2.13\text{H}_2\text{O}\,,$$

n_{exit} (mole of exit gases)

$$= 5.11 + 0.166 + 0.93 + 27.1 + 2.13 = 35.43\,,$$
$$100 \cdot 33\,318 = 35.43 \cdot 40 \cdot (T_{\text{th}} - T_{\text{atm}})\,,$$

$$T_{\text{th}} = 2624\,\text{K}\,.$$

The ash softening temperature is $\geq 1250\,^{\circ}\text{C}$ and $T_{\text{out}} \leq 1250\,^{\circ}\text{C} = 1523$ K.

100 kg of fuel generates 1056.71 of exhaust flue gas with m_{gas} for a 34.89 kg/s of flow rate of fuel, $m_{\text{gas}} = 368.68$ kg/s.

To find T_{out} we use

$$A_{\text{furnace}} = \frac{G m_{\text{f}} c_{\text{p}}}{T_{\text{th}}^3}\left[\frac{1}{m}\left(\frac{T_{\text{th}}}{T_{\text{out}}} - 1\right)\right]^{1/0.6}\,, \quad (16.85)$$

where G is the furnace quality factor, M is the temperature field coefficient, T_{th} is the theoretical combustion temperature, A_{furnace} is the total surface area of furnace, and m_{f} is the mass flow rate of fuel.

Substituting all these values in (16.85) we find $T_{\text{out}} = 1365.95$ K.

T_{out} is < 1523 K (ash softening temperature), so the design is safe.

16.29 Strength Calculations

Special care must be taken in the design and stress analysis of steam generators because of the application of high pressure and temperature involved in the system. Allowable stresses in the pressure vessel depend on the nature of the loading in the pressure vessel and the response to this loading.

Stress can be classified into:

1. Primary stress
2. Secondary stress
3. Peak stress

The *primary stress* is developed by the mechanical load; it can cause mechanical failure of the vessel. An example of this kind of stress is that produced by internal pressure such as in a steam drum. *Secondary stress* is due to mechanical load or thermal expansion. *Peak stress* is concentrated in highly localized area at abrupt geometry changes.

16.29.1 Mathematical Formulae for Stress

The basic equation for the longitudinal stress σ_1 and hoop stress σ_2 in a vessel of thickness of h, longitudinal radius r_1, and circumferential stress r_2, which is subjected to a pressure p is given by

$$\frac{\sigma_1}{r_1} + \frac{\sigma_2}{r_2} = \frac{p}{h}\,. \quad (16.86)$$

From this equation, and by equating the total pressure load with the longitudinal forces acting on a transverse section of this vessel, the stresses in the commonly used shells of revolution can be found.

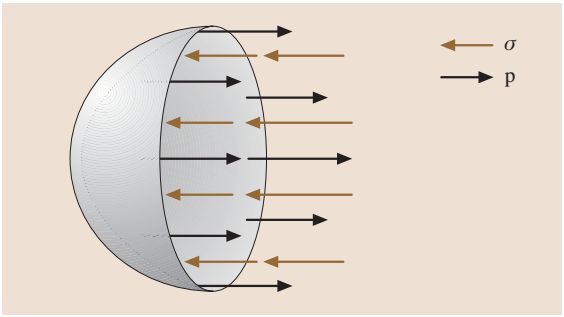

Fig. 16.49 Cross-sectional view of spherical vessel

16.29.2 Stress Analysis Methods

Stress analysis of pressure vessel can be performed by analytical or experimental methods. The general shapes of a pressure vessel are spheres, cylinders, and ellipses.

Spherical Vessel ($r_1 = r_2 = r$). Consider a spherical pressure vessel with radius r and wall thickness h subjected to an internal pressure. All four normal stresses on a small stress in the wall must be identical, due to symmetry. Furthermore there can be no shear stress. The normal stresses σ can be related to the pressure p by inspecting the free-body diagram of the pressure vessel. To simplify the analysis, cut the vessel in half as illustrated in Fig. 16.49.

The stress around the wall must have a net resultant to balance the internal pressure across the cross section

$$\sigma h 2\pi r = p\pi r^2 ,$$

$$\sigma_1 = \frac{pr}{2h} , \tag{16.87}$$

$$\sigma_2 = \frac{pr}{2h} . \tag{16.88}$$

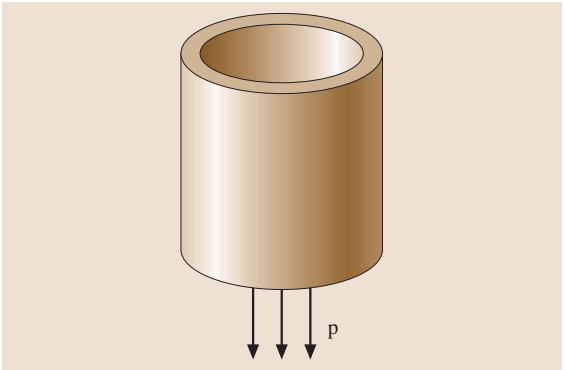

Fig. 16.50 Stress analysis of cylindrical vessel

Cylindrical Vessel ($r_1 = \infty$, $r_2 = r$).

$$\sigma_1 = \frac{pr}{2h} , \tag{16.89}$$

$$\sigma_2 = \frac{pr}{h} . \tag{16.90}$$

Conical Vessel $r_1 = \infty$, $r_2 = r/\cos\alpha$, Where α is the Half-Cone Angle.

$$\sigma_1 = \frac{pr}{2h\cos\alpha} , \tag{16.91}$$

$$\sigma_2 = \frac{pr}{h\cos\alpha} . \tag{16.92}$$

Elliptical Vessel.

$$\sigma_1 = \frac{pr_2}{2h} , \tag{16.93}$$

$$\sigma_2 = \frac{p}{h}\left(r_2 - \frac{r_2^2}{2r_1}\right) . \tag{16.94}$$

16.29.3 Design Pressure and Temperature

Generally, the design pressure is the maximum allowable working pressure. It should not be less than the highest set pressure of any safety valve. The determination of the allowable stresses is based upon the design temperature T, which should not be taken to be less than the mean wall metal temperature (through thickness) expected under operating conditions for the part considered. The design temperature is to be stated by the manufacturer on the drawings of the pressure parts submitted for consideration.

The design of pressure parts is based on the allowable stress S in $\mathrm{N/mm^2}$.

The minimum thickness of straight tubes is to be determined as

$$t = \frac{pD_o}{20SE + p} + C , \tag{16.95}$$

where p is the design pressure (bar), t is the minimum thickness (mm), D_o is the outside diameter (mm), S is the allowable stress ($\mathrm{N/mm^2}$), E is the weld efficiency of longitudinally welded tubes, and C is the corrosion allowance (mm).

The efficiency factor E is the welding efficiency of the longitudinal joint or of ligaments between tube holes or other openings.

16.30 Heat Transfer Calculation

16.30.1 Heat Exchangers

Heat exchangers play a vital role in power plant to transfer heat from hot to cold fluids. Heat exchangers with different flow configurations such as parallel flow, counterflow, and crossflow types are generally used.

Heat Transfer Analysis in a Counterflow Heat Exchanger

A counterflow heat exchanger, where the fluid moves in parallel but opposite direction, is shown in Fig. 16.51.

The thermal design of a heat changer involves the calculation of the surface area required to transfer heat at a given rate for given flow rates and fluid temperatures. The size of the heat exchanger can be obtained from the general heat transfer equation,

$$Q = U_o A_o \Delta T_{lm} \,, \tag{16.96}$$

where A_o is the outside heat transfer surface area based on the outside diameter of the tube, U_o is the overall heat transfer coefficient based on the outside diameter of the tube, and ΔT_{lm} is the log mean temperature difference

$$\Delta T_{lm} = \frac{\Delta T_1 - \Delta T_2}{\ln(\Delta T_1 / \Delta T_2)} \,, \tag{16.97}$$

where $\Delta T_1 = T_{h1} - T_{c2}$ and $\Delta T_2 = T_{h2} - T_{c1}$ for a counterflow heat exchanger.

16.30.2 Flow Resistance

Friction resistance values for the actual pipes and volume flows may be obtained from special charts made for the pipes or tubes considered.

Minor pressure losses due to fittings as bends, elbows, valves, and similar may be calculated as

$$p_2 = \xi \frac{\rho v^2}{2} \text{ or expressed as } \textit{head} \tag{16.98}$$

$$h_{loss} = \xi \frac{v^2}{2} g \,, \tag{16.99}$$

where ξ is the minor loss coefficient, p_{loss} is the pressure loss (Pa = N/m^2), ρ is the density (kg/m^3), v is the flow velocity (m/s), h_{loss} is the head loss (m), and g is the acceleration of gravity (m/s^2).

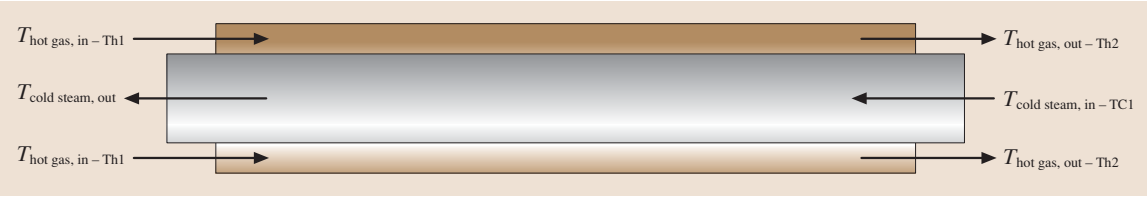

Fig. 16.51 Heat transfer along a heat exchanger

16.31 Nuclear Reactors

Nuclear reactors are devices designed to maintain a chain reaction producing neutrons generated by the fission of heavy nuclei. Nuclear power plants utilizing power reactors are dedicated to generate heat, mainly for electricity production. They are operated in more than 50 countries [16.17].

16.31.1 Components of a Nuclear Reactor

The major components of a nuclear reactor are:

1. The fuel core
2. The moderator and coolant
3. The control rods
4. The reactor vessel

Fuel Core

The fuel core contains the nuclear fuel and is the part of the reactor where the fission reaction takes place. The nuclear fuel may be either natural or enriched uranium. Natural uranium contains 0.71% fissile ^{235}U and 99.28% fertile ^{238}U and fertile thorium Th-232. The enriched uranium is produced in a gaseous diffusion process and is expected to have a ^{235}U content of 2–33%.

The nuclear fuel is generally contained in cylindrical rods surrounded by cladding materials. The fuel-rod

cladding materials must not only be able to maintain the shape of the fuel rod, but also to sustain the reactor conditions. Materials used for these components include aluminum, magnesium, stainless steel, and graphite.

Moderator and Coolant

The moderator is the substance used in a nuclear reactor to reduce the energy of fast neutrons to thermal neutrons. Liquid and solid materials with low atomic mass number and low neutron capture cross section should be suitable. These include light water, heavy water, carbon, and beryllium.

The reactor coolant is used to remove heat from the reactor fuel core. The conditions for a better coolant include high specific heat, high thermal conductivity, and high boiling point at low pressure. The coolant should also have low power demand for pumping, low cost, and a high degree of stability in the reactor environment.

Control Rods

Control rods are used to slow down or speed up a chain reaction. Elements like boron and cadmium are used in a control rod to absorb fast neutrons and thereby control the chain reaction. An automatic retractable mechanism helps to insert the control rods into the fuel core or withdraw them to slow down or speed up the chain reaction. Shim rods, regulating rods, and safety rods are three different types of control rods.

Reactor Vessel

The reactor vessel is a tank-like structure that holds the reactor core and other internal components. The walls of the vessel are designed for a high-pressure radiation environment. In most cases the vessel walls are lined with thick steel slabs to reduce the flow of radiation from the core. As indicated in the last section, nuclear fission generates large amounts of neutrons and gamma rays, both of which are very harmful. Because of these, biological shielding is required around the reactor vessel. This shield consists of concrete blocks, which may be up to 2 m thick.

16.31.2 Types of Reactors

There are four types of reactors:

1. Pressurized water reactors (PWR)
2. Boiling water reactors (BWR)
3. Pressurized heavy-water reactor (PHWR)
4. Gas-cooled reactors (Magnox)

When ^{235}U is bombarded with neutrons, fission reactions take place, releasing neutrons that fission more atoms of ^{235}U. In order that the freshly released neutrons are able to fission further uranium atoms, their speeds must be reduced to a critical value. Therefore, for the reaction to be sustained, nuclear fuel rods must be embedded in neutron speed-reducing agents (such as graphite and heavy water) called moderators. For reaction control, rods made of neutron-absorbing material (boron steel) are used which, when inserted into the reactor vessel, control the amount of neutron flux, thereby controlling the range. A schematic diagram of a nuclear power plant is shown in Fig. 16.52. The heat released by the nuclear reaction is transported to a heat exchanger via primary coolant (CO_2, water etc.). Steam is then generated in the heat exchanger, which is used in a conventional manner to generate electric energy by means of a steam turbine. Various types of reactors are used in practice for power plant purposes, viz. advanced gas reactors (AGR), boiling water reactors (BWR), heavy-water-moderated reactors, etc.

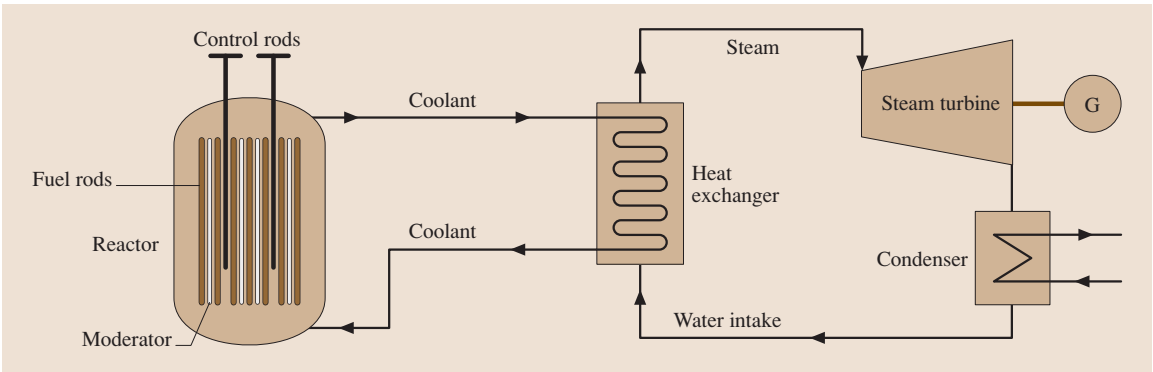

Fig. 16.52 Schematic view of a nuclear power plant

The CANDU reactor using natural uranium (in oxide from), moderated using pressurized heavy water is adopted in India. Its schematic diagram is shown in Fig. 16.53.

The associated merits and problems of nuclear power plants as compared to conventional thermal plants are discussed in the next paragraphs.

Merits and Demerits of Nuclear Power Plants

Merits. A nuclear power plant is totally free of air pollution and requires little fuel in terms of volume and weight; it therefore poses no transportation problems and may be sited, independently of nuclear fuel supplies, close to load centers. However, safety considerations require that they are normally located far away from populated areas.

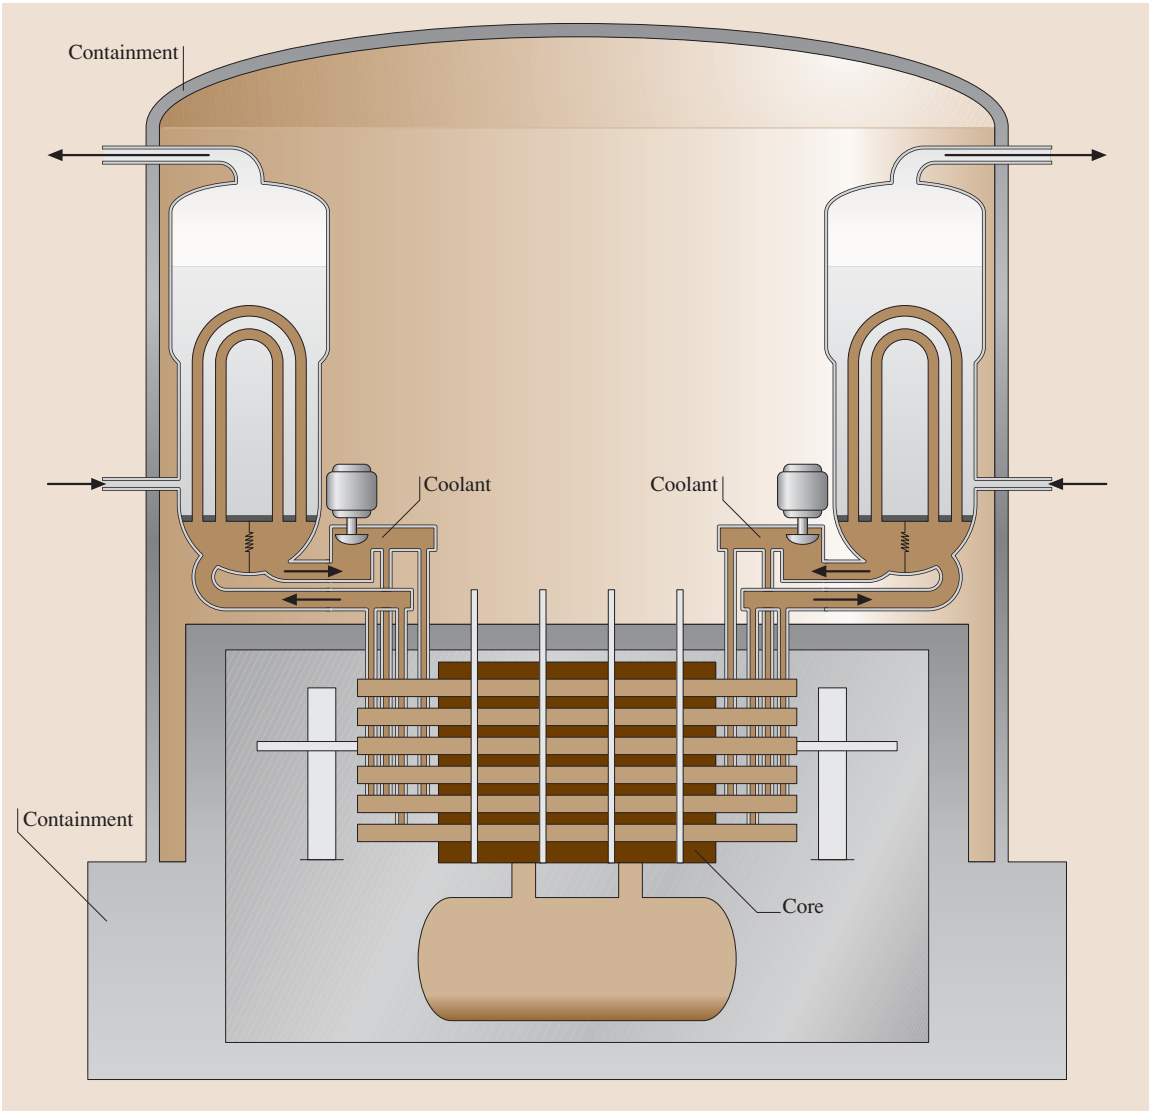

Fig. 16.53 CANDU reactor. Pressurized heavy-water-moderated design adopted in India

Demerits. Nuclear reactors produce radioactive fuel waste, the disposal of which poses serious environmental hazards. The rate of nuclear reaction can be lowered only by a small margin, so that the load on a nuclear power plant can only be marginally reduced below its full load value. Because of the relatively high capital cost against running cost, the nuclear plant should operate continuously as the base load station. Whenever possible, it is preferable to support such a station with a pumped storage scheme mentioned earlier. The greatest danger in a fission reactor is in the case of the loss of coolant in a accident. Even with the control rods fully lowered quickly, called a scram operation, fission continues and its afterheat may cause the vaporization and dispersal of radioactive material.

World uranium resources are quite limited, and at the present rate may not last much beyond 50 years. However, there is a redeeming feature. During the fission of ^{235}U some of the neutrons are absorbed by the more abundant uranium isotope ^{238}U (enriched uranium contains only about 3% of ^{235}U while most of it is ^{238}U) converting it to plutonium (^{239}U), which in itself

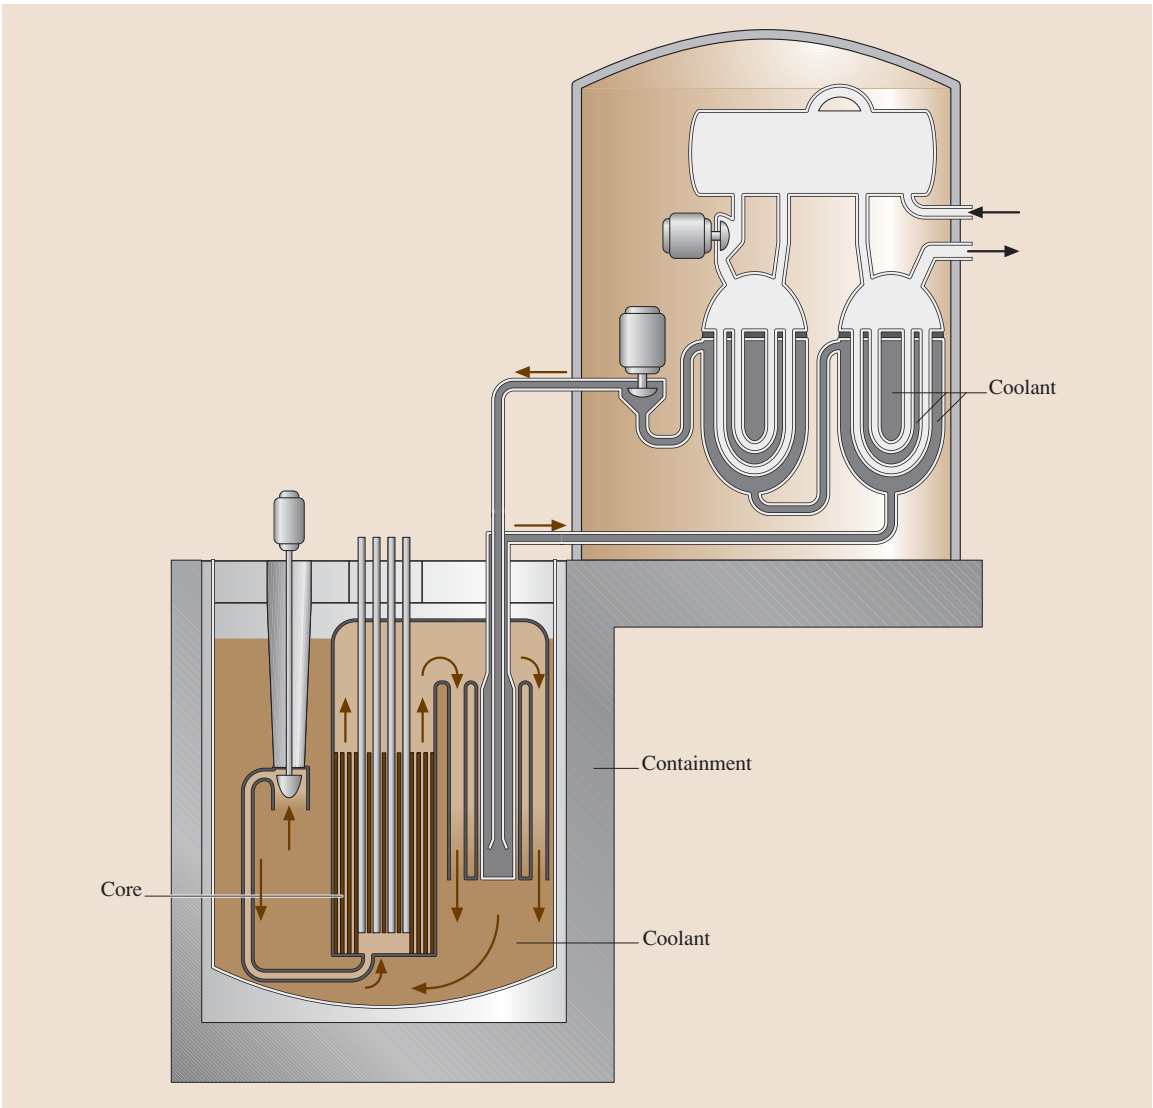

Fig. 16.54 A fast breeder reactor

is a fissionable material and can be extracted from the reactor fuel waste by a fuel reprocessing plant. Plutonium can then be used in the next-generation reactors (fast breeder reactors (FBRs)), thereby considerably extending the life of nuclear fuels. The FBR technology is being intensely developed as it will extend the availability of nuclear fuels at predicted rates of energy consumption to several centuries.

Figure 16.54 shows the schematic diagram of an FBR. It is essential that, for breeding operation, the conversion ratio (fissile material generated/fissile material consumed) is more than unity. This is achieved by fast-moving neutrons so that no moderator is needed, although the neutrons do slow down slightly through collision with structural and fuel elements. The energy density/kg of fuel is very high and so the core is small. It is therefore necessary that the coolant should possess good thermal properties; hence liquid sodium is used. The fuel for an FBR consists of 20% plutonium plus 8% uranium oxide. The coolant, liquid sodium, leaves the reactor at 650 °C at atmospheric pressure. The heat transported in this way is led to a secondary sodium circuit which transfers it to a heat exchanger to generate steam at 540 °C.

With a breeder reactor the release of plutonium, an extremely toxic material, make the environmental considerations very stringent.

An experimental fast breeder test reactor (FBTR) (40 MW) has been built at Kalpakkam alongside a nuclear power plant. FBR technology is expected to reduce the cost of electric energy so that it compares favorably with that from conventional thermal plants.

16.32 Future Prospects and Conclusion

Various advanced power generation technologies have been described in this chapter. Many regions of the world are experiencing fast growing electricity demand. Advanced technologies such as IGCC, ultra-supercritical cycles, and advanced gasification molten carbonate fuel cell cycles allow this electricity demand to be met and emission levels from power plants to meet air quality standards. Fluidized-bed combustion is an environmentally benign and proven technology for the disposal of solid wastes and the generation of electrical energy. Technological advancement will improve the reliability and efficiency of energy conversion process. The integrated gasification combined cycle will be able to exploit various kinds of low-grade energy resources such as biomass, low-grade coal, oil residues etc., for the sake of efficient power production. The development of advanced materials to withstand high temperatures as well as high pressures will enhance the thermal efficiency to 55%. Even a fraction of a percentage improvement in efficiency can mean huge savings in annual fuel cost.

Cogeneration of heat as well as electric power is one of the attractive options from the cost–benefit point of view; it saves 30–40% of fuel input energy. A combined cycle employing cogeneration using a multicomponent fluid such as an ammonia–water mixture will improve the thermal efficiency further. Effective utilization of renewable sources of energy including hydropower, solar, wind, and biomass is one of current the challenging tasks for researchers. The potential of solar power is unlimited; it is our prime task to utilize this energy in a more effective way. The development of solar technology seeks to achieve efficient operation even though solar energy intensity varies according to weather and time of day.

With the end of coal reserves in sight in the not too distant future, the immediate practical alternative source of large-scale electric energy generation is nuclear energy. The latest power plant technologies and dedicated research will lead to efficiencies approaching the Carnot efficiency in the near future.

17. Electrical Engineering

Seddik Bacha, Jaime De La Ree, Chris Oliver Heyde, Andreas Lindemann, Antje G. Orths, Zbigniew A. Styczynski, Jacek G. Wankowicz

Electricity is the most flexible form of energy accessible to humans. It can be transported over long distances, and transformed into almost any other kind of energy like heat, radiation or kinetic energy. Electrical engineering is very closely coupled especially to mechanical engineering but also to many other fields of engineering.

This chapter will give an overview of the theoretical fundamentals of electric phenomenon and some practical electric processes and application. It should be understood as a basic source of information about the most important issues in electrical engineering. For further reading the references will give a deeper insight into the mentioned scientific fields. The reader will get information about the fundamentals of electrical engineering in Sect. 17.1. Here the physical phenomenon of electric currents and voltages are explained. The electrical aspects of the main electrical machines transformer, generators and motors are explained in the Sects. 17.2, 17.3 and 17.5.

Power electronics have become a very important issue in transformation of different forms of electricity and in control of machinery. The reader will be informed about the basic working principles of this scientific field in Sect. 17.4.

This chapter places a emphasis on the section *Electric Power Transmission and Distribution* (17.6). In this section the fundamentals of electricity transport, distributed generation (especially from renewable sources) and the energy system protection are given.

17.1 Fundamentals

In electric engineering most of the phenomenon can be explained using some fundamental laws. These law are explained in Sect. 17.1.1. In the following subsections the basics about the electric circuits, starting from the DC current, and ending with the explanation of AC circuits with capacitance and inductance [17.1, 2]. The section closes with comments about multi phase networks and the behavior of some materials important for electrical engineering [17.1, 3].

17.1.1 Electric Field Basics

Fields and Equations

The electromagnetic field (EMF) in any given area of space should comply with the laws of electrodynamics [17.4]. This field can be described by the five field parameters presented in Table 17.1.

Based on experimental knowledge, four laws are known to be valid for electromagnetic fields: Maxwell's laws; in integral form they can be written as Ampère's, Faraday's, and Gauss's laws.

Ampère's Law. The first of Maxwell's laws is often called the general Ampère's law (17.1a)

$$\oint_C \boldsymbol{H}\,\mathrm{d}\boldsymbol{s} = \int\int_A \left(\boldsymbol{J} + \frac{\partial \boldsymbol{D}}{\partial t}\right)\mathrm{d}\boldsymbol{A} \tag{17.1a}$$

to which is added

$$I = \int\int_A \boldsymbol{J}\,\mathrm{d}\boldsymbol{A} \tag{17.1b}$$

and

$$\oint_C \boldsymbol{H}\,\mathrm{d}\boldsymbol{s} = I + \frac{\partial}{\partial t}\int\int_A \boldsymbol{D}\,\mathrm{d}\boldsymbol{A}\,. \tag{17.1c}$$

Ampère's law (17.1a) requires that the line integral (circulation) of the magnetic field intensity $\boldsymbol{H}$ around a closed contour $\boldsymbol{s}$ is equal to the sum of the line current I and electric displacement $\boldsymbol{D}$ through the surface $\boldsymbol{A}$.

Induction – Faraday's Law.

$$\oint_c \boldsymbol{E}\,\mathrm{d}\boldsymbol{s} = -\frac{\partial}{\partial t}\int\int_A \boldsymbol{B}\,\mathrm{d}\boldsymbol{A} \tag{17.2}$$

Faraday's law of induction requires that the line integral (circulation) of the electric field intensity $\boldsymbol{E}$ is equal to the negative time derivative of the magnetic flux density through the surface $\boldsymbol{A}$.

Magnetism – Gauss's Law.

$$\int\oint_A \boldsymbol{B}\,\mathrm{d}\boldsymbol{A} = 0 \tag{17.3}$$

Gauss's law states that the net magnetic flux out of any closed surface $\boldsymbol{A}$ is zero. This amounts to a statement about the sources of a magnetic field. For a magnetic dipole, in any closed surface the magnetic flux directed inward toward the south pole is equal to the flux outward from the north pole. The net flux will always be zero for dipole sources. If there were a magnetic monopole source, this would give a nonzero area integral. Furthermore, the divergence of a vector field is proportional to the point-source density, so the form of Gauss's law for magnetic fields is therefore a statement that there are no magnetic monopoles.

Electricity – Gauss's Law.

$$\int\oint_A \boldsymbol{D}\,\mathrm{d}\boldsymbol{A} = Q \tag{17.4}$$

The electric flux outside any closed surface is proportional to the charge Q.

The field parameters are related to three equations (17.5)–(17.7), which refer to materials of different physical properties

$$\boldsymbol{J} = \sigma\boldsymbol{E}\,, \tag{17.5}$$

$$\boldsymbol{D} = \varepsilon\boldsymbol{E}\,, \tag{17.6}$$

$$\boldsymbol{B} = \mu\boldsymbol{H}\,. \tag{17.7}$$

The current density and electric displacement are proportional to the electric field strength, while the flux

Table 17.1 Field parameters and symbols

	Field parameters	Symbol
Electric field	Electric displacement	$\boldsymbol{D}$
	Electrical field strength	$\boldsymbol{E}$
Magnetic field	Flux density	$\boldsymbol{B}$
	Magnetic field strength	$\boldsymbol{H}$
Electric flow field	Current density	$\boldsymbol{J}$

density is proportional to the magnetic field strength. The *electrical conductivity* σ, the *dielectric coefficient* ε and the *permeability* μ are generally tensors, but in isotropic substances may also be scalars.

The field equations are only applicable to rapidly changing processes, but can be adapted to slow processes, for application at typical technical frequencies. Each of these equations can be reduced for constant field parameters.

Electrostatic Field

Electrostatic field is a field of constant – in time – field parameters created by stationary charges. It is often called the electric field. Assuming constant field parameters and a static charge (on a dielectric surface), the following equation is valid

$$\oint_S \boldsymbol{E}\,\mathrm{d}\boldsymbol{s} = 0 \tag{17.8}$$

Equations (17.4), (17.6) and (17.8) together represent the basic relations for electrostatics.

The dielectric coefficient ε can be described as the product of the *permittivity of free space* ε_0 (vacuum) and the *relative permittivity* ε_r

$$\varepsilon = \varepsilon_0 \varepsilon_r \,, \tag{17.9}$$

where

$$\varepsilon_0 = 8.85 \times 10^{-12}\,\mathrm{A\,s/V\,m}\,.$$

The same is also valid for the permeability μ

$$\mu = \mu_0 \mu_\mathrm{r} \,, \tag{17.10}$$

with

$$\mu_0 = \frac{4\pi}{10} \times 10^{-6} = 1.25610^{-6}\,\mathrm{V\,s/A\,m}\,.$$

The electrical field strength (17.8) can also be described by (17.11).

$$\boldsymbol{E} = -\mathbf{grad}\,\varphi \,, \tag{17.11}$$

where ϕ is the scalar potential function.

From this, it is clear that the voltage is independent of the path of integration taken between two points and only depends on the difference of the potentials

$$\boldsymbol{V}_{12} = \int_1^2 \boldsymbol{E}\,\mathrm{d}\boldsymbol{s} = V_1 - V_2\,. \tag{17.12}$$

The electrostatic field can be illustrated using the equipotential lines, $\phi = \mathrm{const}$, and orthogonal field lines, which run over the tangential vector of the electrical field; see Fig. 17.1.

The electric force in an electrical field is defined as

$$\boldsymbol{F} = \int_Q \boldsymbol{E}\,\mathrm{d}Q \tag{17.13}$$

and can be created with a single point charge in the simplest case.

Consider two particles separated by a distance of $\boldsymbol{r}$ (in m) carrying charges of Q_1 and Q_2 coulombs, respectively. The force on Q_2 is given by

$$\boldsymbol{F}_2 = Q_2 \boldsymbol{E}\,, \tag{17.14}$$

where $\boldsymbol{E}$ is the electric field due to all charges except Q_2. In the present case there is only one charge other than Q_2. Let Q_1 be located at the origin of the spherical coordinates, then

$$\boldsymbol{E} = \frac{Q}{4\pi\varepsilon r^2}\boldsymbol{r}_0\,. \tag{17.15}$$

Using (17.15) for the electric field due to a point charge, we can deduce Coulomb's law

$$\boldsymbol{F}_2 = \boldsymbol{r}_0 \frac{Q_1 Q_2}{4\pi\varepsilon r^2}\,. \tag{17.16}$$

As one can see, the electric force between two charged particles is proportional to the product of the two charges and inversely proportional to the square of the distance between them. The unit vector $\boldsymbol{r}_0$ points into the direction of the connection line between two particles. If Q_1 and Q_2 are opposite in sign, the force is attractive, otherwise it is repulsive.

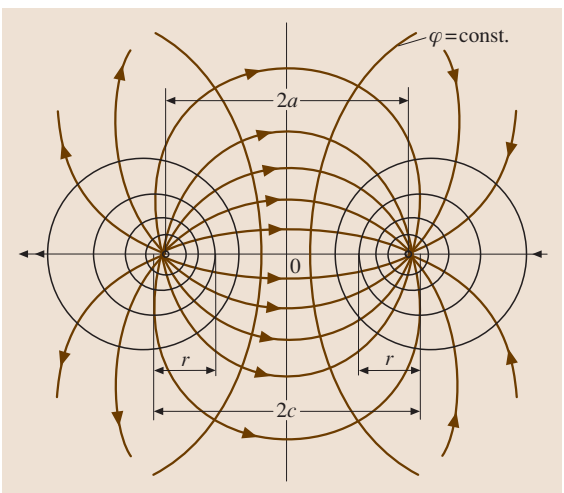

Fig. 17.1 Field characteristic [17.2]

Stationary Flow Field

Stationary flow field is an electric field in conducting surrounding. I an static stationary field all floating currents are constant in time. The current that passes through a surface is determined by the integral of the current density (17.17). The relationship between the electrical field strength $\boldsymbol{E}$ and current density $\boldsymbol{S}$ is given by (17.5).

$$I = \int\int_A \boldsymbol{S}\mathrm{d}\boldsymbol{A} \tag{17.17}$$

If a voltage V is present between two points of an electric circuit, the resistance R exists due to the constant conductivity σ. Based on (17.12) and (17.1b) the relation (17.18) known as Ohm's law can be written

$$R = \frac{V}{I} = \frac{1}{\sigma}\int_1^2 \boldsymbol{E}\,\mathrm{d}s \Big/ \int\int_A \boldsymbol{S}d\boldsymbol{A}\,. \tag{17.18}$$

The current flow generates losses in resistance, which turns into heat. Using *Joule's law* (Ohmic loss per volume p) this value can be determined exactly using

$$p = \sigma E^2 = (1/\sigma)S^2\,. \tag{17.19}$$

Stationary Magnetic Field

Stationary magnetic field is a field constant in time created by permanent magnets or direct current. Using Ampère's law for stationery conditions the path of integration of $\boldsymbol{H}$ along the contour $\boldsymbol{s}$ is equal to the total current I that flows through this area

$$\oint_S \boldsymbol{H}\,\mathrm{d}\boldsymbol{s} = I\,. \tag{17.20}$$

The relationship between field strength and flux density is still valid

$$\boldsymbol{B} = \mu\boldsymbol{H}\,.$$

Lastly, the characteristic of magnetization (flux density $\boldsymbol{B}$ across field strength) is nonlinear for ferromagnetic materials.

17.1.2 Electric Circuits

Direct-Current (DC) Circuits

This section discusses circuits composed of direct-voltage sources and ohmic resistance, which are connected by electrical conductors. The resistance through which the electric current flows causes a voltage drop, which is defined using (17.18)

$$V = RI$$

and, respectively

$$I = GV\,, \tag{17.21}$$

where I is the direct current, that is characterized by constant in time value and sense while $G = 1/R$ is the reciprocal of the resistance R, usually called the conductance.

The electric power P is the product of current I and voltage V and is defined as

$$P = VI = RI^2 = V^2/R\,. \tag{17.22}$$

The direct-voltage source can be presented as an ideal source (ideal voltage V source) connected in series with an internal resistance R_s, e.g., a battery. The source can also be represented as a load-independent DC current source I_s connected in parallel to an internal resistance R_s, see Fig. 17.2.

Under the condition that current density $\boldsymbol{S}$ is a constant value the resistance R can be also calculated on the basis of parameters that describe geometrical and material properties of a conductor such as length l, cross-section A, and resistivity ρ

$$R = \rho l/A\,. \tag{17.23}$$

The parameter $\rho = 1/\kappa$ is called the material resistivity and depends generally on physical properties

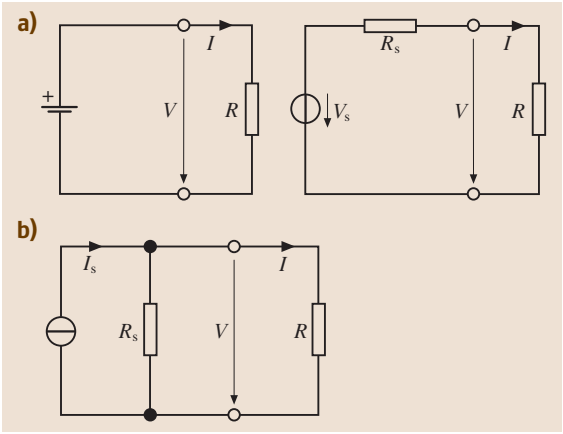

Fig. 17.2a,b Voltage and current sources: (a) imposed voltage; (b) imposed current

of the material and its temperature. It has a linear characteristic for many materials. The resistivity ρ_{20} – determined at a temperature of 20 °C – is a reference value for calculations of the parameter ρ using (17.24). The resistivity ρ_{20} is a material constant.

$$\rho = \rho_{20}(1 + \alpha(\vartheta - 20\,^{\circ}\mathrm{C}))\,, \tag{17.24}$$

where ϑ is the actual temperature of a conductor and α is the specific temperature coefficient.

Kirchhoff's Laws

- Kirchhoff's current law (KCL). The first Kirchhoff law says that, at each node in any electrical network and at each moment of time, the algebraic sum of all currents leaving a node is zero

$$\sum_{i=1}^{n} I_i = 0\,. \tag{17.25}$$

- Kirchhoff's voltage law (KVL). One of the most significant aspects of series circuits is described by the second Kirchhoff law, which states that the algebraic sum of the voltage rises and drops over all elements in any closed loop is equal to zero

$$\sum_{i=1}^{n} V_i = 0 \tag{17.26}$$

Using these two equations the values of parallel and serial connected resistances can be calculated:

- For serial connection

$$R_{\mathrm{res}} = \sum_{i=1}^{n} R_i \tag{17.27}$$

- For parallel connection

$$G_{\mathrm{res}} = \sum_{i=1}^{n} G_i = \sum_{i=1}^{n} \frac{1}{R_i} = \frac{1}{R_{\mathrm{res}}} \tag{17.28}$$

Kirchhoff's laws can also be used as variables in time-dependent currents and voltages. Taken together, these laws have created the basis of network theory.

Example 17.1: The calculation of the cross current in bridge circuits

Let us now consider a bridge circuit as an example circuit. In Fig. 17.3 the load-independent voltage source supplies the circuit, which is composed of the

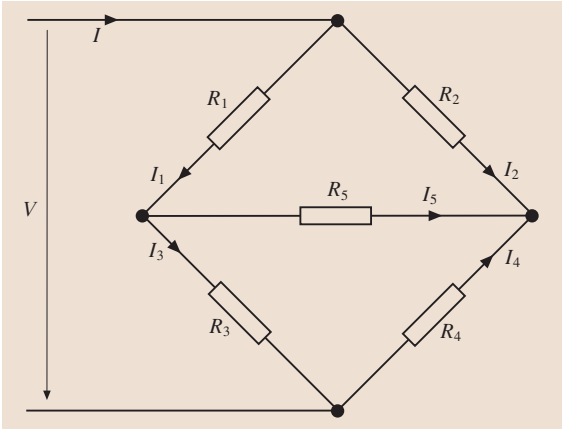

Fig. 17.3 Bridge circuit

bridge sections $R_1, \ldots, R_4$ and one cross branch R_5. The network has four nodes $n = 4$, and three independent equations $(n - 1 = 3)$ can be created on the basis of the first Kirchhoff law (17.24).

$$\begin{aligned} I &= I_1 + I_2\,, \\ I &= I_3 + I_4\,, \\ I_5 &= I_1 - I_3\,. \end{aligned} \tag{17.29}$$

On the basis of the second Kirchhoff law (17.26) a next set of equations can be written

$$\begin{aligned} 0 &= R_1 I_1 + R_3 I_3 - V\,, \\ 0 &= R_1 I_1 + R_5 I_5 - R_2 I_2\,, \\ 0 &= R_3 I_3 - R_5 I_5 + R_4 I_4\,. \end{aligned} \tag{17.30}$$

Taking into account these equations the current in the cross branch can be calculated as

$$\begin{aligned} I_5 = V(R_2 R_3 - R_1 R_4) \big/ [&R_5(R_1 + R_3)(R_2 + R_4) \\ &+ R_1 R_3(R_2 + R_4) + R_2 R_4(R_1 + R_3)]\,. \end{aligned} \tag{17.31}$$

The cross current I_5 disappears in a balanced bridge. This is valid when

$$\frac{R_1}{R_2} = \frac{R_3}{R_4}\,. \tag{17.32}$$

Example 17.2: Converting a star connection into a delta connection

This transformation is often used to simplify the calculation of larger networks.

In Fig. 17.4 the star connection with resistances R_1, R_2, and R_3 follows the same currents and voltage drops

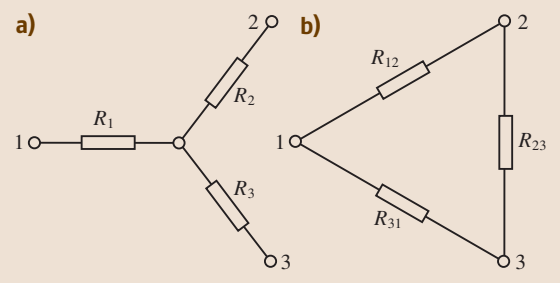

Fig. 17.4a,b Connection types: (a) star connection; (b) delta connection

with regard to points 1, 2, and 3 as the delta connection with resistances R_{12}, R_{23}, and R_{31} only when the following equations are fulfilled

$$R_1 = \frac{R_{31}R_{12}}{R_{12}+R_{23}+R_{31}}\,, \tag{17.33}$$

$$R_{12} = R_1 + R_2 + \frac{R_1 R_2}{R_3}\,, \tag{17.34}$$

$$R_2 = \frac{R_{12}R_{23}}{R_{12}+R_{23}+R_{31}}\,, \tag{17.35}$$

$$R_{23} = R_2 + R_3 + \frac{R_2 R_3}{R_1}\,, \tag{17.36}$$

$$R_3 = \frac{R_{23}R_{31}}{R_{12}+R_{23}+R_{31}}\,, \tag{17.37}$$

$$R_{31} = R_3 + R_1 + \frac{R_3 R_1}{R_2}\,. \tag{17.38}$$

Capacitor

The relationship between the capacitance C, charge Q, and voltage V is given

$$C = \frac{Q}{V} = \int\limits_A \int \boldsymbol{D}\,\mathrm{d}\boldsymbol{A} \Big/ \int\limits_D \boldsymbol{E}\,\mathrm{d}s\,. \tag{17.39}$$

The simplest example of a capacitor (Fig. 17.5) is the parallel plate capacitor. It consists of two conductive plate shaped electrodes separated by a dielectric.

By disregarding the side effects and using (17.5–17.7) we can define the following relationships

$$\varphi = \frac{Q}{\varepsilon A}x\,, \tag{17.40}$$

$$E = \frac{Q}{\varepsilon A} = \frac{V}{d}\,, \tag{17.41}$$

$$C = \frac{Q}{V} = \varepsilon\frac{A}{d}\,. \tag{17.42}$$

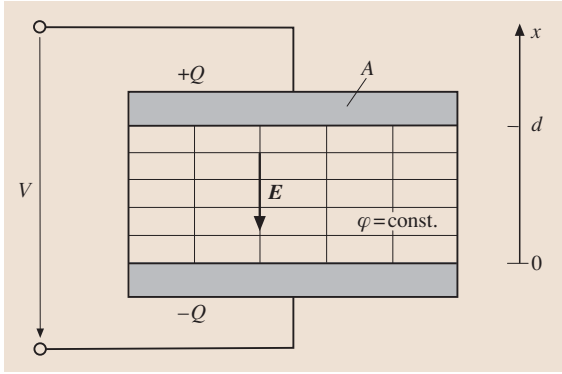

Fig. 17.5 Principle circuit of capacitor [17.2]

The equations (17.39–17.41) are also suitable for variable charge q and voltage v

$$i = \frac{\mathrm{d}q}{\mathrm{d}t} = C\frac{\mathrm{d}v}{\mathrm{d}t}\,. \tag{17.43}$$

The energy W_S in the capacitor can be generally calculated by the formula

$$W_s = \int\limits_0^V q\,\mathrm{d}v = \frac{1}{2}CV^2\,. \tag{17.44}$$

Faraday's Law

Faraday's law is a fundamental relationship which comes from Maxwell's equations. It serves as a succinct summary of the ways a voltage (or EMF) may be generated by a changing magnetic environment. The induced EMF in a coil is equal to the negative (Lenz's law) of the rate of change of magnetic flux times the number of turns in the coil. It involves the interaction of the charge with the magnetic field.

This law shows exactly that any change in the magnetic environment of a coil of wire will cause a voltage (electromagnetic field) to be *induced* in the coil. Regardless of which way the change is produced, a voltage will be generated. The change could be produced by changing the magnetic field strength, moving a magnet toward or away from the coil, moving the coil into or out of the magnetic field, rotating the coil relative to the magnet, etc.

$$v_i = -N\frac{\mathrm{d}\Phi}{\mathrm{d}t}\,, \tag{17.45}$$

where N is the number of turns and Φ is the magnetic flux.

Inductor

An inductor is a two-terminal device that consists of coiled conducting wire. A current flowing through the device produces a magnetic flux which forms closed loops encircling the coils making up the inductor. Suppose that the coil contains N turns and that the flux passes through each turn.

In a linear inductor, the magnetic flux linkage ψ is directly proportional to the current flowing through the device.

The equation (17.46) defines the so-called inductance L with the unit Henry

$$L = \frac{\psi}{I} = \frac{\sum \Phi_n}{I} \,. \tag{17.46}$$

Using (17.45) and (17.46), an important relationship for inductors can be obtained

$$V = L\frac{\mathrm{d}i}{\mathrm{d}t} \,. \tag{17.47}$$

Clearly, as i increases, a voltage is generated between the terminals of the inductor, the polarity of which is shown in Fig. 17.6. This voltage opposes an increase in i, as if this were not the case and the polarity was reversed, the induced voltage would *aid* the current.

Just as work was performed in moving charges between the plates of a capacitor, work is necessary to establish the flux in the inductor. The work energy required in this case is said to be stored in the magnetic field.

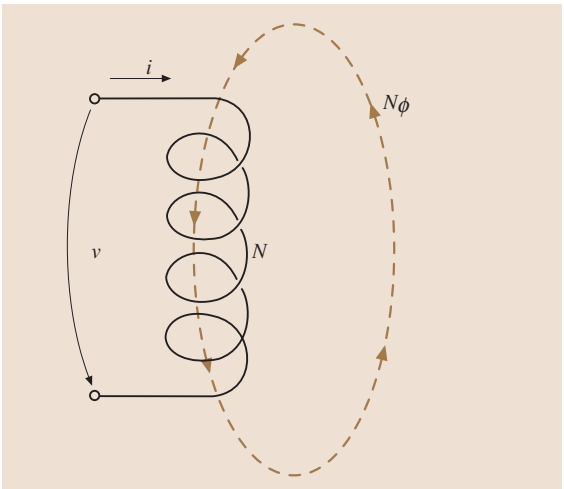

Fig. 17.6 Principle of an inductor

The energy stored in an inductor is given by

$$W_\mathrm{m} = \int_0^I \Phi \,\mathrm{d}i = \frac{1}{2} L I^2 \,. \tag{17.48}$$

Magnetic Materials

The behavior of materials in a magnetic field can be described as:

- Paramagnetic
- Diamagnetic
- Ferromagnetic

The permeability μ_r of the first two types of materials is approximately unity. However, ferromagnetic materials, particularly iron, nickel, and cobalt behave differently. In the presence of a magnetic field they produce con-

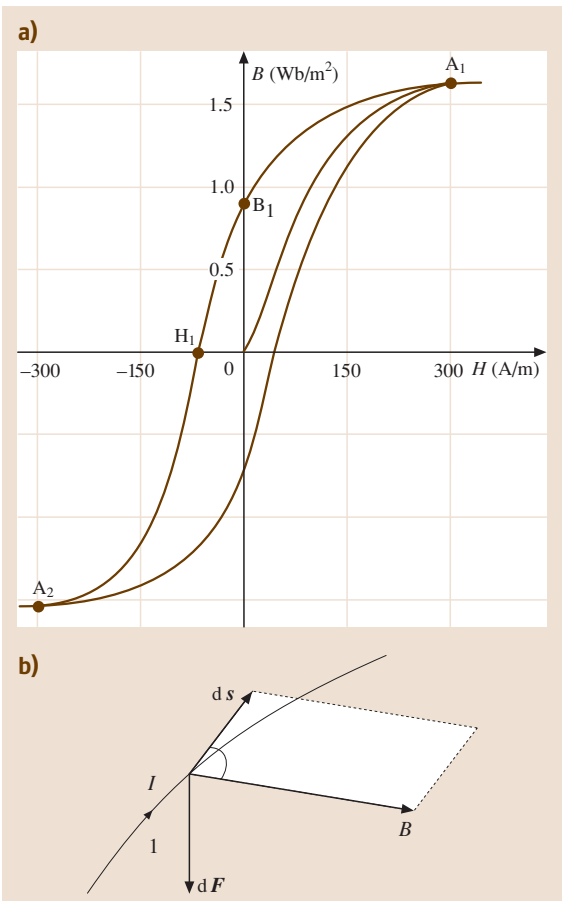

Fig. 17.7 **(a)** Hysteresis curve; **(b)** conductor l leading current I

siderably more magnetic flux density than air. The magnetic flux density B reinforcement is expressed by

$$B = J + \mu_0 H = \mu_0 (M + H) , \tag{17.49}$$

where J is the magnetic polarization and M is the magnetization.

Ferromagnetic materials show magnetization characteristics in the form of a hysteresis curve $B = f(H)$, see Fig. 17.7a. After initial magnetization to the point A_1, the H field is decreased by reducing the current in the coil, the magnetic flux density B is also reduced, but the B–H curve does not follow the original magnetization curve. Note that at point B_1 the current in the coil of a toroid is equal to zero, as is H, yet the residual magnetic flux density B is nonetheless present in the toroid.

The residual flux is due to the fact that the magnetic moments of some of the domains in the ferromagnetic materials are still aligned in the same direction. The magnitude of this residual B is called the remanence. If we now reverse the current to reverse the H, the B–H curve will trace a curve $B_1 H_1$, as shown in Fig. 17.7. Note that it takes some negative value of H to null the B field. The value of H_1 in the negative direction of the initial magnetization, necessary to nullify the magnetic inductance B field, is called the coercive force or coercivity. If the reverse current is increased beyond this point, the magnetic inductance B begins to reverse and the B–H curve follows the curve $H_1 A_2$. If the current is now reduced, the B–H curve traces a new path $A_2 A_1$. The closed loop $A_1 B_1 H_1 A_2 A_1$ is called a hysteresis loop. If the current is varied in a smaller cycle, the corresponding hysteresis loop will be smaller. If the material is brought to saturation in both ends of the magnetization curve, the remanence B is called the retentivity of the ferromagnetic material, and the coercive force H is called the coercivity of the material.

In general both soft and hard magnetic materials are useful in electrical engineering. The first are used for constructing magnetic circles in electrical machines (slim hysteresis curve), while hard magnetic materials are used in permanent magnets.

Electromagnetic Field Forces

An electromagnetic field can be defined by the force it produces. Generally, the force in a field is defined as

$$\boldsymbol{f}_v = (\boldsymbol{S} \times \boldsymbol{B}) - \frac{1}{2} \boldsymbol{H}^2 \mathbf{grad}\, \mu . \tag{17.50}$$

The first part of (17.50) gives the current density force, which affects the current leading conductor in the external field from B induction. The second part appears only for position-dependent permeability and is expressed as a permeable force density.

For the length element $\mathrm{d}\boldsymbol{s}$ of an electrical conductor the force is expressed as

$$\mathrm{d}\boldsymbol{F} = I(\mathrm{d}\boldsymbol{s} \times \boldsymbol{B}) . \tag{17.51}$$

The force is determined for a cable with length l, which is located in a vertical magnetic field (Fig. 17.7b)

$$F = BIl . \tag{17.52}$$

The so-called *right-hand rule* is applied to determine the direction of the magnetic force.

A magnetic force can also be specified for two parallel electrical conductors. The current I_1 generates the field strength H at a distance r in conductor 1, in agreement with (17.1a)

$$H = I_1/(2\pi r) . \tag{17.53}$$

A second conductor located at the distance d and carrying the current I_2 is affected by the force

$$F = \frac{\mu_0}{2\pi} \frac{I_1 I_2}{d} l . \tag{17.54}$$

The value of the forces in conductors 1 and 2 is the same. When both the current in the two conductors is in the same direction electrostatic attraction occurs. If, on the other hand, the direction of the current in the two conductors is different then repulsion occurs.

Moreover, mechanical tensions are produced on the interface of a magnetic field, between areas with differential permeability. On the interface between iron and air longitudinal pull and lateral pressure develop.

If a magnetic field with inductance B passes vertically through a surface that combines areas with μ_1 and μ_2, a specific force σ is accrued normal to this surface

$$\sigma = \frac{1}{2} \left(\frac{1}{\mu_1} - \frac{1}{\mu_2} \right) B^2 . \tag{17.55}$$

When $\mu_1 = \mu_0$ for air and $\mu_2 = \mu_0 \mu_r \gg \mu_0$ for iron the electrostatic attraction force through surface A can be defined by

$$F = \frac{1}{2\mu_0} B^2 A . \tag{17.56}$$

This is applied in electromagnets carrying ferromagnetic loads.

17.1.3 Alternating Current (AC) Engineering

Alternating Current Quantities

For a periodic current waveform $i(t)$ with period T and frequency $f = 1/T$ the following definitions can be written

- The average value

$$\bar{i} = \frac{1}{T}\int_0^T i\,\mathrm{d}t \tag{17.57}$$

- The effective, root-mean-square (RMS) value

$$I = \sqrt{\frac{1}{T}\int_0^T i^2\,\mathrm{d}t} \tag{17.58}$$

The average value $\bar{v}$ and the RMS value V of an alternating voltage $v(t)$ are defined in a similar way.

The AC waveform current containing a DC component consists of a fundamental frequency and higher harmonics that are integer multiples of the fundamental frequency. The RMS value of such a current is

$$I = \sqrt{\bar{i}^2 + I_1^2 + I_2^2 + I_3^2 + \ldots} = \sqrt{\bar{i}^2 + I_{\approx}^2}\,. \tag{17.59}$$

The deformation of an alternating current through harmonics can be calculated using the distortion factor

$$k_\mathrm{i} = \sqrt{1 - \left(\frac{I_\mathrm{i}}{I}\right)^2}\,. \tag{17.60}$$

In this case a fundamental current will be defined as

$$i = \hat{i}\cos(\omega t + \varphi)\,, \tag{17.61}$$

where $\hat{i}$ is the peak value of the current and $\omega = 2\pi f$ is the angular speed.

The average value $\bar{i}$ of the current i (17.57) is zero while the effective value is

$$I = \hat{i}/\sqrt{2}\,. \tag{17.62}$$

The same refers to voltages and therefore

$$V = \frac{\hat{v}}{\sqrt{2}}\,. \tag{17.63}$$

RMS value of a current I refers directly to the Ohmic resistance by thermal energy dissipated by this both at flow of direct current or its alternating equivalent of defined RMS value which produces the same thermal effect.

Active power P produced by current I of given RMS value can be written as

$$P_\mathrm{V} = R\frac{1}{T}\int_0^T i^2\,\mathrm{d}t = RI^2\,. \tag{17.64}$$

Currents like that in (17.61) flow in branches with linear elements if the applied voltages and currents also have a sine waveform with a fundamental frequency, and transition processes have faded away.

Alternating Current Parameters

Every alternating current parameter is represented by its:

- Amplitude
- Effective value
- Frequency
- Phasing ($t = 0$)

Applying these parameters the current and voltage can be expressed as follows

$$i = \mathrm{Re}\left(\sqrt{2}I\mathrm{e}^{\mathrm{j}(\omega t+\varphi_i)}\right) = \mathrm{Re}\left(\sqrt{2}\underline{I}\mathrm{e}^{\mathrm{j}\omega t}\right)\,, \tag{17.65}$$

with $\underline{I} = I\mathrm{e}^{\mathrm{j}\varphi_\mathrm{i}}$

$$v = \mathrm{Re}\left(\sqrt{2}V\mathrm{e}^{\mathrm{j}(\omega t+\varphi_u)}\right) = \mathrm{Re}\left(\sqrt{2}\underline{V}\mathrm{e}^{\mathrm{j}\omega t}\right)\,, \tag{17.66}$$

with $\underline{V} = V\mathrm{e}^{\mathrm{j}\varphi_u}$.

Now, by giving the angular frequency ω the current and voltage can be sufficiently described by using the complex parameters $\underline{I}$ and $\underline{V}$, which contain information about the absolute value and phasing.

The ratio of $\underline{I}$ to $\underline{V}$ is complex and denotes the impedance $\underline{Z}$, which consists of the component's resistance R and reactance X. Its multiplicative inverse gives the admittance $\underline{Y}$, which consists of the conductance G and the susceptance B

$$\underline{Z} = \underline{V}/\underline{I} = R + \mathrm{j}X\,, \tag{17.67}$$

$$\underline{Y} = \underline{I}/\underline{V} = 1/\underline{Z} = G + \mathrm{j}B\,. \tag{17.68}$$

The passive linear elements in alternating current circuits are:

- Ohmic resistance
- Capacitors
- Inductors

By using (17.65)–(17.68) it is very easy to evaluate these elements for AC

$$v_R = Ri \rightarrow V_R = RI \rightarrow Z_R = R\,, \tag{17.69}$$

$$i_\mathrm{c} = C\frac{\mathrm{d}v}{\mathrm{d}t} \rightarrow I_\mathrm{c} = \mathrm{j}\omega CV \rightarrow Z_\mathrm{c}\,,$$

$$\underline{Z}_\mathrm{c} = 1/\mathrm{j}\omega C = -\mathrm{j}X_\mathrm{c}\,, \tag{17.70}$$

$$v_\mathrm{l} = L\frac{\mathrm{d}i}{\mathrm{d}t} \rightarrow V_\mathrm{L} = \mathrm{j}\omega LI \rightarrow Z_\mathrm{L}\,,$$

$$\underline{Z}_\mathrm{L} = \mathrm{j}\omega L = \mathrm{j}X_\mathrm{L}\,. \tag{17.71}$$

Accordingly, in relation to the voltage the current phase is shifted by $-\pi/2$ by an inductor, and by $+\pi/2$ by a capacitor. A resistance does not produce an angular phase shift.

Electric Power

In one-phase circuits the momentary value of electric power is expressed by

$$p(t) = v(t)i(t)\,. \tag{17.72}$$

When the current and voltage have a sine waveform one can use (17.65) and (17.66) to deduce

$$\begin{aligned} p(t) &= VI[\cos\varphi + \cos(2\omega t + \varphi_\varepsilon)] \\ &= P + S\cos(2\omega t + \varphi_\varepsilon)\,, \end{aligned} \tag{17.73}$$

where $\varphi = \varphi_u - \varphi_i$ and $\varphi_\varepsilon = \varphi_u + \varphi_i$.

P is the active power, Q the reactive power, and S the apparent power. Some additional important equations (Fig. 17.8b) are given below

$$P = VI\cos\varphi\,, \tag{17.74}$$

$$S = VI\,, \tag{17.75}$$

$$Q = \sqrt{S^2 - P^2} = VI\sin\varphi\,. \tag{17.76}$$

In complex form, the power can be written

$$S = P + \mathrm{j}Q\,. \tag{17.77}$$

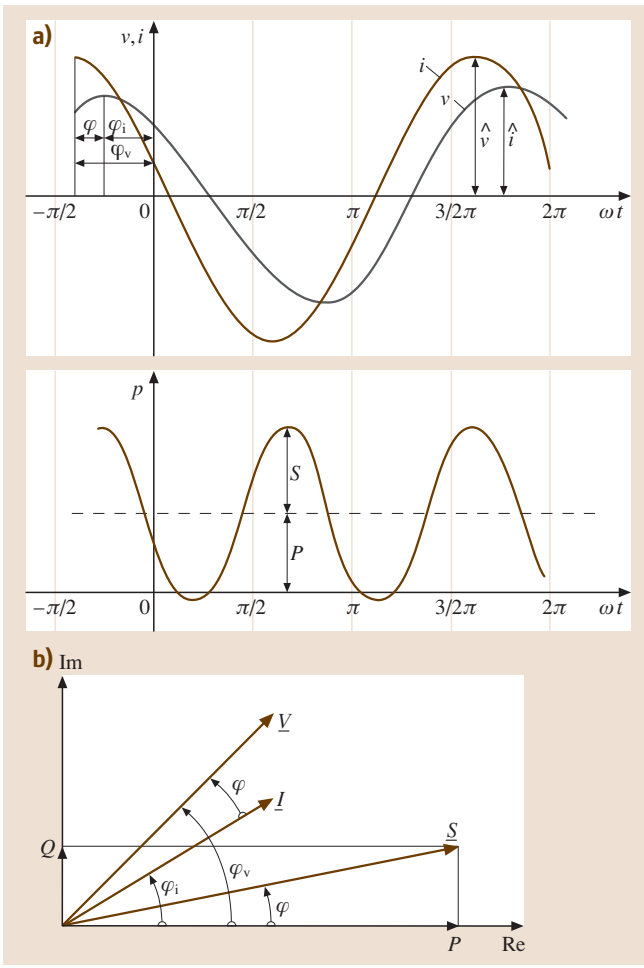

Fig. 17.8a,b Alternating values diagram: **(a)** characteristics of current, voltage, and power; **(b)** phasor diagram [17.2]

Three-Phase Current

The three-phase current system can be connected in one of two topologies: star or delta connection (Fig. 17.9).

The three-phase system is symmetrical when its values have equal amplitudes with equal frequencies and every phase is delayed by $2\pi/3$.

This can be applied to the voltage system

$$\begin{aligned} v_1 &= \sqrt{2}V\cos\omega t \rightarrow \underline{V}_1 = V\,, \\ v_2 &= \sqrt{2}V(\cos\omega t - 2\pi/3) \rightarrow \underline{V}_2 = V\,\mathrm{e}^{-\mathrm{j}2\pi/3}\,, \\ v_3 &= \sqrt{2}V(\cos\omega t - 4\pi/3) \rightarrow \underline{V}_3 = V\,\mathrm{e}^{\mathrm{j}2\pi/3}\,. \end{aligned} \tag{17.78}$$

Generally, the three phases are labeled as follows:

- U (1 phase), L_1 – line 1
- V (2 phase), L_2 – line 2
- W (3 phase), L_3 – line 3

In Fig. 17.9 the symmetrical star and delta connections are shown. The line-to-line voltages V_{12}, V_{23}, and V_{31}, and the line-to-line currents I_1, I_2, and I_3, together follow the relations given below.

Star Connection

The line-to-line currents are equal to the line-to-neutral currents

$$I_1 = I_{1N}\,; \quad I_2 = I_{2N}\,; \quad I_3 = I_{3N}\,.$$

The line-to-line voltages are equal to the differences of the line-to-neutral voltages

$$\begin{aligned} V_{12} &= V_{1N} - V_{2N} \\ V_{23} &= V_{2N} - V_{3N} \\ V_{31} &= V_{3N} - V_{1N}\,. \end{aligned} \tag{17.79}$$

If they are symmetrical

$$\begin{aligned} I_\mathrm{L} &= I_\mathrm{iN}\,, \\ V_\mathrm{L} &= \sqrt{3}V_\mathrm{iN}; \end{aligned}$$

as well as

$$I_N = -I_1 - I_2 - I_3 = 0 \,.$$

The neutral line does not carry a current and is dispensable.

Delta Connection

The line-to-line currents are equal to the difference between the line-to-neutral currents

$$\begin{aligned} I_1 &= I_{12} - I_{31} \\ I_2 &= I_{23} - I_{12} \\ I_3 &= I_{31} - I_{23} \,. \end{aligned} \tag{17.80}$$

The line-to-line voltages are equal to the line-to-neutral voltages

$$\begin{aligned} V_{12} &= V_{UV} \\ V_{23} &= V_{VW} \\ V_{31} &= V_{WU} \,. \end{aligned} \tag{17.81}$$

If they are symmetrical

$$\begin{aligned} V_L &= V_{iN} \,, \\ I_L &= \sqrt{3} I_{iN} \,. \end{aligned} \tag{17.82}$$

In three-phase systems the power is independent of the circuit type

$$P = \sqrt{3} V_L I_L \cos\varphi = S \cos\varphi \,. \tag{17.83}$$

The active power is constant in time, and the reactive power is defined as

$$Q = \sqrt{3} V_L I_L \sin\varphi = S \sin\varphi \,. \tag{17.84}$$

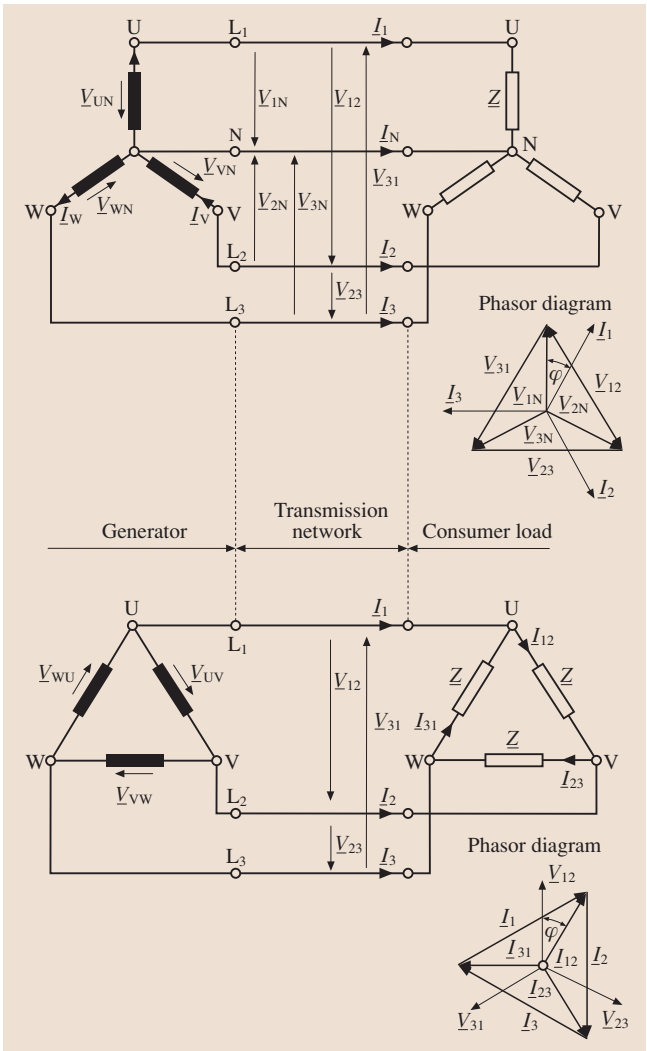

Fig. 17.9 Symmetrical three-phase system in the star and delta connections

Symmetrical Components. Figure 17.10 shows the systems with symmetrical currents and voltage, which are characterized by equal amplitudes and a delay of each phase by $2\pi/3$. An asymmetrical load, and especially asymmetrical short circuits, create an asymmetrical system. The method of symmetrical components will be used to analyze the circuits in this section.

Symmetrical components are used to analyze non symmetrical network conditions. Usually networks are supposed to work symmetrical, which means that loads are distributed equally to all phases and no disturbance takes place. However, if an unsymmetrical situation occurs, the method of symmetrical components is applied. This method allows for separation of the unsymmetrical phasors into three systems of symmetrical phasors.

The equations (17.85) and (17.86) show the transformation to symmetrical components and the back transformation. The three systems can be described as follows:

- Positive sequence system: three phasors each shifted by 120°, rotating in the same direction as the original phasors (index 1)

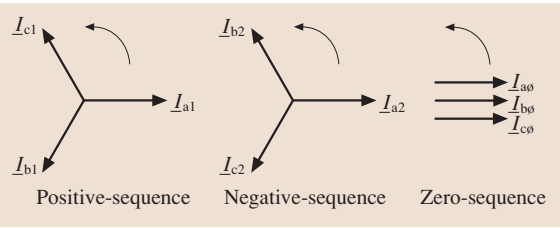

Fig. 17.10 Symmetrical components

- Negative sequence system: three phasors each shifted by 120°, rotating in the same direction but with different phase sequence (acb) (index 2)
- Zero sequence system: all phasors point to the same direction (index 0)

$$\begin{pmatrix} \underline{I}_0 \\ \underline{I}_1 \\ \underline{I}_2 \end{pmatrix} = \frac{1}{3} \begin{pmatrix} 1 & 1 & 1 \\ 1 & \underline{a} & \underline{a}^2 \\ 1 & \underline{a}^2 & \underline{a} \end{pmatrix} \begin{pmatrix} \underline{I}_\mathrm{U} \\ \underline{I}_\mathrm{V} \\ \underline{I}_\mathrm{W} \end{pmatrix} , \qquad (17.85)$$

where $a = \mathrm{e}^{\mathrm{j}2\pi/3}$

$$\begin{pmatrix} \underline{I}_\mathrm{U} \\ \underline{I}_\mathrm{V} \\ \underline{I}_\mathrm{W} \end{pmatrix} = \frac{1}{3} \begin{pmatrix} 1 & 1 & 1 \\ 1 & \underline{a}^2 & \underline{a} \\ 1 & \underline{a} & \underline{a}^2 \end{pmatrix} \begin{pmatrix} \underline{I}_0 \\ \underline{I}_1 \\ \underline{I}_2 \end{pmatrix} . \qquad (17.86)$$

Furthermore, phase currents from symmetrical components can be recalculated each time.

Now an unsymmetrical system is composed of three symmetrical systems which can be analyzed with the methods explained above. Unsymmetrical system conditions are mainly caused by unsymmetrical short-circuits or heavily unsymmetrical loads.

The symmetrical components method is effective in short-circuit calculations of electrical machines and networks.

Transfer Locus Diagram. A transfer locus for one complex surface is a geometrical area for the end points of all phasors and depends on one real parameter. which is usually the angular frequency ω, but may also be the frequency of oscillation.

Taking into account the circuit in Fig. 17.11a, the impedance transfer locus will be represented as $\underline{Z} = R + \mathrm{j}\omega L$.

The result for the admittance $\underline{Y} = 1/Z$ is a semicircle, because $\underline{Z}(\omega)$ is only valid for positive imaginary values.

By suitable scale fitting and fixed applied voltage $\underline{V}$, the $\underline{Y}(\omega)$ locus also represent the current locus $\underline{I}(\omega)$. In this case the voltage drops on resistance and inductance add to the supplied voltage.

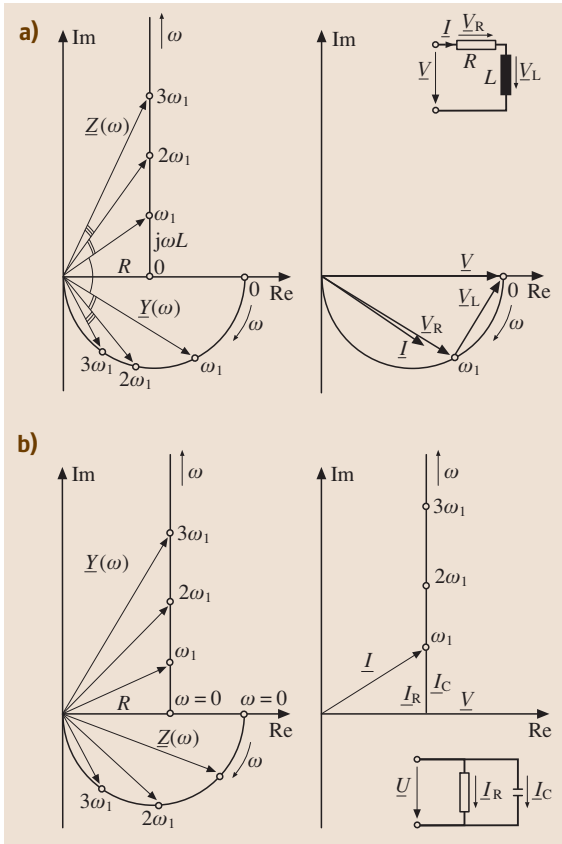

Fig. 17.11a,b Transfer locus diagram of an RL load: **(a)** serial circuit; **(b)** parallel circuit

The complex admittance of the circuit, which consists of the parallel connected resistance and inductance, can be seen in Fig. 17.11b.

$$\underline{Y} = \frac{1}{R} + \mathrm{j}\omega C \qquad (17.87)$$

More complicated circuits naturally create more highly organized transfer locus diagrams.

Oscillating Circuits and Filters

Passive equivalent circuits, which consist of capacitors and inductors, are oscillatory structures. Excitation between different energy storages (capacitors and inductors) could create interchange in the form of oscillations. A circuit is resonant at a certain frequency if the reactive components of the impedance (admittance) are equal to zero. Parallel and serial resonant circuits are two of the simplest resonant circuits. In the parallel circuit, it is assumed that current is the excitation and the

Table 17.2 Resonant circuit parameters

Circuit	Serial $\underline{Z} = R + \mathrm{j}(\omega L - \frac{1}{\omega C})$	Parallel $\underline{Y} = G + \mathrm{j}(\omega C - \frac{1}{\omega L})$
Resonance	$\omega_0 = \frac{1}{\sqrt{LC}}$, $Z_0 = \sqrt{\frac{L}{C}} = \frac{1}{Y_0}$	$\omega_0 = \frac{1}{\sqrt{LC}}$, $Z_0 = \sqrt{\frac{L}{C}} = \frac{1}{Y_0}$
Damping	$d_\mathrm{s} = \frac{1}{2}\frac{R}{Z_0} = \frac{1}{2Q_r}$ $\underline{Y} = Y_0 \frac{1}{2d_\mathrm{r} + \mathrm{j}\left(\frac{\omega}{\omega_0} - \frac{\omega_0}{\omega}\right)}$ $\underline{I} = \underline{Y}\,\underline{V}$	$d_\mathrm{p} = \frac{1}{2}\frac{G}{Y_0} = \frac{1}{2Q_\mathrm{p}}$ $\underline{Z} = Z_0 \frac{1}{2d_\mathrm{p} + \mathrm{j}\left(\frac{\omega}{\omega_0} - \frac{\omega_0}{\omega}\right)}$ $\underline{V} = \underline{Z}\,\underline{I}$

voltage the response, the converse being true in the serial case. Hence, the impedance of one can be obtained from the admittance of the other by interchanging L and C and replacing R in the serial circuit by G in the parallel circuit. Consequently, we can treat one of the circuits in detail and apply the results to the other one simply by interchanging the appropriate parameters.

Table 17.2 summarizes the most important parameters for resonant circuits, where d is the damping and Q is the performance.

For resonant circuits we typically consider the functions $\underline{Y}/\underline{Y}_0$ for serial and $\underline{Z}/\underline{Z}_0$ for parallel circuits.

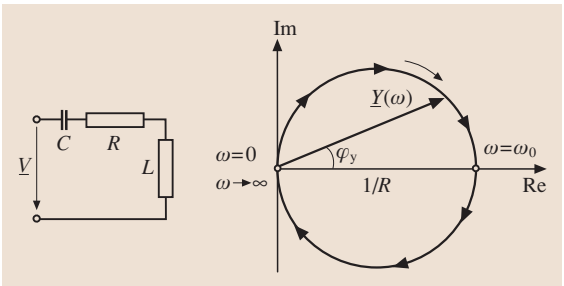

Fig. 17.12 Transfer locus diagram of a serial oscillating circuit

Four Terminals

An active four-terminal network consists of two terminal network input terminals (I_1, V_1) and two output terminals (I_2, V_2). An active four-terminal network consists of current or voltage sources, otherwise it is passive.

For passive terminal networks the following relations can by written:

Chain form (forward)

$$\begin{pmatrix} \underline{V}_1 \\ \underline{I}_1 \end{pmatrix} = \begin{pmatrix} \underline{A}_{11} & \underline{A}_{12} \\ \underline{A}_{21} & \underline{A}_{22} \end{pmatrix} \begin{pmatrix} \underline{V}_2 \\ \underline{I}_2 \end{pmatrix} \qquad (17.88)$$

Resistance form

$$\begin{pmatrix} \underline{V}_1 \\ \underline{V}_2 \end{pmatrix} = \begin{pmatrix} \underline{Z}_{11} & \underline{Z}_{12} \\ \underline{Z}_{21} & \underline{Z}_{22} \end{pmatrix} \begin{pmatrix} \underline{I}_1 \\ \underline{I}_2 \end{pmatrix}$$

Conductance form

$$\begin{pmatrix} \underline{I}_1 \\ \underline{I}_2 \end{pmatrix} = \begin{pmatrix} \underline{Y}_{11} & \underline{Y}_{12} \\ \underline{Y}_{21} & \underline{Y}_{22} \end{pmatrix} \begin{pmatrix} \underline{V}_1 \\ \underline{V}_2 \end{pmatrix}$$

Hybrid form

$$\begin{pmatrix} \underline{V}_1 \\ \underline{I}_2 \end{pmatrix} = \begin{pmatrix} \underline{H}_{11} & \underline{H}_{12} \\ \underline{H}_{21} & \underline{H}_{22} \end{pmatrix} \begin{pmatrix} \underline{I}_2 \\ \underline{V}_2 \end{pmatrix}$$

Normally, these coefficients can be determined by a short- and open-circuit investigation. The four-terminal network will be symmetrical if the resistance takes the form $Z_{22} = Z_{11}$ and $Z_{21} = Z_{12}$. The relations (17.88) are very useful for calculating more advanced circuits, e.g., filters. A passive terminal network can be characterized by two equivalent circuits: T or Π (Fig. 17.13).

For the T circuit using (17.89)

$$A_{11} = A = 1 - 2\omega^2 LC \qquad (17.89)$$

and $\omega_g = 1/\sqrt{LC}$.

The real impedance at the pass band will be defined as the characteristic impedance Z_W

$$Z_\mathrm{W} = \sqrt{\frac{A_{12}}{A_{21}}} = \sqrt{\frac{L}{C} - \omega^2 L^2}\,. \qquad (17.90)$$

Filters. Filters are circuits which are frequency selective [17.5]. By using various combinations of reactance and resistance, filter circuits can be made to either emphasize or deemphasize selected ranges of frequencies. There are four kinds of filters:

- Low-pass filters
- High-pass filters

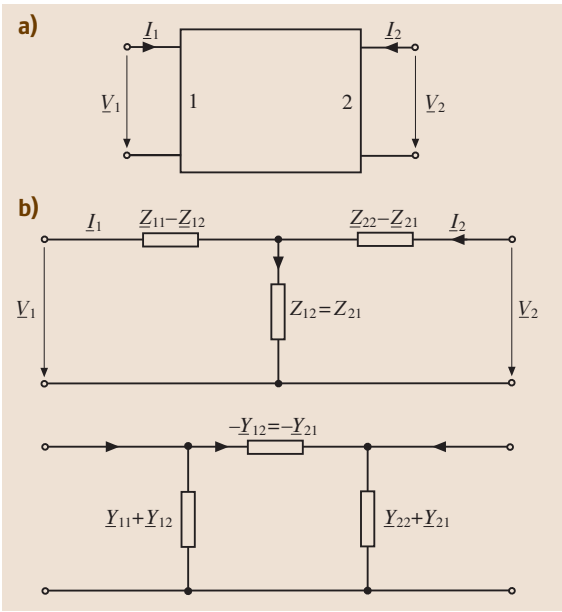

Fig. 17.13a,b Active four-terminal networks: **(a)** general circuit; **(b)** T and Π circuit [17.2]

- Resonant filters
- Multiple resonant filters

Properties of high-pass filters can be explained as follows. At first series RL and RC circuits are considered (Fig. 17.14). For the RC circuit in Fig. 17.14a the output is taken across the resistor for the high-pass filter. In this circuit, most of the input voltage drops across C at low frequencies (all of it at 0 Hz) because X_C is very large compared to R. As the frequency increases, X_C decreases so that less voltage is dropped across C and more across R. At very high frequencies X_C is so small compared to R that essentially all of the input voltage is dropped across R.

For the RL high-pass circuit shown in Fig. 17.14b, the output must be taken across the inductor. In this way, the output is zero at 0 Hz and increases as the frequency increases because of the larger voltage drop across X_L.

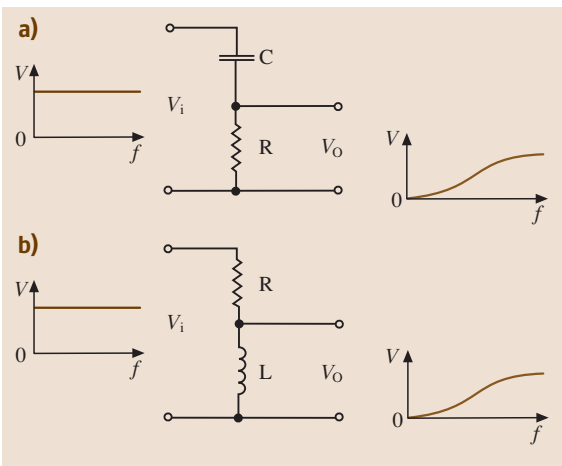

Fig. 17.14a,b High-pass filters: **(a)** series RC; **(b)** series RL

17.1.4 Networks

Transient Phenomena

Very often in networks transient phenomena take place, which consist of stationary state changes in passive elements. The states are characterized by currents or voltages at the clamps of the components and generally are excited by the switching processes taking place in the network.

The calculation of the transient phenomena can be carried out in the time domain. Moreover, for linear network systems, the Laplace transformation, which converts time functions into simple corresponding s-domain functions, can also be applied. For such systems, the operator equations resulting from a direct Laplace transformation can be created and solved by simple algebraic operations.

As mentioned, transient phenomena arise due to the closing and opening of the circuit switches. The state of the system before the switching occurs is described as the initial state. From general field theory it is known that the energy stored either in a magnetic field, in the case of an inductance, or in an electric field, in the case of a capacitor, cannot change its value the instant the switching takes place. From this law the transient phenomena in the network arise:

1. Calculation in time domain (state equation)
   The calculation of transient phenomena can be carried out by integration of the differential equations based on the set of Kirchhoff's laws for the given network. In a linear system with constant element parameters, the differential equations for the independent currents and voltages at the energy-storage components can be expressed as follows

$$\frac{\mathrm{d}x(t)}{\mathrm{d}t} = \mathbf{A}x(t) + \mathbf{B}v(t)\,. \qquad (17.91)$$

   For a general description, $x(t)$ describes the state vector, $\mathbf{A}$ is interpreted as the state matrix, $\mathbf{B}$ is the

excitation matrix, and $v(t)$ represents the input signals which result from active elements in the circuit. The solutions to the above equations can be stated as shown in the following expression

$$x(t) = \mathrm{e}^{A(t-t_0)}x(t_0) + \int_{t_0}^{t} \mathrm{e}^{A(t-\tau)}\mathbf{B}v(\tau)\,\mathrm{d}\tau\ , \tag{17.92}$$

where $x(t_0)$ is the initial state vector, which disappears for zero initial conditions. The solution to this problem can also be expressed as the sum of a transient-state component and a steady-state component

$$x(t) = x_\mathrm{t}(t) + x_\mathrm{s}(t)\ . \tag{17.93}$$

The steady-state component $x_\mathrm{s}(t)$ can be solved by commonly used calculation procedures valid for steady-state AC and DC analysis. The transient element $x_\mathrm{t}(t)$ can be computed in this case with the help of a simplified formula

$$x_\mathrm{t}(t) = \mathrm{e}^{A(t-t_0)}x_\mathrm{t}(t_0)\ , \tag{17.94}$$

where the initial condition for the above equation is stated as the difference between the initial condition $x(t_0)$ and the initial condition for the steady-state component at the instant t_0

$$x_\mathrm{t}(t_0) = x(t_0) - x_\mathrm{s}(t_0)\ .$$

It can be seen that the solution of the transient phenomena is reduced to the calculation of the e^{At} component. In order to calculate this element, three main methods are used:

- The Sylvester equation
- The Cayley–Hamilton theorem
- Eigenvalue decomposition with Jordan form representation

Among these methods only the eigenvalue transformation will now be explained in an example. Assuming that the state matrix $\mathbf{A}$ is square, the eigenvalues for this matrix can be calculated with the help of the formula

$$\det(\mathbf{A} - \mathbf{I}s) = 0\ . \tag{17.95}$$

The calculated values s_k are the basis for obtaining the eigenvectors that build the transformation matrix $\mathbf{T}$. This matrix allows us to transfer the square matrix $\mathbf{A}$ into Jordan form $\mathbf{A}_\mathrm{j}$. The sought component e^{At} can be reformulated as

$$\mathrm{e}^{At} = \mathbf{T}^{-1}\mathrm{e}^{A_\mathrm{j}t}\mathbf{T}\ . \tag{17.96}$$

The elements of the Jordan matrix contain the linear combination of the exponential and polynomial function dependent on the multiplication factors and values of the eigenvalue of the state matrix $\mathbf{A}$.

2. Laplace Transformation

Transient phenomena in a network can be calculated with the help of the Laplace transformation as well. Using operator methods based on the Laplace transformation, the state equation can be written in the following form

$$(s\mathbf{I} - \mathbf{A})\boldsymbol{X}(s) - \boldsymbol{X}(t_0) = \boldsymbol{B}\boldsymbol{V}(s)\ , \tag{17.97}$$

where I is the identity matrix. The input signal is transformed into s-domain by the following integral

$$\mathrm{Im}[f(t)] = F(s) = \int_0^\infty f(t)\mathrm{e}^{-st}\,\mathrm{d}t\ . \tag{17.98}$$

After solving the much easier algebraic equation in s-domain, the solution needs to be transformed back from the s-domain into time domain

$$\mathrm{Im}^{-1}[F(s)] = f(t) = \int_{\sigma-j\infty}^{\sigma+j\infty} F(s)\mathrm{e}^{st}\,\mathrm{d}s\ . \tag{17.99}$$

The initial conditions for the state variables are considered by the Laplace transformation and are contained in the input signals (excitation signals). To obtain the Laplace function, correspondence tables can be a useful tool. The solution of the transient phenomena is obtained by the inversion of the square matrix $(\mathbf{I}s - \mathbf{A})$ and multiplication by its excitation vector $\boldsymbol{B}\boldsymbol{V}(s) + \boldsymbol{X}(t_0)$. As a result of this approach, the polynomial functions for the state variables are obtained and written as

$$x_i(s) = \frac{N_i(s)}{D_i(s)}\ . \tag{17.100}$$

Assuming that the denominator can be described by the polynomial function with stated poles

$$D_i(s) = (s - s_1)^{m_1}(s - s_2)^{m_2}\ldots(s - s_r)^{m_r} \tag{17.101}$$

and that the polynomial order equals

$$n = m_1 + m_2 + \ldots m_r\ , \tag{17.102}$$

the state i is represented as the following time function

$$x_i(t) = \sum_{k=1}^{r}\sum_{l=1}^{m_k} \frac{a_{kl}}{(m_k - l)!}t^{m_k - 1}\mathrm{e}^{s_k t}\ , \tag{17.103}$$

where the coefficients are evaluated from the expression

$$a_{kl} = \frac{1}{(l-1)!}\frac{\mathrm{d}^{l-1}}{\mathrm{d}s^{l-1}}\left[\frac{(s-s_k)^{m_k}N_i(s)}{D_i(s)}\right]\Bigg|_{s=s_k} . \tag{17.104}$$

The above approach is appropriate if the grade of the numerator is less than that of the denominator. Otherwise the numerator must be divided into two parts: polynomial parts for which the reverse Laplace transformation is the sum of the Dirac's function with the order equal to the grade individual polynomial component, and rational parts for which the above presented approach can be applied.

Selecting the analytical method suitable for finding the state variables of the given circuit depends on the number of variables, the input characters, and the network structure, but nowadays numerical methods based on the state equation are preferred.

3. Circuit with inductive and resistive load

If the network consists of a serial connection of a resistance, inductance, and voltage source (Fig. 17.15), the equation for such a structure can be written as

$$V_0(t) = V_\mathrm{R} + V_\mathrm{L} , \tag{17.105}$$

$$L_0\frac{\mathrm{d}i}{\mathrm{d}t} + R_0 i = v_0(t) . \tag{17.106}$$

For an assumed zero initial condition at the coil and a constant voltage supply $v_0(t) = V_0$, the above expression can be calculated with the help of the derivative common approach or Laplace transformation and written in the following form

$$i = \frac{V_0}{R_0}\left(1 - \mathrm{e}^{-t/T}\right), \quad T = \frac{L_0}{R_0} . \tag{17.107}$$

The response of the current increases due to the exponential function (Fig. 17.16a) with a time constant $T = L_0/R_0$. When excitation is an AC (alternating) voltage of the form

$$v(t) = \sqrt{2}V\cos(\omega t + \varphi) , \tag{17.108}$$

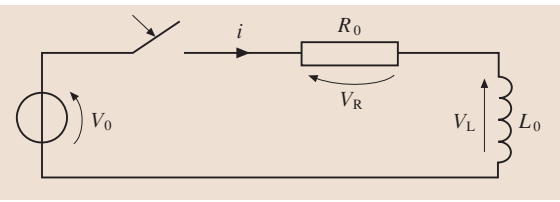

Fig. 17.15 Electric circuit of resistance R_0 and inductance L_0 in series

the solution of the derivative equation can be formulated

$$i(t) = \sqrt{2}I\left[\cos(\omega t + \varphi - \phi) - \mathrm{e}^{-t/T}\cos(\varphi - \phi)\right], \tag{17.109}$$

where Z is the impedance module, described as $\sqrt{R_0^2 + \omega^2 L_0^2}$, $I = V/Z$ is the effective (RMS) current value, and ϕ is the shift angle defined as $\phi = \arctan\omega T$ dependent on the angular speed of the AC voltage and the time constant. The transient state in this case is characterized by both the oscillatory state resulting from the sinus waveform excitation and the instantaneous state, which depends on the moment of switching the source (Fig. 17.16b). This undesirable instantaneous state has a maximum value for $\varphi = \phi$ and disappears when the condition $|\varphi - \phi| = \pi/2$ is reached. If the coil has a significant inductance compared to the resistance $R \ll \omega L$ and is switched on at the maximum of the excitation voltage, the current instantaneously reaches

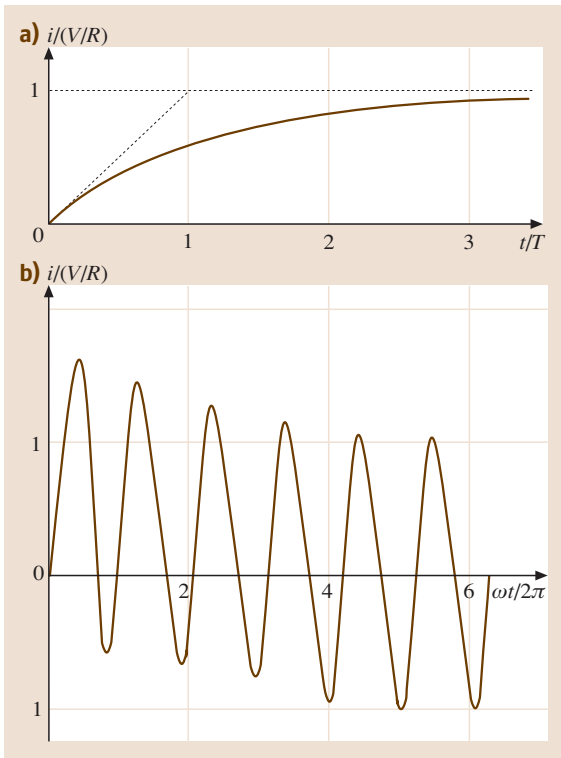

Fig. 17.16a,b Switch processes by resistance–inductance load: **(a)** at a DC voltage source; **(b)** at an AC voltage source

the steady state with the angular speed of the voltage, but if the source is switched on during the zero crossing of the voltage, the transient current can achieve twice the magnitude of the stationary state.

4. Circuit with a resonance branch
When we consider the serial connection of a constant voltage source, a resistor, a coil, and a capacitor with zero initial conditions presented in Fig. 17.17, the equation for such a framework can be defined as

$$L_0 \frac{\mathrm{d}i}{\mathrm{d}t} + R_0 i + \frac{1}{C_0} \int i \, \mathrm{d}t = V_0 \,. \tag{17.110}$$

The solution of this equation in the time domain is represented by the linear combination of two exponential functions in the form

$$i = A_1 \mathrm{e}^{p_1 t} + A_2 \mathrm{e}^{p_2 t} \,. \tag{17.111}$$

To find the parameters p_1 and p_2, the second-order characteristic equation resulting from the derivative approach has to be calculated

$$p^2 + 2\delta p + \omega_0^2 = 0 \,, \tag{17.112}$$

where $\omega_0^2 = 1/(L_0 C_0)$ is the resonant frequency and $\delta = R_0/2L_0$ is the damping factor.
The expression above has two roots

$$p_{1,2} = -\delta \pm \sqrt{\delta^2 - \omega_0^2} \,. \tag{17.113}$$

Due to the different characteristic values, which depend on the damping factor and the resonant frequency, we can distinguish three main cases:

– Overdamped circuit. When the element values are such that $\delta^2 > \omega_0^2$ here are two real roots that give the following response

$$i = \frac{V_0}{\alpha L_0} \mathrm{e}^{-\delta t} \sinh(\alpha t) \,, \tag{17.114}$$

where $\alpha = \sqrt{\delta^2 - \omega_0^2}$.

– Critically damped circuit. This occurs when the element values exactly satisfy the condition $\delta^2 = \omega_0^2$. In this case we say that the roots are repeated. The expression to solve such a problem is written

$$i = \frac{V_0}{L_0} t \mathrm{e}^{-\delta t} \,. \tag{17.115}$$

– Underdamped circuit. When the characteristic equation yields complex roots, we say that the circuit is underdamped because its natural response exhibits an oscillatory behavior. The solution for this case is expressed as

$$i = \frac{V_0}{\omega L_0} \mathrm{e}^{-\delta t} \sin(\omega t) \,, \tag{17.116}$$

where $\omega = \sqrt{\omega_0^2 - \delta^2}$ is the damped frequency. The current characteristics for all three cases are presented in Fig. 17.18. The solution for nonzero initial conditions is more complicated and contains additional components resulting from the energy stored in the inductive and capacitive elements.
In addition, in the case of an AC instead of DC source, we obtain state variables that are a combination of the given harmonic excitation from the source and instantaneous responses.

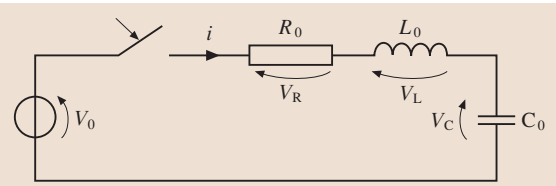

Fig. 17.17 Electric circuit with a resistance R_0, impedance L_0, and capacitance C_0 in series

Network Analysis

Circuit theory includes all issues dealing with the dynamic and stationary behavior of the network. The principles for the calculation of the behavior of the circuit are based on the two fundamental Kirchhoff's laws:

- Kirchhoff's current law (KCL), which says that, for all times t, the algebraic sum of the currents flowing toward a node and the currents flowing away from that node is equal to zero (17.25), and
- Kirchhoff's voltage law (KVL), which says that, for all closed node sequences (meshes) and for all

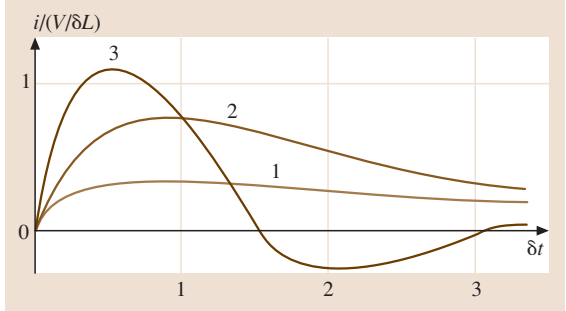

Fig. 17.18 Pure resonance circuit switching: 1 – overdamped circuit, 2 – critically damped circuit, and 3 – underdamped circuit

times t, the algebraic sum of all node-to-node voltages around the chosen closed node sequence is equal to zero (17.26)

Network analysis is based on the above laws. The first Kirchhoff law is used for node analysis and the second is applied to mesh analysis.

To study wide circuit systems, a topological approach can be used to facilitate the network calculation. This allows one to build the equation systems for the given circuit and to compute them with the help of numeric techniques.

The interconnection properties of the circuit can be best defined by a circuit graph. A circuit graph is specified by a set of nodes together with a set of branches. If for each branch an orientation is given, indicated by an arrow on the branch, we call the graph a directed graph or digraph. Only directed graphs have practical meaning for circuit calculation. The fundamental terms for network analysis are nodes, branches, meshes, and trees. As an illustrative example the circuit in Fig. 17.3 can be assigned a graph with $b = 6$ branches and $k = 4$ nodes. Figure 17.3 has been slightly modified as shown in Fig. 17.19.

Based on this graph we can conclude that the circuit results in $p = k - 1$ independent equations and that the fundamental node matrix, commonly called the admittance matrix, created for this circuit has the following form

$$G = \begin{pmatrix} G_1 + G_2 & -G_1 & 0 \\ -G_1 & G_1 + G_3 + G_5 & -G_3 \\ 0 & -G_3 & G_3 + G_4 \end{pmatrix} . \tag{17.117}$$

This matrix is symmetrical, which is always the case when the circuit does not have controlled active elements. The admittance matrix is created in the following way:

- Main diagonal components $G_{i,i}$: the positive sums of all the conductances and *susceptances* which are connected to the node i, and
- Nondiagonal components $G_{i,j}$: diagonal components that reflect the mutual negative conductance between connected nodes i and j

The number of independent equations m in mesh analysis can be calculated from the formula $m = b - k + 1$. In order to create the equations for mesh current studies, the tree of the circuit must first be assigned. This term plays a central role in graph theory. A tree is a subgraph of the connected digraph and satisfies the following three fundamental properties:

- It is connected.
- It contains all nodes of the circuit.
- It has no loops.

The branches, which create the loops with the tree branches, assign the mesh current and are called chords or co-trees. In each equation only one chord and arbitrary tree paths are taken into account. The above mentioned rules can be used in writing down the mesh impedance matrix. For Fig. 17.20 this matrix is expressed as

$$R = \begin{pmatrix} R_1 + R_3 & -R_1 & -R_3 \\ -R_1 & R_1 + R_2 + R_3 & -R_5 \\ -R_3 & -R_5 & R_3 + R_4 + R_5 \end{pmatrix} . \tag{17.118}$$

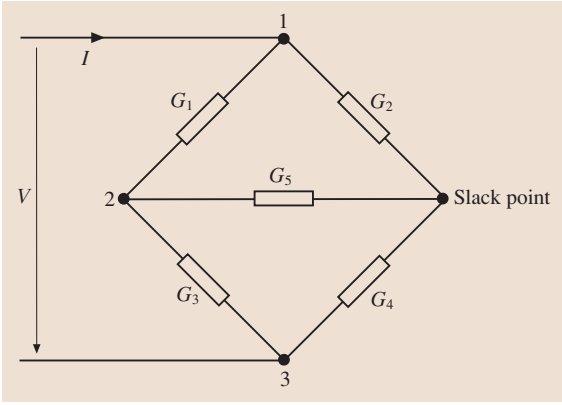

Fig. 17.19 Bridge circuit with four nodes and six branches

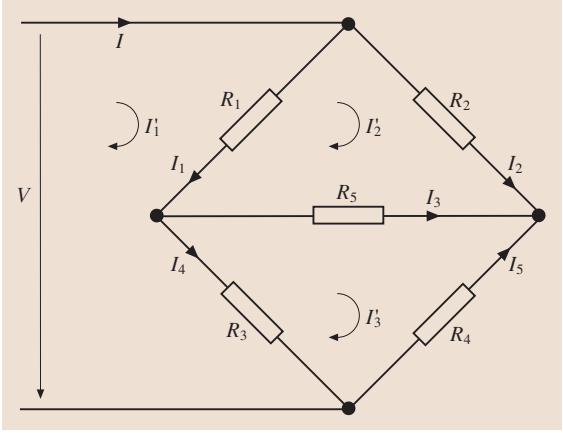

Fig. 17.20 Bridge circuit with I'_1, I'_2, and I'_3 mesh currents

It is dependent on the assumed mesh current directions (see I_1', I_2', and I_3', in Fig. 17.20).

The diagonal components of the mesh impedance matrix contain resistances that appear in the loops created by tree branches and chords. The nondiagonal elements of the matrix are built from the mutual resistances of the assumed tree branches.

The presented matrices provide the basis to calculate the currents and voltages at the clamps of the load. For practical reasons, node analysis is more often used in calculations due to the simple construction procedure. For mesh analysis, the allocation of arrows to the branches plays a very important role, and becomes complicated for large systems.

17.1.5 Materials and Components

Conductors, Semiconductors, and Insulators

The specific resistance for the various materials used in electrical components can range from 10^{-6} to 10^{20} Ω cm (Fig. 17.21) [17.6]. The basis for current conduction is electrons and p-hole mobility. Based on their different carrier types and carrier mobility, three main groups of materials can be distinguished:

- Metallic conductors (especially Cu, Al, Ag)
- Semiconductors (Si, Ge, Se, as well as compounds of the third and fifth groups of the periodic table)
- Insulators (organic and inorganic compounds such as porcelain, glass, and mica)

The semiconductors are elementary elements for electronic and power electronic circuits [17.7]. If a dice (junction) has an undisturbed and pure structure than at low temperatures it does not conduct any carriers and behaves as an insulator. Carrier mobility can be induced by heat or light irradiation.

Because of different dopants in the semiconductors a distinct group of carrier types appear. When the acceptors (the third column of the periodic table) dope the donors (the fifth column of the periodic table), various p- and n-carriers arise.

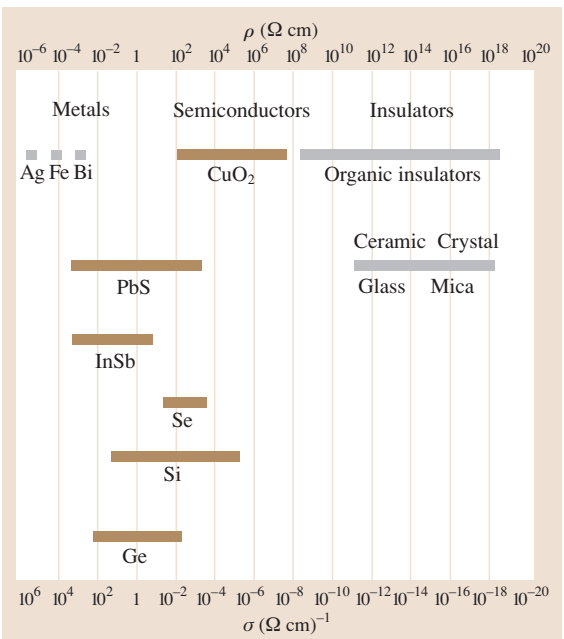

Fig. 17.21 Specific resistance for electrical materials

Special Properties of Conductors

Superconductor. The behavior of metallic conductors is dependent on temperature. In an ordinary working range of the conductor wires exhibit linear dependency. In the low-temperature range some metals and metal alloys possess superconductive properties. When approaching the so-called absolute zero temperature, at the temperature T_c the resistance vanishes completely.

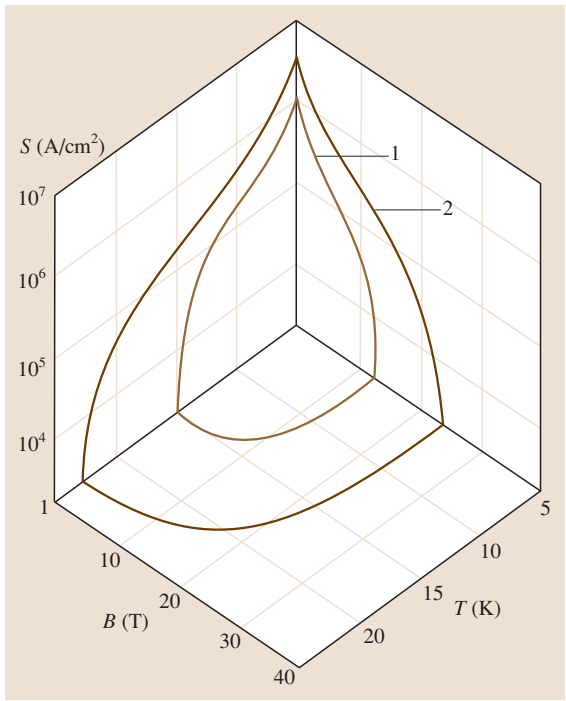

Fig. 17.22 Jump temperature of superconductors: 1 – NbTi, 2 – Nb_3Sn

In order to keep the superconductive effect, certain critical values of the current density and external magnetic field cannot be exceeded (Fig. 17.22). Superconductors can be used in energy engineering for electrical machines, distribution feeders, and storage systems. For this purpose, high-temperature superconductors have been designed based on compounds of NbTi ($T_c = 9.3\,\mathrm{K}$), Nb_3Sn ($T_c = 18.0\,\mathrm{K}$) and V_3Ga. For example, superconductance for a Ni and Ti compound is achieved at a temperature of 4.2 K, a current density of $70\,\mathrm{kA/cm^2}$, and a critical magnetic flux density of 8 T. Due to the low temperature that must be maintained for superconduction, adequate cooling materials – most often liquid helium (LHe) and liquid nitrogen (LN_2) – and appliances are required. Recently, new technologies have been being developed to obtain high-temperature superconductors in which the superconductive properties appear at temperatures of about 100 K. The compound $YBa_2Cu_3O_7$, for example, exhibits the zero-resistance effect at 93 K. High-temperature superconductors have the advantage of lower cost and higher efficiency. For example, in order to achieve the superconducting temperature for such materials, cheaper nitrogen instead of high-priced helium can be used. Additionally less energy is needed to maintain the appropriate conditions.

However, due to their low critical current density and some problems with the production of superconductor components, their practical application still lies in future.

Hall Effect. When current flows through a metal strip with a rectangular cross-section a magnetic field perpendicular to it generates a voltage between the two opposite margins of that metal strip; this is known as the Hall voltage. This Hall effect can serve to measure the magnetic field. Furthermore, based on this effect the currents in wires can be measured with the help of special equipment.

In order to use the Hall effect for measurements, a thin flat blank with a high Hall factor is applied. For example, a Hall-effect probe made of InAs materials achieves a Hall voltage of about 100 mV at currents of about 0.1 A and a magnetic induction of 1 T.

Seebeck and Peltier Effects. Two further effects are the Seebeck and Peltier effects which both concern the thermovoltage. A thermovoltage is produced by two wires connected to each other as a thermocouple. In a closed circuit loop the thermovoltage is noticeable when the two brazed points have different temperatures. The Seebeck effect states that the generated voltage between two different metal wires connected in one circuit is proportional to the difference of temperatures between the two thermo-elements. One of these joints is usually kept at a fixed reference temperature, for instance in a container filled with water and ice (for a reference temperature of 0 °C). When a copper wire is connected to a constantan wire in one circuit and a temperature difference of 100 K exists, a thermovoltage of 4.15 mV is produced. A second effect, known as the Peltier effect, is the inverse of the Seebeck effect. Current flowing through a thermocouple irrespectively to Joule heat feeds the one brazed point with heat which is dissipated from the other brazed point. The Peltier thermal effect is proportional to the current flowing in the circuit. This phenomenon can be found in various circuit elements subjected to cooling.

Materials in an Electric Field

Insulation materials are characterized by their relative permittivity ε_r and electric breakdown strength E_d. In an electric field the molecules are polarized by the electric charge. The electric field strength is combined with the polarization by a formula

$$P = \chi_e \varepsilon_0 E\,, \tag{17.119}$$

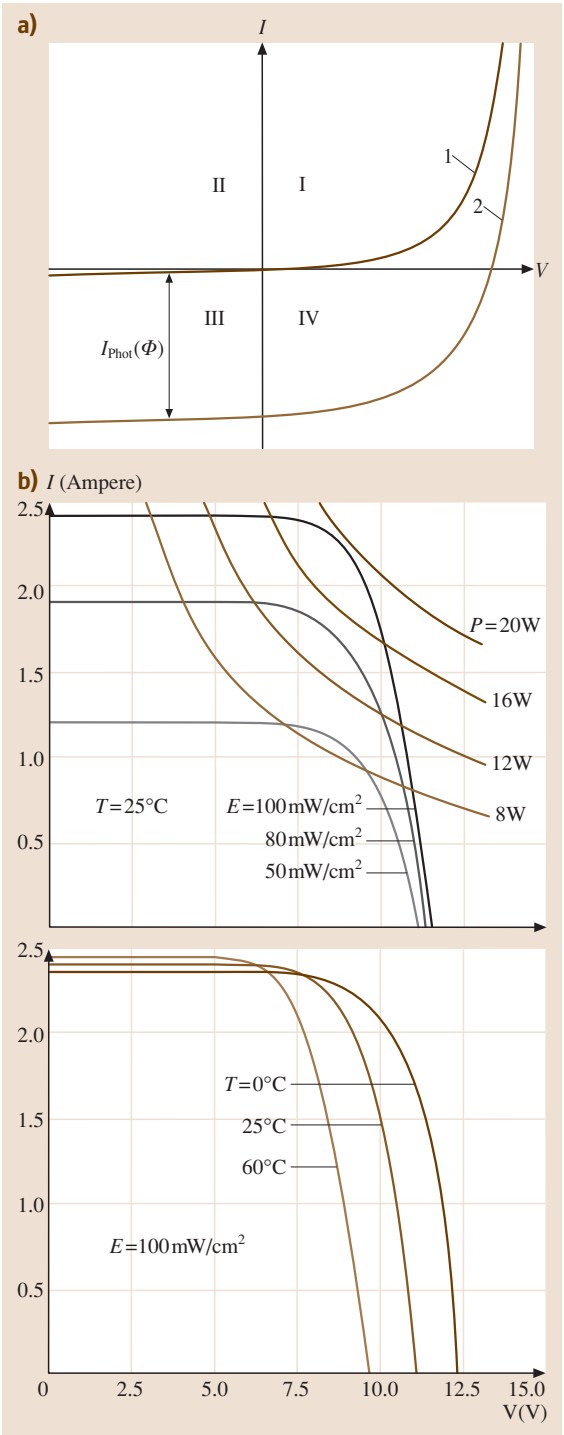
where $\chi_e = \varepsilon_1 - 1$ is the dielectric susceptibility.

Some dielectric materials have a nonlinear relationship between polarization and electric field strength and show ambiguous hysteresis properties. This behavior is called ferroelectricity.

Piezoelectricity. Some crystals can become polarized by applying pressure or tensile stress. On the opposite edges of the crystal surface charges arise with different signs. Reciprocally, for these materials it is possible to apply an electrical field which causes a change in the length of the material. This change is dependent on the polarization and direction of that field.

In general, piezoelectric materials are used for the conversion of electromechanical oscillations. For example, piezoelectric transducers are applied in measurement techniques, microphones, and especially in quartz clocks. The most recent application for piezoelectric transducers is in drive devices and in the field of noise reduction.

Photovoltaic Solar Cells. Solar cells are photovoltaic (PV) elements with a p–n junction in which light irradiation causes the separation between the electrons and p-holes and a voltage can develop [17.8]. The energy



generated can be used to supply a load connected to the photovoltaic element. The behavior of the photovoltaic elements is described by its diode characteristic, which is dependent on light irradiation; therefore the negative photocurrent is shifted with respect to the real diode curve (Fig. 17.23a). A photovoltaic element works in the fourth quadrant between the short-circuit current and the open-circuit voltage.

Solar cells can be produced from mono- or polycrystalline and amorphous silicon. Silicon cells based on different technologies differ in terms of their efficiency factor and expenditure in manufacturing; commercial cells have an efficiency value of 10–20%. Through serial and parallel connection of these cells, solar modules are obtained. Figure 17.23b illustrates the characteristics of a solar module that contains 5×4 multicrystalline cells with a $10\times10\,\mathrm{cm}^2$ surface area. The standard test conditions (STC) for solar modules are a module temperature of 25 °C, light irradiation of $100\,\mathrm{mW/cm}^2$, and a light spectrum of AM = 1.5. This system generates about 19.2 W of power at its maximum-power point (MPP).

Solar generators are used as the main energy source in satellite technology. Due to its renewable and environmentally friendly properties these generators are beginning to play a very important role in energy technology.

Materials in a Magnetic Field

The magnetic properties of materials are defined by the magnetic susceptibility χ_m, which describes the connection between the magnetization M and magnetic field intensity H

$$M = \chi_\mathrm{m} H\,; \quad \chi_\mathrm{m} = \mu_\mathrm{r} - 1. \tag{17.120}$$

The following material groups can be distinguished:

- Paramagnetic materials, where the μ_r called relative magnetic permeability value is slightly greater than 1 (e.g., $\chi_\mathrm{m} = 0.21\times10^{-4}$ for Al)
- Diamagnetic materials, where the μ_r value is slightly smaller than 1 ($\chi_\mathrm{m} = -0.19\times10^{-4}$ for Ag)
- Ferromagnetic materials, where the χ_m value is much greater than 1 and can be up to 1×10^5 (e.g., Fe, Ni, Co, and some alloys)

Fig. 17.23a,b Characteristics of a PV converter. **(a)** Photo element as diode with photocurrent, 1 – traditional diode, 2 – solar cell; **(b)** solar module (AEG PQ 10/20)◀

The magnetization characteristics $B(H)$ or $M(H)$ of ferromagnetic materials exhibit saturation and hysteresis properties. If this material is excited by a pulsating field then magnetization losses arise, composed of eddy currents and hysteresis losses.

Ferromagnetic materials in an external magnetic field exhibit elastic length changes. This phenomenon is called magnetostriction and is utilized in the generation of ultrasonic oscillations. The magnetostriction phenomenon is also responsible for unpleasant noise from transformers.

Electrolytic Charge Transfer

The charge transport of currents through electrolytes (bases, acids, salines and fused salts) follows the ions, namely the positive cations and negative anions. Negative ions in a fluid conductor migrate from cathode to anode while positive ions migrate in the opposite direction under the influence of an electric field. This phenomenon is accompanied by material transport, and its effect is utilized technically in electrolysis.

Electrodeposition is the use of electrolysis to separate materials. This technique makes it possible to achieve a high level of cleanliness of the separated materials. For example copper obtained from the electrolysis process exhibits a cleanness of about 99.9%. Aluminum produced by electrodeposition involves the additional materials of bauxite and cryolite in fluid state. Electroplating is the production of metallic coatings using an electrolysis procedure (for example, nickel plating).

17.2 Transformers

17.2.1 Single-Phase Transformers

Working Principle and Equivalent Circuit Diagram

A simple transformer device has two magnetically coupled windings [17.9]. One side of the transformer is called the primary winding and the other side is the secondary winding. The transformer consists of copper windings and an iron core carrying flux which produces magnetic coupling between the two windings of the transformer (Fig. 17.24). Depending on construction principles, usage, power rating, and other factors we can distinguish between the following groups and subgroups:

- Usage: power, regulating, generator, and transmission transformers
- Power rating: small, medium, and large power transformers, and high-performance transformers
- Type of cooling: oil-immersed and dry-type transformers
- Core type: core- and shell-type transformers
- Transformation ratio: step-up and step-down transformers
- Arrangement of windings: separate winding transformers and auto-transformers
- Number of phases: single- and three-phase transformers, grouped into three- and five-limb cores

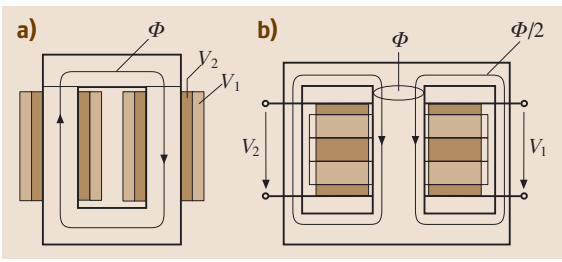


Fig. 17.24a,b Single-phase transformer construction: **(a)** UI transformer; **(b)** EI transformer

The transformer can be mathematically analyzed as a reverse two-port network. The magnetic properties are characterized by the inductivity of the windings, L_1 and L_2, and the mutual inductivity M. Currents flowing through the windings induct primary and secondary flux that are combined with each other as written below

$$\Psi_1 = L_1 i_1 + M i_2 \,,$$
$$\Psi_2 = L_2 i_2 + M i_1 \,. \qquad (17.121)$$

For the transformer a coefficient k is defined to describe the coupling

$$k = \frac{M}{\sqrt{L_1 L_2}} \,, \quad 0 \le k \le 1 \,. \qquad (17.122)$$

The coupling coefficient k of a physical transformer is determined by a number of factors: the magnetic properties of the core on which the primary and secondary coils are wound, the number of turns of each coil, the coils' relative positions and their physical dimensions. If k is close to zero, we say that the coils are

loosely coupled, as is the case for air-core transformers. If k is close to one, we say they are tightly coupled as occurs for iron-core transformers.

The windings in a real transformer also have resistances, so that, for the assumptions above, the following pair of equations in the time domain can be formulated

$$v_1 = R_1 i_1 + L_1 \frac{\mathrm{d}i_1}{\mathrm{d}t} + M \frac{\mathrm{d}i_2}{\mathrm{d}t} ,$$
$$v_2 = R_2 i_2 + L_2 \frac{\mathrm{d}i_2}{\mathrm{d}t} + M \frac{\mathrm{d}i_1}{\mathrm{d}t} . \qquad (17.123)$$

In Fig. 17.25a a schematic transformer that consists of resistances, self-inductances, and mutual inductance is presented for which the above expressions apply. This formulation can be used for steady-state AC analysis of the system, after being simplified to

$$\underline{V}_1 = (R_1 + \mathrm{j}\omega L_1)\underline{I}_1 + \mathrm{j}\omega M \underline{I}_2 ,$$
$$\underline{V}_2 = (R_2 + \mathrm{j}\omega L_2)\underline{I}_2 + \mathrm{j}\omega M \underline{I}_1 , \qquad (17.124)$$

where ω is the angular speed of the AC excitation.

In order to simplify the AC circuit calculations when transformer devices are used, the turn ratio is introduced

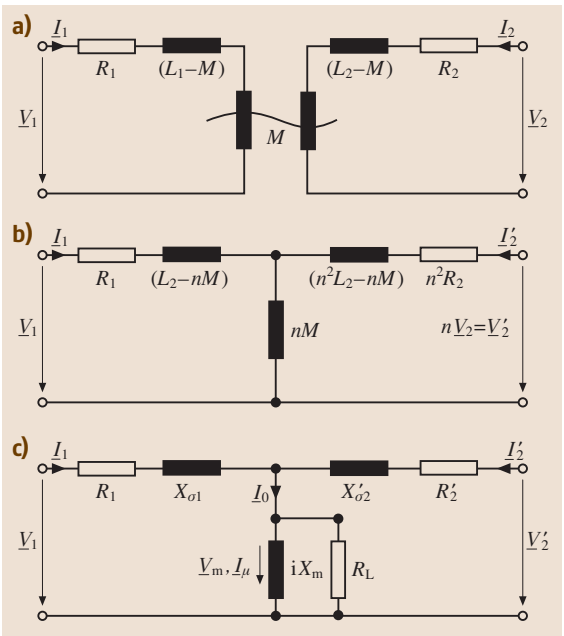

Fig. 17.25a–c Transformer schema with two windings: **(a)** principle circuit; **(b)** conversion of secondary side into primary side; **(c)** circuit for AC analyses [17.2]

and denoted as n

$$n = \frac{N_1}{N_2} . \qquad (17.125)$$

Using this ratio the transformer can be interpreted as one galvanically coupled circuit, forming a T-equivalent network (Fig. 17.25b,c). Therefore, the quantities of the secondary side have to be recalculated in order to be based on the primary side using the following equations

$$\underline{V}'_2 = n\underline{V}_2 , \quad \underline{I}'_2 = \underline{I}_2/n \qquad (17.126)$$

and, for passive elements the following connections are fulfilled

$$\underline{R}'_2 = n^2 R_2 , \quad L'_2 = n^2 L_2 . \qquad (17.127)$$

These relations obey the invariant-power condition for this two-port network study. The introduced turn ratio coefficient allows us to identify the simple connection between the main flux Φ_m that reflects current generated in the cross branch and the leakage fluxes Φ_1 and Φ_2 induced by the primary and secondary windings of the transformer.

The inductive transformer elements appear as the main inductivity L_m and the leakage inductivities $L_{\sigma 1}$ and $L_{\sigma 2}$. These parameters are reflected by the following relation

$$L_\mathrm{m} = nM , \quad L_{\sigma 1} = L_1 - L_\mathrm{m} ,$$
$$L_{\sigma 2} = L_2 - M/n . \qquad (17.128)$$

For transformer analysis it is very important to take into account not only the winding losses but also the magnetizing losses in the transformer core. This can be done by an additional parallel resistance R_L connection to the main inductivity in the T-network schema. The losses in the core result from eddy currents and magnetization of the hysteresis loop. The hysteresis losses are proportional to the working frequency and the eddy-current losses are proportional to the square of the working frequency. If a transformer works with fundamental frequency $f = \omega/2\pi$ then all of the circuit parameters can be described in complex numbers with assigned reactances as shown in Fig. 17.25c.

Voltage Induction

A current i flowing through a winding of the transformer core produces a magnetic field around the core.

If the excited current is time varying then it generates a time-varying voltage that, when transferred to the primary side of the transformer, takes the following form

$$V_\mathrm{m} = w_1 \frac{\mathrm{d}\Phi_\mathrm{m}}{\mathrm{d}t} = -\frac{\mathrm{d}\Psi_\mathrm{m}}{\mathrm{d}t} \,. \tag{17.129}$$

If the flux changes to a sine function then the inducted voltage will also have a sine waveform with the same frequency as the drawn current. The effective (RMS) value of the voltage is described as

$$V_\mathrm{m} = \frac{\omega}{\sqrt{2}} w_1 \Phi_\mathrm{m} = 4.44 f w_1 \hat{B} A_\mathrm{Fe} \,. \tag{17.130}$$

The generated voltage is proportional to the working frequency f, the winding number w_1, the magnetic induction magnitude $\hat{B}$, and the cross-section A_Fe.

No-Load and Short-Circuit Conditions

When the secondary winding of the transformer works in the open circuit, this means that $\underline{I}_2 = 0$, and the voltage at the output clamps of transformer is approximated by the formula

$$\underline{V}_{20} \approx \underline{V}_1 / n \,. \tag{17.131}$$

In this case, the current $\underline{I}_0$ in the primary winding is moved back by about 90° with respect to the supply voltage. The active power for such a working condition of the transformer reflects mainly the eddy current and hysteresis losses due to magnetization of the core, and the reactive power results from the almost purely inductive character of the device. The relations for these working conditions are expressed in the following form

$$P = V_1 I_0 \cos\varphi_0 \,, \quad Q = V_1 I_0 \sin\varphi_0 \tag{17.132}$$

for the active and reactive power, respectively.

The characteristic value for the transformer is an open-circuit current, which is defined as the ratio of the current I_0 in the open-circuit condition to the nominal current of the transformer

$$i_0 = \frac{I_0}{I_\mathrm{N}} \,. \tag{17.133}$$

This factor amounts to only a few percent. The P and Q quantities in the open-circuit condition serve as the basis for calculating the mentioned parameter R_L, which reflects the losses in the core, and X_m, which describes the main inductance in the transformer circuit.

The no-load characteristics $V_1 = f(I_0)$ exhibit the saturation features of the transformer, which must be taken into account during transformer design.

If a transformer works in short-circuit conditions of the secondary winding the following conditions are fulfilled

$$\underline{V}_2 = 0 \,, \quad \underline{I}_{2s} \approx -n\underline{I}_1 \,. \tag{17.134}$$

The flux produced by the current flowing in the primary winding is almost completely compensated by the flux produced by the current in the secondary winding.

The wire resistances and leakage reactance can be roughly obtained with the help of the following expressions

$$\begin{aligned} &\underline{Z}_\mathrm{s} = R_\mathrm{s} + \mathrm{j}X_\mathrm{s} \,, \quad R_\mathrm{s} = R_1 + n^2 R_2 \,, \\ &X_\mathrm{s} = \omega\left(L_{\sigma 1} + n^2 L_{\sigma 2}\right) \,. \end{aligned} \tag{17.135}$$

Figure 17.26 illustrates a further connection between the quantities in graphical form and introduces the term relative short-circuit voltage, which is defined as

$$v_\mathrm{s} = X_\mathrm{s} \underline{I}_\mathrm{N} / \underline{V}_\mathrm{N} \,. \tag{17.136}$$

For a power transformer these values can be up to 6%.

Phasor Diagram

In order to better understand the phenomena arising in the transformer, a phasor diagram is often used. In such a case the secondary-side quantities are transferred to the primary winding of the transformer and the relationship between currents and voltages at the clamps of the transformer are as follows

$$\begin{aligned} &\underline{V}_1 = (R_1 + \mathrm{j}\omega L_\mathrm{s})\underline{I}_1 + \mathrm{j}\omega L_\mathrm{m}\underline{I}_\mu \,, \\ &\underline{V}_2 = \mathrm{j}\omega L_\mathrm{m}\underline{I}_\mu + (R'_2 + \mathrm{j}\omega L'_{\sigma 2})\underline{I}'_2 \,, \end{aligned} \tag{17.137}$$

where $\underline{I}_\mu = \underline{I}_1 + \underline{I}'_2$ is defined as a magnetization current. If the additional core losses represented by the

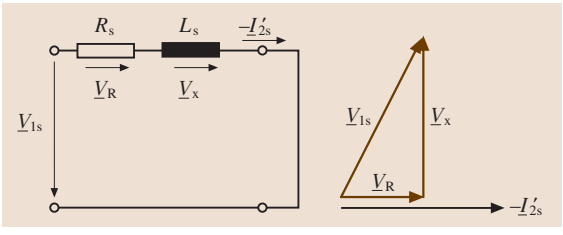

Fig. 17.26 Schema of a phasor diagram in short circuit

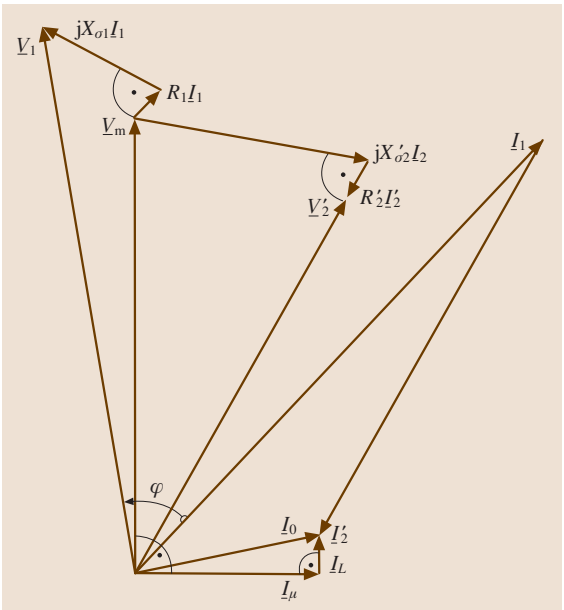

Fig. 17.27 Phasor diagram of transformer operation at resistance–inductance load [17.2]

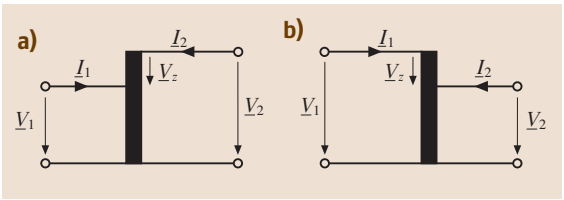

Fig. 17.28a,b Auto-transformer: **(a)** step-up; **(b)** step-down

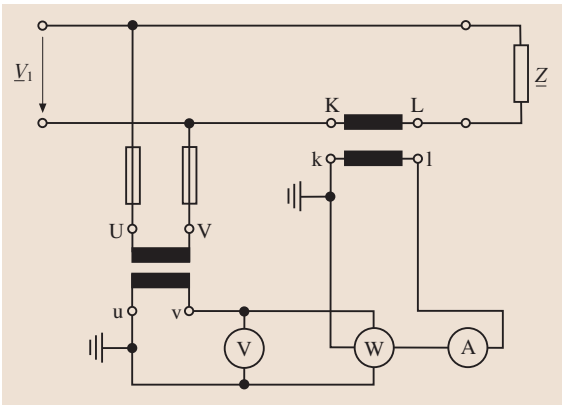

Fig. 17.29 Instrument transformer for voltage and current in a single-phase circuit

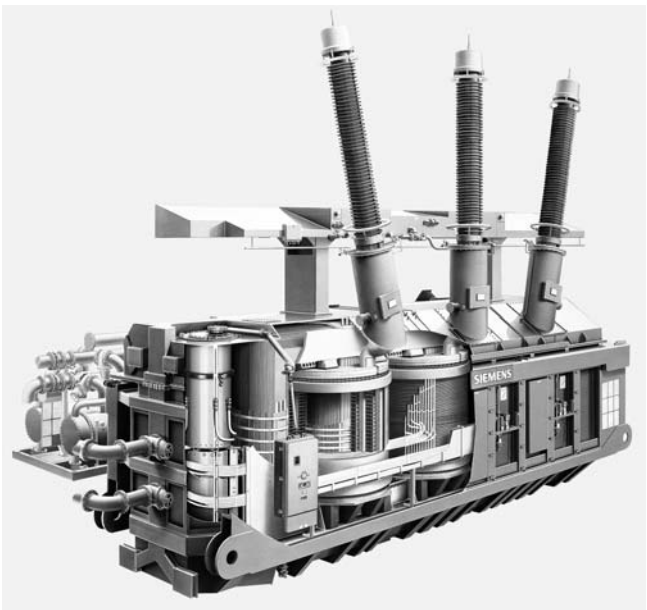

Fig. 17.30 Three-phase power transformer for public energy supply > 150 MVA (SIEMENS)

resistance R_L are taken into account, the behaviors of the currents and voltages at the transformer are described by the phasor diagram in Fig. 17.27.

It can be seen that the magnetization current is shifted back by 90° with respect to the main voltage, denoted by $\underline{V}_m = j\omega L_m \underline{I}_\mu$. The whole current $\underline{I}_0$ characterizes properties of the main flux in the transformer and can be divided into two geometric components: the primary and the related secondary current.

Transformer are called auto-transformer if the primary windings is part of the secondary windings or vice versa. The windings of the auto-transformer do not have galvanic separation, as shown in Fig. 17.28. Auto-transformers have lower leakage reactances, lower losses, and smaller exciting current when the voltage ratio does not differ too greatly from 1 : 1. The disad-

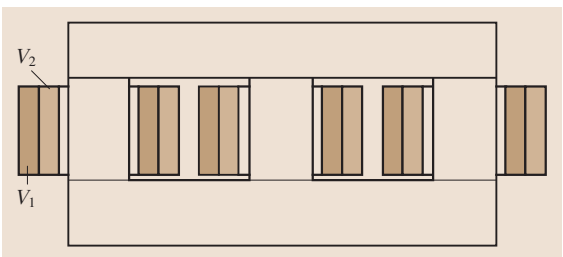

Fig. 17.31 Three-phase transformer construction

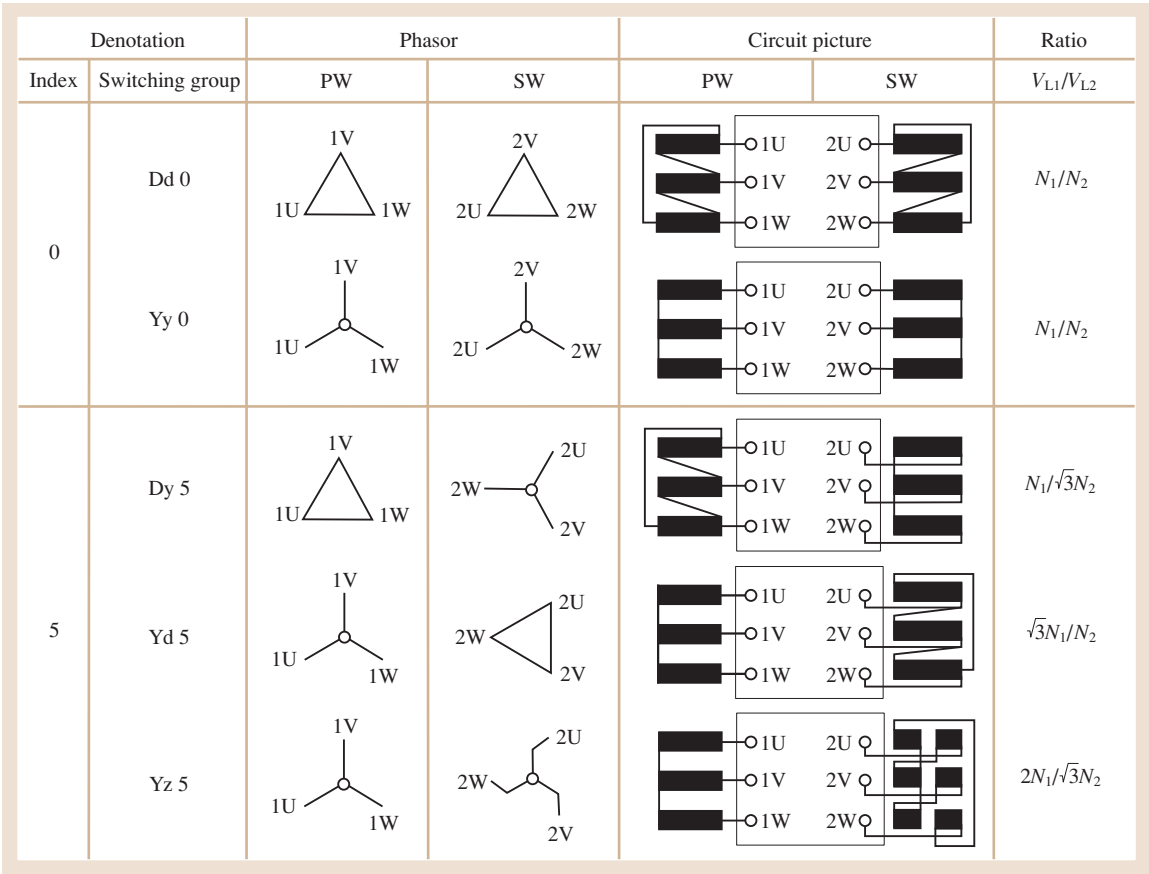

Fig. 17.32 Connection groups of three-phase transformers [17.1]

vantage is the direct electric connection between the high- and low-voltage sides.

17.2.2 Instrument Transformers

The instrument transformer is a device that uses the principles of a transformer to convert network currents and voltages into quantities that can be processed by other measurement instruments, protective or metering devices or control systems (Fig. 17.29). The norm for voltage measurement is 100 V, whereas for current measurement it is either 1 or 5 A. The secondary side of the instrument transformer is galvanically separated and, in particular, this property makes it possible to measure high-voltage systems. The total measurement error of these devices depends on the sum of the magnitude error and angle error. Depending on the accuracy levels of the instrument, they are grouped into several classes which characterize the allowable percentage error (class 0.1, 0.2, or 1.0).

Current Transformers

The primary and secondary windings in a current transformer are coupled by a ferromagnetic sheeting or toroidal core with low leakage inductivity. If high currents are measured, the core with the secondary winding is mounted around the primary winding. This way the primary winding usually consists of one turn. The resistance (burden) connected to the secondary side is used for the current measurement.

Since the accuracy is strongly depending on the existing of the current I_0, metal sheeting with high permeability in the operating range is used. Additional errors occur, when the core gets saturated by primary currents containing DC components.

Voltage Transformers

A voltage transformer works basically in open-circuit mode of the secondary winding. Because of this, it can be treated as an ideal transformer in which a simple connection between the measured input and read output appears. This relation can be described with the help of a basic expression which results from working in an open-circuit connection.

17.2.3 Three-Phase Transformers

Three-phase transformers consist of the three primary and three secondary windings coupled on one core (Fig. 17.31) [17.10]. Advantages of three-phase transformers are that they cost less, weigh less, and require less floor space in comparison to three separate single-phase transformers. The core of a three-phase transformer consists mainly of magnetic steel sheeting. In order to avoid magnetization losses silicated steel sheets with a thickness of 0.35 mm are mainly used.

For three-phase transformers the two elementary core forms, three and five limb, are applied. The windings consist of insulated copper wires. The power transformers are located in the transformer shell and are immersed in oil, which simultaneously maintains the insulation and cooling of the windings. Very often air can also be used as a cooling agent.

Transformer windings are classified in terms of their groups of connections (Fig. 17.32) [17.9]. The high-voltage side is written in upper-case letters and the low-voltage side is written in lower-case letters and for both groups an integer number is used to describe the angular difference in terms of 30° multiples between the phasors of the low- and high-voltage sides of the three-phase transformer.

The nominal short-circuit voltage for a three-phase transformer is defined in the same way as a single-phase transformer. The primary voltage excites the nominal current in the primary windings at short circuit on the secondary side (see Fig. 17.26).

The voltage difference between the primary and the secondary sides results from the appearing resistance, the leakage inductance, and the character of the load

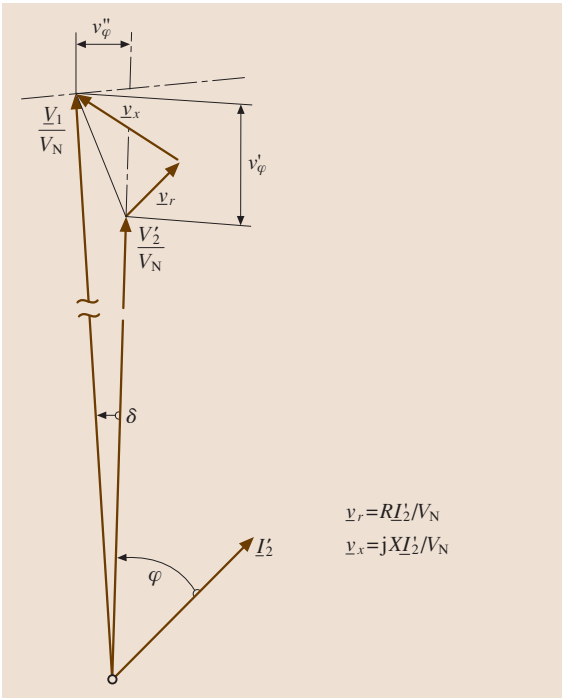

Fig. 17.33 Vector diagram for voltage change calculations

on the secondary side of the transformer. At nominal current, the relative voltage change with respect to the nominal voltage is defined as (Fig. 17.33)

$$\Delta v = v'_\varphi + 1 - \sqrt{1 - v''^2_\varphi}\,, \tag{17.138}$$

where

$$\begin{aligned} v'_\varphi &= v_\mathrm{r}\cos\varphi + v_\mathrm{x}\sin\varphi\,, \\ v''_\varphi &= v_\mathrm{x}\cos\varphi - v_\mathrm{r}\sin\varphi\,. \end{aligned} \tag{17.139}$$

The quantities v_r and v_x are the relative ohmic and inductive voltage drops, respectively.

The electrical data for transformers up to 40 MVA are standardized. By tapping the windings, the output voltage level can be regulated. This is used to ensure the rated voltage level during long-time changes of the load connected to the transformer.

17.3 Rotating Electrical Machines

17.3.1 General Information

Electrical machines convert mechanical energy to electrical energy (generator) or electrical energy to mechanical energy (motor) [17.11]. Energy conversion in almost all motors and generators takes place when a change in magnetic flux is associated with mechanical motion.

Each machine consists of at least one stationary part, the stator, and one rotating part, the rotor. According to Faraday's law, voltages are generated in windings or coils by:

1. Rotating a magnetic field past the windings or coils
2. Rotating the coils through a magnetic field, or
3. By designing the magnetic circuit so its reluctance changes with rotation of the rotor

Machine Types

In general, electrical machines can be divided into three types based on their mode of operation [17.1].

Induction Machines. As a general rule induction machines consist of a three-phase stator winding fed with AC currents, and a short-circuit three-phase rotor winding. Power is transmitted from the rotating magnetic field generated by the stator windings, through the air gap, to the rotor, which rotates asynchronously. A special form of this machine may be provided with slip-rings to gain access to the rotor windings.

Synchronous Machines. The majority of synchronous machines have a stator three-phase winding, and a rotor winding energized by a DC source that rotates at a constant speed proportional to the ratio of the applied frequency and the number of poles. For medium-sized and large machines a field coil is used on the rotor, while for small machines permanent magnets may be used instead.

Direct-Current Machines. A direct current (DC) machine may be viewed as a synchronous machine inside out. The commutator winding is placed at the rotor whereas the magnetic flux is produced in the stator. This can be achieved with a field coil or permanent magnets. The AC voltages induced in the rotor windings are converted to DC voltages through the action of the mechanical commutator. The commutator is mounted on the rotor shaft and connects groups of coils to the external terminals by means of brushes.

Nonrotating Machines. Linear machines are nonrotating machines, and their construction can be either induction or synchronous. They are used as short or long stator linear motors.

Types of Construction and Shaft Heights

The different types of construction for rotating electrical machines are described in IEC 60034.

Machines for industrial use, especially three-phase asynchronous (induction) machines, are produced according to IEC 60072. The construction of the machine is connected with nominal power and protection degree.

Degrees of Protection

Rotating machines are classified according to their size and protection provided by the enclosure as follows:

- Protected against human contact with parts that are under voltage
- Protected against contact and ingress of foreign bodies
- Protected against water ingress

This protection is described in IEC 60034-5. The degree of protection is represented by a symbol formed from a number and a letter, which consists of: IP + two digits + sometimes extra letters, e.g., IP 23 S.

The first digit of the code is for protection against contact and ingress of foreign parts whose size ranges between 1 mm and 50 mm. The second is for protection against water ingress. The digit 0 means that this machine is not protected (in the order of 0–6 for the first digit and 0–8 for the second digit). The second digit indicates that the machine is protected against either dripping water, dripping water at a tangential deviation up to 15°, spray water, shower water, stream water or that the machine is protected from dipping or immersion.

The special letters in the IP code are:

- W – weatherproof machine
- S – machines that are checked for water protection while stationary
- M – machines that are checked for water protection during operation

Losses and Efficiency

Using IEC 60034-2:1972 (IEC 60034-2A:1974 + A1:1995 + A2:1996) the total losses in an electrical

machine are determined as the sum of the following individual losses:

- Exciter circuit losses (only for DC and synchronous machines)
- Constant losses (iron, friction, and airing losses)
- Load-dependent losses (current heat losses)
- Load-dependent losses (other)

Let P_L be the sum of all losses. The efficiency of a machine η is defined as the ratio between the power output P_2 and total input power P_1

$$\eta = \frac{P_2}{P_1} = \frac{P_2}{P_2 + P_L} = \frac{P_1 - P_L}{P_1} . \qquad (17.140)$$

Efficiency as a function of the load is characterized by the maximum value η_{max}; this is the working point at which the load-independent losses are equal to the load-dependent losses. Machines for normal use are designed in such a way that η_{max} occurs for a load value below the nominal load, e.g., $P_2 = (7/8)P_N$.

Heating and Cooling

The heating of a machine (especially of the windings) has to be limited in order to guarantee the lifecycle of the machine. For this reason temperature limits exist, which depend on the class of insulation material used. The allowable temperature increase is given at an ambient air temperature of 40 °C. The hotspot temperature is considered based on the measurable temperature. The temperature limits rise for machines with insulation classes E, B, F, and H are specified in IEC 34-1. The given values are valid for windings in nominal operation and are specified using the resistance method. This method enables the engineer to determine the heat produced from increasing resistance and to calculate the temperature coefficient of the conducting material. The heat will be delivered to the primary cooling medium, in which it can be replaced or recooled using a secondary coolant. The cooling medium may be:

- Gaseous (air or hydrogen)
- Liquid (water or oil)

Duty Cycles

The heating of the machine is the result of magnitude and time-load characteristic. Four types of operating conditions are defined (Fig. 17.34):

- Continuous operation
- Short-time rating operation
- Periodic operation
- Nonperiodic operation

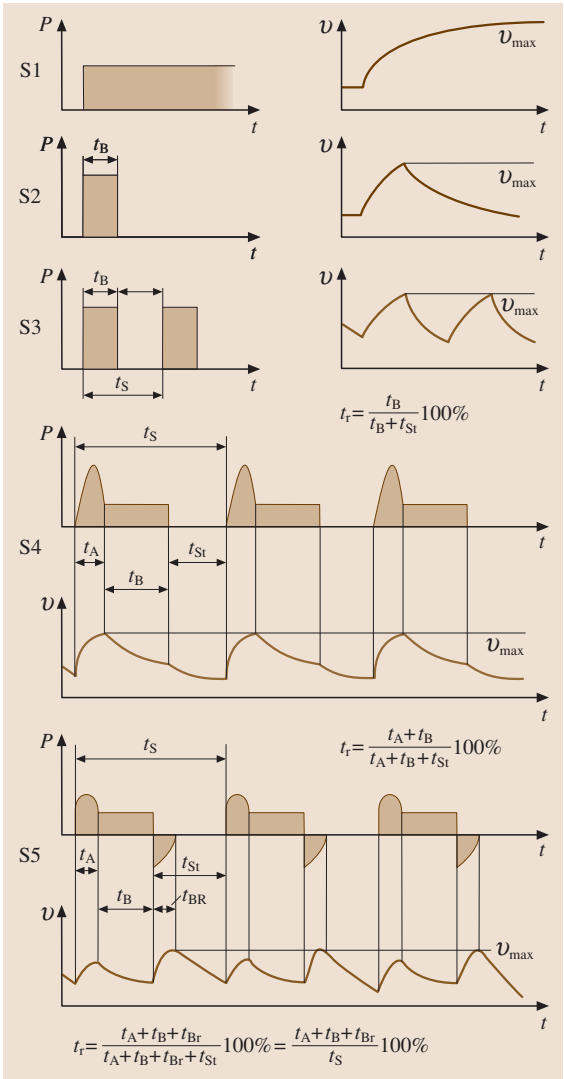

Fig. 17.34 Types of operation (S1 – continuous operation, S2 – short-circuit operation, S3 – impulse operation, S4 – impulse operation with influence of starting process, S5 – impulse operation with electrical acceleration) [17.1]

As one may expect, the same machine can be used more efficiently, compared to mode S1, when they are run in modes S2 or S3 because the upper temperature limit is not exceeded.

Vibrations and Noise

In electric machines mechanical oscillations occur as a result of magnetic excitation and imbalances. These oscillations can be assessed using ISO 2373.

The measured, effective oscillation speed v_{eff} also defines the peak value of the equivalent oscillation speed v_{eq} by taking into account the harmonic oscillations

$$v_{\text{eq}} = \sqrt{2} v_{\text{eff}} \,. \tag{17.141}$$

This value can be estimated using three degrees of oscillation strength:

- N – normal
- R – reduced
- S – special

As the name suggests, N is the most common oscillation strength for electrical machines. Accordingly, for machines with a size between $H = 132$ to 225 the critical value of allowable oscillation strength is $v_{\text{eff}} = 2.8\,\text{mm/s}$. Using the oscillating frequency f, the equivalent amplitude can also be calculated.

$$\hat{s} = \sqrt{2}/(2\pi f) v_{\text{eff}} \,, \tag{17.142}$$

where f is the frequency of the oscillation.

Noise in electrical machines can come from the following sources:

- Aerodynamic noise
- Magnetic noise
- Bearing and brushing noise

For environmental protection it is very important to construct low-noise electrical machines.

The noise perceived by human ears is dependent on the frequency and the amplitude of the noise source. It can be estimated by comparing the measured values with a weighting curve which gives the limit values of the noise (EN 60034-9). To verify the noise level, the sound pressure level L_{p} needs to be measured at idle speed so that the sound power level L_{W} can be calculated.

$$L_{\text{W}} = L_{\text{P}} + 10\,\text{lg}(S/S_0) \,, \tag{17.143}$$

$$S_0 = 1\,\text{m}^2 \,, \tag{17.144}$$

where S is the envelope area.

Electromagnetic Interference

Due to commutation processes electrical machines produce long-term disturbances. Switching operation evokes noncontinuous disturbances. The requirements for disturbances are described in EN 55014. Therein the limit values of interference voltage in the frequency range 0.15–30 MHz and interfering power, or alternatively the interfering field strength, in the range 30–300 MHz are stated. Figure 17.35 presents the common-mode interference voltage and interfering power. Generally, disturbance problems belong to the area of electromagnetic compatibility (EMC) [17.12]. Machines are described as EMC compatible when they can function in an electromagnetic field without influencing the function and environment of other machines that work in the same field.

Rotating Fields in Three-Phase Machines

Synchronous and induction machines with a three-phase system are called three-phase or rotating-field machines. The stator carries three-phase windings, whose coil sides lie in slots.

The currents i_{a}, i_{b}, and i_{c}, which flow in the U, V, and W windings, respectively, make up the symmetrical

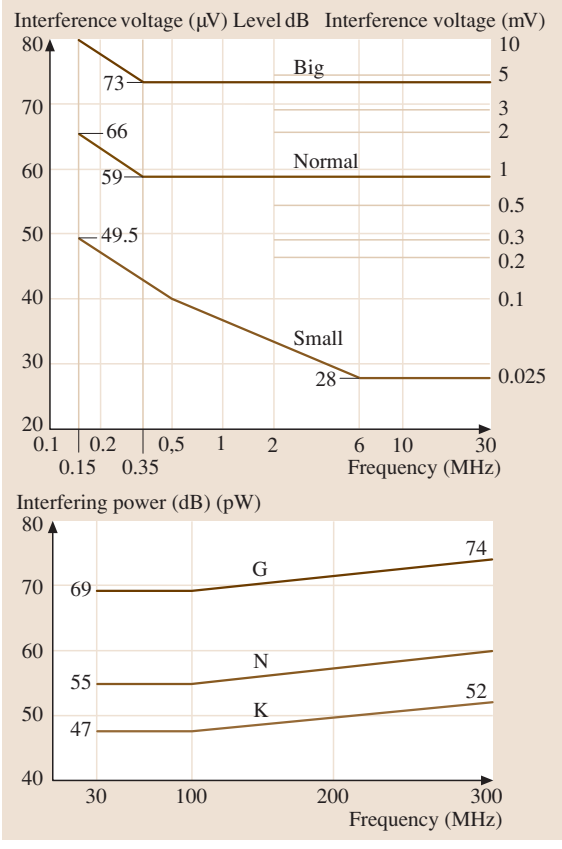

Fig. 17.35a,b Radio interference: **(a)** limit values of interference voltage; **(b)** limit values of interfering power by continuous interference [17.1]

three-phase system

$$i_a(t) = \hat{I}\cos(\omega t - \varphi)\,,$$
$$i_b(t) = \hat{I}\cos(\omega t - \varphi - 2\pi/3)\,,$$
$$i_c(t) = \hat{I}\cos(\omega t - \varphi - 2\pi/3)\,. \qquad (17.145)$$

These currents can also be described using a vector diagram, as shown in Fig. 17.36.

The currents produce the field excitation, which will be described through Ampère-turns. The Ampère-turns of three lines can be written

$$\Theta_{s,1}(\xi, t) = \Theta_{s,1}\cos(\omega t - \varphi - \xi)$$
$$\Theta_{s,1} = \frac{3}{2}\frac{4}{\pi}\frac{w\xi_1}{2p}\hat{I}\,, \qquad (17.146)$$

where w is the number of windings, ξ is the winding factor for the fundamental wave, and $2p$ is the number of poles in the machine.

This case can be also illustrated using the space vector method, as shown in Fig. 17.36. First, another complex surface has to be defined, which can be introduced as a sectional plane for a stator with two poles.

Next, the Ampère-current turns are defined

$$\underline{i}_s = i_a + i_b\,e^{-j\frac{2\pi}{3}}\,. \qquad (17.147)$$

Using the symmetrical system (17.147) $\underline{i}_s = \hat{I}_s\,e^{j\omega t}$ with $\underline{\hat{I}}_s = \frac{3}{2}\hat{I}\,e^{-j\varphi}$ and relating the phasor of the Ampère-turns

$$\underline{\theta}_s = \hat{\theta}_{s,1}\,e^{j\omega t} \quad \text{with} \quad \underline{\hat{\theta}}_{s,1} = \hat{\theta}_{s,1}\,e^{-j\varphi}$$

the location-dependent functional characteristic becomes, in connection with (17.146),

$$\theta_s(\xi, t) = \mathrm{Re}\left(\underline{\theta}_{s,1}\,e^{j(\omega t - \xi)}\right).$$

Figure 17.36 illustrates the current time phasor as well as the space vector of Ampère-turns. The space vector method is very useful for investigating the steady and dynamic operation of three-phase machines.

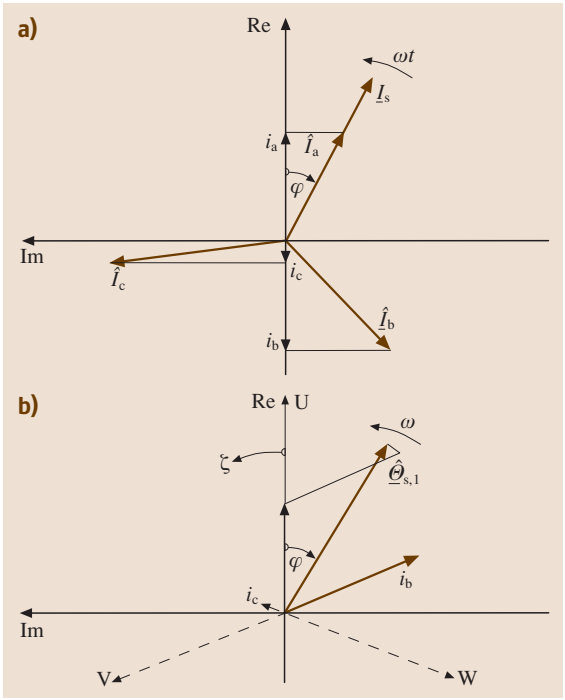

Fig. 17.36a,b Rotating field in rotating electrical machines. **(a)** Phasor diagram of currents; **(b)** space vector diagram of Ampère-turns

17.3.2 Induction Machines

Types

Induction machines are also called asynchronous machines because their operating speed is slightly lower than the synchronous speed in the motor mode and slightly greater than the synchronous speed in the generator mode.

Asynchronous machines (Fig. 17.37) are rugged, relative inexpensive, and require very little maintenance. They range in size from a few watts to about 10 000 hp. The speed of an induction motor is nearly constant, dropping by only a few percent when going from no load to full load. The significant disadvantages of induction machines are:

- The speed is not easily controlled
- The starting current may be five to eight times the full-load current
- The power factor is low and lagging when the machine is lightly loaded

The number of poles is usually 2, 4, or 6, and rarely 8 or 10.

The stator core and rotor windings of a three-phase induction machine are exactly like those of a synchronous machine. The only difference in construction between the two machines is in the rotor. In fact, an induction machine rotor of proper dimensions may be inserted in the bore of a synchronous machine stator, and the resulting induction machine will operate perfectly well.

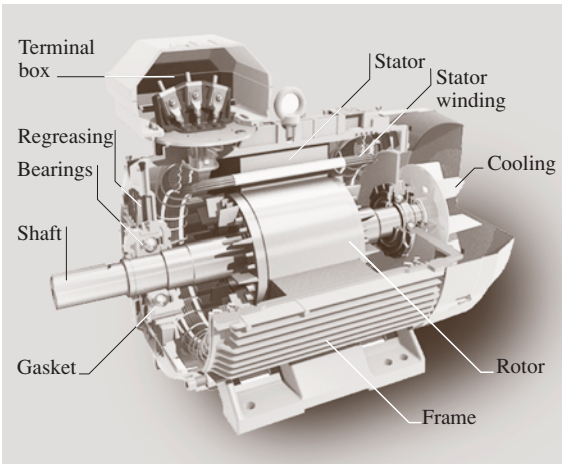

Fig. 17.37 Induction machine (ABB)

There are two types of induction machine rotors: wound and squirrel cage (short circuit). In either case, the rotor windings are contained in slots in a laminated iron core that is mounted on the shaft. In small machines, the rotor lamination stack is pressed directly onto the shaft. In larger machines, the core is mechanically connected to the shaft through a set of spokes called a *spider*.

The winding of a wound rotor is a polyphase winding consisting of coils placed in slots in the rotor core; it is almost always three phase and connected in a star format. The three terminal leads are brought to slip-rings mounted on the shaft. Carbon riding on these slip rings is shorted together for normal operation. External resistances are inserted into the rotor circuit to improve the starting characteristics. As the motor accelerates, the external resistances are gradually reduced to zero.

Squirrel-cage rotor windings consist of solid bars of conducting material in the rotor slots. These rotor bars are shorted together at the two ends of the rotor by end rings. In large machines, the rotor bars may be made of cooper alloy, driven into the slots and brazed into the end rings. The core laminations for such rotors are stacked in a mould, which is then filled with molten aluminum.

Equivalent Circuit Diagram and Circle Diagram

Figure 17.38 shown the equivalent circuit for an induction machine. The asynchronous machine with a squirrel-cage rotor is most suitable for such investigations, because the rotor resistance is independent of the slip. If such a machine is fed from a network with symmetrical voltage $\underline{V}_1$ and constant frequency f_1 the synchronous rotational speed n_s or angular speed Ω_s of the machine is defined as

$$\Omega_s = 2\pi f_1/p = \omega_1/p \tag{17.148}$$

or $n_s = 60 f_1/p$ in min^{-1}.

If this machine idles with asynchronous Ω then the rotor has the slip s opposite to the fundamental rotating field.

$$\begin{aligned} s &= 1 - (\Omega/\Omega_s)\,, \\ f_2 &= s f_1\,, \\ \omega_2 &= s\omega_1\,, \end{aligned} \tag{17.149}$$

where f_2 is the standardized (actual) frequency.

The equivalent circuit of the induction machine in Fig. 17.38 is similar to a transformer equivalent circuit.

The stator leakage inductance, magnetizing inductance, and rotor leakage inductance calculated on the stator side are described by the reactance parameters $X_{\sigma 1}$, X_n, and $X'_{\sigma 2}$ for the frequency ω_1. For the conversion of the rotor parameters to the stator side the factor ω_1/ω_2 is used. As a result the slip-dependent resistance R'_2/s appears on the rotor side. The current transfer locus (Fig. 17.39) describes the operating behavior.

The two significant points of this diagram are the idle speed point $P_0\,(s=0)$ and the point $P_\infty\,(s=\infty)$. Through a third point, e.g., the short-circuit point P_K at standstill of the machine ($s=1$) the circle is completely defined; its center is at point A and its diameter is given by the section $\overline{P_0 P_\Phi}$.

Similar to transformers, iron losses can be considered by using extra resistance in the cross branch in Fig. 17.38.

Operating Characteristics

The characteristic $M(\Omega)$ exhibits a breakdown torque M_k with the assigned breakdown slip s_k. The torque at $s=1$ is called the breakaway torque M_A. $M(s)$ can be

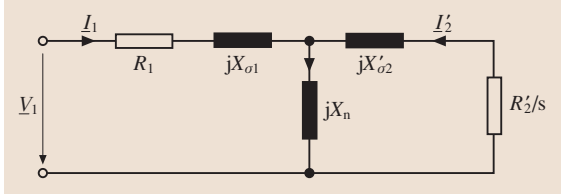

Fig. 17.38 Equivalent circuit of an asynchronous machine

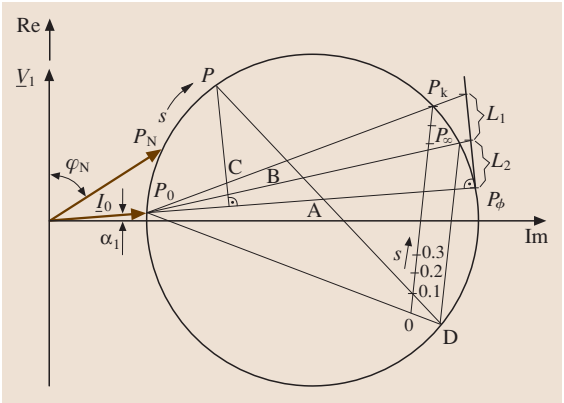

Fig. 17.39 Current transfer locus diagram

expressed as

$$M = M_k \frac{2(s/s_k)}{1+(s/s_k)} ,$$

with

$$s_k = \frac{R'}{X'_{\sigma 2} + X_{\sigma 1} \| X_n}$$

and

$$M_k = \frac{3}{2} \frac{V_1^2 (1-\sigma)}{\Omega_s \sigma X_1} \qquad (17.150)$$

by neglecting the stator resistance R_1.

According to IEC 60034, the relative breakdown torque M_k/M_N has to be greater than 1.6.

The machine works as a generator when the slip has negative values. At standstill the input current is equal to the short-circuit current, whose relative value I_A/I_N can be between 3 and 7 depending on machine construction.

The current of an idle running machine consists primarily of a reactive component which provides the required magnetization (Fig. 17.40). The operation characteristic (Fig. 17.40b) illustrates the interesting current, the power factor $\cos\varphi$, and the efficiency η depending on the mechanical output power.

The relationship between the input electric power P_{in} and the output mechanical power P_{out} of the induction motor is shown in the power-flow diagram in Fig. 17.41.

The input power to an induction motor P_{in} is in the form of three-phase voltages and currents. The first losses encountered in the machine are the Ohmic losses in the stator winding $3I^2R$ (the stator copper loss P_{SCL}).

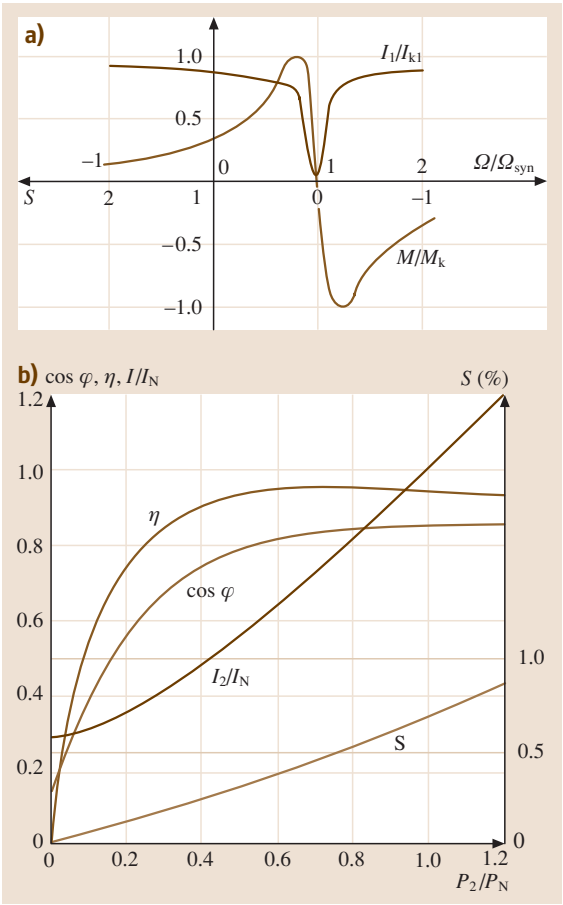

Fig. 17.40a,b Operation characteristic of an induction machine: **(a)** characteristic of current and torsion; **(b)** operation characteristic (load dependent) [17.1]

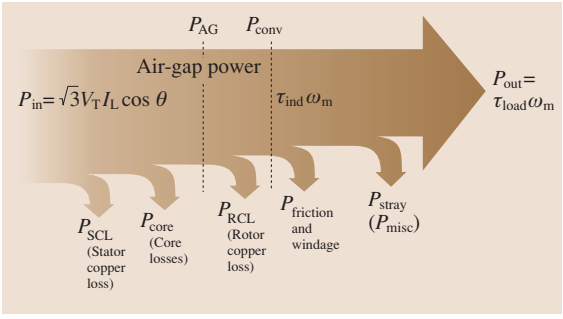

Fig. 17.41 Power flow diagram of an induction machine

The power lost as hysteresis and eddy currents in the stator is expressed as core losses (P_{core}). The power remaining at this point is transferred to the rotor across

the air gap between the stator and the rotor. This power is called the air-gap power P_{AG} of the machine. After the power is transferred to the rotor, some of it is lost as ohmic losses (the rotor copper loss P_{RCL}), and the rest is converted from electrical to mechanical power (P_{conv}). Finally, the friction and windage losses $P_{F\&W}$ and stray losses P_{misc} are subtracted. The remaining power is the output of the motor P_{out}.

Single-Phase Motors

In the examples above, it was assumed that the induction machines were fed with a three-phase symmetrical source.

Single-phase-fed induction motors, which are important in the small power sector, cannot produce a starting torque because of the missing rotating field in the stator.

To solve this problem, a split-phase motor is used in most cases. An extra start-up winding is arranged in addition to the major winding. Through a capacitor (capacitor start motor) or a higher resistance a phase shift of the current in the start-up winding is achieved. After reaching a defined speed the start-up winding can be switched of, e.g., with a centrifugal switch.

17.3.3 Synchronous Machines

Types

Like other electrical machines, synchronous machines may be operated either as a motor or as a generator.

In a synchronous generator, a DC current is applied to the rotor winding, which produces a rotor magnetic field. The rotor of the generator is then turned by a prime mover, producing a rotating magnetic field within the machine. This rotating magnetic field induces a three-phase set of voltages within the stator windings of the generator.

The rotor of a synchronous generator is a large electromagnet. The magnetic poles on the rotor can be:

- Salient – the magnetic pole sticks out of the rotor surface
- Nonsalient – the magnetic pole is constructed flush to the surface

Non-salient-pole rotors are normally used for two- and four-pole rotors. Because the rotor is subjected to changing magnetic fields, it is constructed of thin laminations to reduce eddy-current losses.

A DC current must be supplied to the field circuit on the rotor. Since the rotor is rotating, a special arrangement is required to provide the DC power to its field windings. There are two approaches to supply this DC power:

- From an external DC source to the rotor by means of slip rings and brushes
- From a special DC source mounted directly on the shaft of the synchronous generator

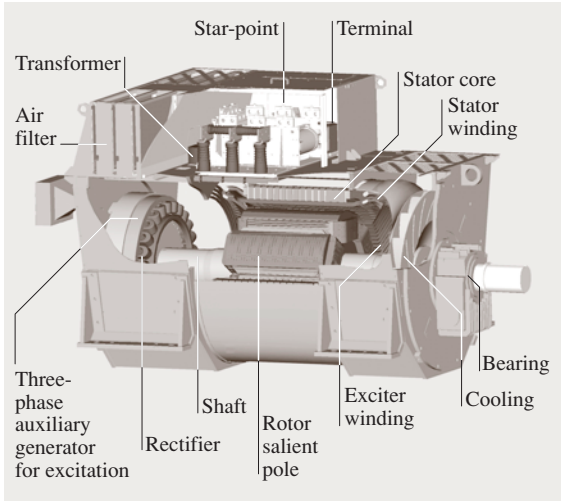

Fig. 17.42 Synchronous generator (ABB)

The largest electrical machines in the world are synchronous generators (Fig. 17.42). Some can produce as much power as 1700 MW. They are constructed as (two- or four-pole) turbogenerators and are driven, for example, by steam turbines. The power of a synchronous machine is limited by its possible rotor dimension (mechanical stress) and allowable armature current (temperature) (Table 17.3).

The limiting power values of two-pole turbogenerators at 50 Hz are described below.

Table 17.3 Synchronous generator power limits

Direct air cooling	80 MVA
Indirect air cooling	150 MVA
Hydrogen cooling without compressors	250 MVA
Hydrogen cooling with 5 bar overpressure	800 MVA
Water cooling, two pole	1200 MVA
Water cooling, four pole	1700 MVA

Operating Characteristics

In order to analyze the electrical behavior, d–q system modeling can be used. In this system it is assumed that the excitation axis is defined as the longitudinal axis (d) and the electrically orthogonal axis is the diagonal axis (q).

The polar wheel angle ϑ is typically used to characterize operation on a network at constant frequency. It represents the electrical angle between the phasor of the terminal voltage $\underline{V}_1$ and the phasor of the magnet wheel voltage $\underline{V}_p$. This magnet wheel voltage is the fictitious induced voltage that would result only from excitation without considering the armature reaction of the current $\underline{I}_1$.

The polar wheel angle ϑ is zero at idle speed. It has a positive value in generator operation and a negative value in motor operation.

Constant values of the voltage and excitation and sinusoidal torque $M(\vartheta)$ result in a circular transfer locus of the current (in Fig. 17.43, neglecting the resistance R_1). Thereafter the torque characteristic shows a breakover point, which depends on the polar wheel voltage in both generator and motor operation.

The quantity X_q/X_d is on the order of 0.7 for large generators and synchronous motors. Figure 17.44a shows the static stability limit of a synchronous generator, which restricts the steady operation area under excitation.

The V-curves can be used to allocate values of the stator current I_1 to the polar wheel voltage V_p (Fig. 17.44b).

Short-Circuit Characteristics

The short-circuit ratio of a synchronous generator is defined as the ratio of the field current required for the rated voltage at open circuit to the field current required for the rated armature current at short circuit. Although the short-circuit ratio adds no new information about the generator beyond what is already known from the saturated synchronous reactance, it is important to know what it is, since the term is occasionally encountered in industry.

In this section, we will survey the terminal three-phase short circuit in a machine with a dashpot cage. The output state is the idle speed at voltage V. Figure 17.45 shows the characteristic of the short-circuit current, which can be approximated by two exponential functions.

In this diagram the transient reactance X'_d and the subtransient reactance X''_d have to be defined, as well as the synchronous reactance, which determines the uninterrupted short-circuit current.

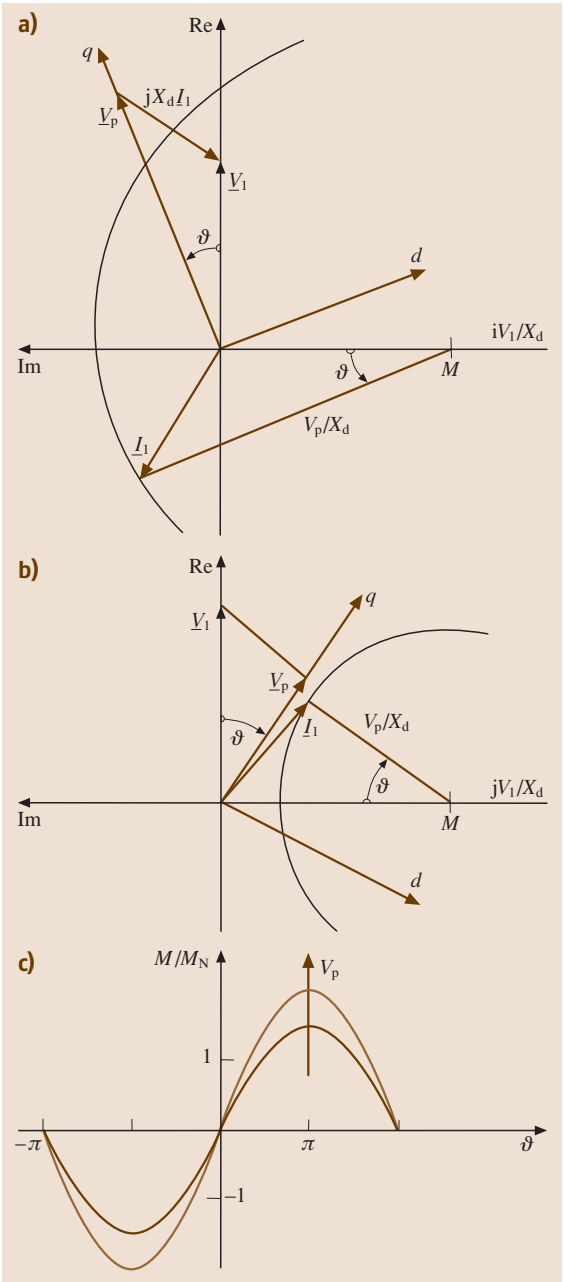

Fig. 17.43a–c Phasor diagram and torque characteristic of a synchronous machine. **(a)** Generator operation, overexcited; **(b)** motor operation, underexcited; **(c)** torque as a function of polar wheel angle

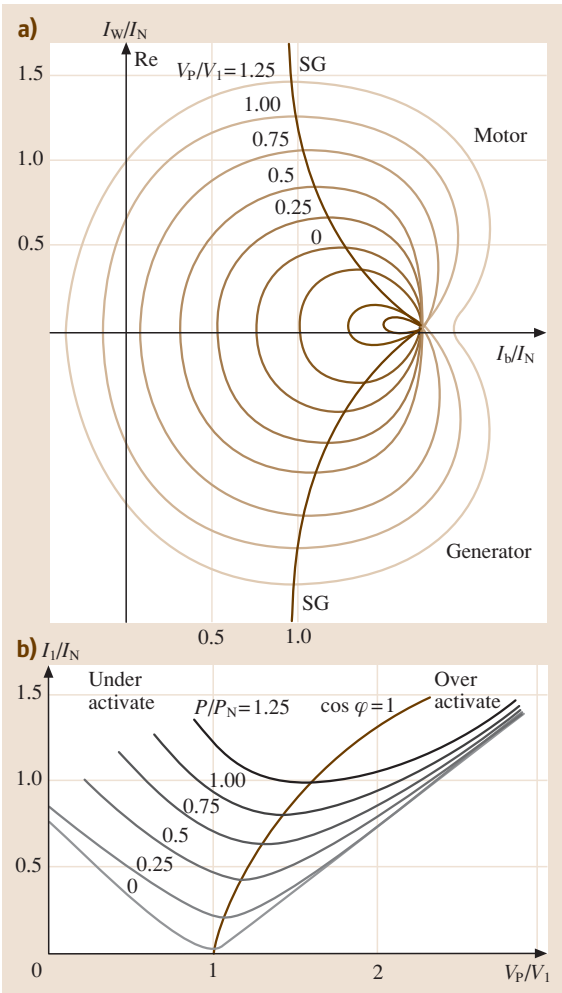

Fig. 17.44a,b Operation characteristic of an synchronous machine. **(a)** Current transfer locus diagram; **(b)** *V*-curves [17.1]

In this case the following parameters are important:

- the uninterrupted short-circuit current

$$I_k = V/X_d \,, \tag{17.151}$$

- The maximum asymmetric short-circuit alternating current transient

$$I'_k = V/X'_d \tag{17.152}$$

- The maximum asymmetric short-circuit alternating current

$$I''_k = V/X''_d \tag{17.153}$$

- The maximum asymmetric short-circuit current

$$I_P = \sqrt{2}\kappa I''_k \approx \sqrt{2}\cdot 1.8 I''_k \tag{17.154}$$

17.3.4 Direct-Current Machines

Types

DC machines are most often used as motors. These motors with permanent magnets are used as auxiliary drives in cars. For industrial uses these machines have a power of 100 kW and engine speed of up to 3000 min^{-1}. They are used as machine tools, hoisting devices, and machines in the basic material and paper industries.

Every DC machine has an armature winding *A* and, except for machines with permanent magnets, one excitation winding. This excitation winding can be implemented as a separate excitation winding *F*, as a shunt excitation *E*, or a series excitation *D* (Fig. 17.46). The armature current flows through the interpole winding *B*, which is responsible for the commutation process. Machines that place high demands on the dynamic system also have a compensation winding Fig. 17.47, which compensates the field of the armature. In this case a current slew rate of $(\text{d}i_A/\text{d}t)/I_N$ of up to 300 s^{-1} can be reached.

Machines for variable-speed drives are produced with laminated iron sheet to suppress the flux delays in the armature as well as in the stator.

Steady-State Operating Characteristics

The characteristic operation behavior of a DC machine is illustrated by the rotational speed and armature current as a function of torque. If constant losses are neglected the following relations apply

$$\Omega = V/c\Phi - R_A/(c\Phi)^2 M \,,$$
$$I_A = 1/(c\Phi)M \,. \tag{17.155}$$

Machines fed with constant voltage and, through shunt excitation, constant flux Φ, feature the typical shunt-wound operation characteristic.

The rotational speed is proportional to the feed voltage in unloaded operation and decreases linearly with increasing load due to the armature circuit resistance. At the same time, the armature current increases linearly, as shown in Fig. 17.48a. Otherwise, in a series-wound machines the flux is associated with the armature current through a curve that demonstrates a saturation characteristic. The unloaded rotational speed is only limited by frictional losses, whereas the rotational speed decreases rapidly with increasing load (Fig. 17.48b).

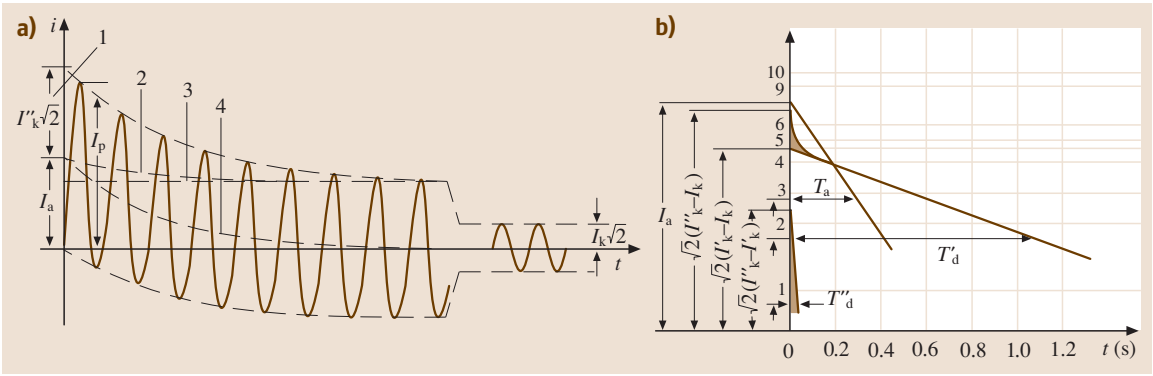

Fig. 17.45a,b Three-phase short-circuit characteristic: **(a)** current characteristic (1 – peak value of the surge short-circuit current, 2 – fast decay of the AC part, 3 – slow decay of the AC part, 4 – decay of the DC part); **(b)** interpretation of the short-circuit characteristic

Transient Operating Characteristics

The dynamic operation characteristics of DC machines play a very important role in industrial use where the dynamical demands are very high. In this section we will only consider machines with separate excitation ($\Phi = \text{const}$). In Fig. 17.49 a linear control circuit is shown. The input parameters are the imposed armature voltage v (the reference variable) and the load torque m_L (the disturbance variable).

The machine will be considered as a homogenous system with a total torque of inertia J. For this reason the structure of this system consists of a closed loop. This loop consists of an integrator with a mechanical time constant of T_M, connected in series to a first-order delay element with an (electrical) armature time constant of T_A. This second-order system has an electromechanical eigenfrequency w, where the periodic case with $d < 1$ results from the time constants

$$w = \omega_0\sqrt{1-d^2}\,,$$
$$\omega_0^2 = 1/(T_A T_M)\,,$$
$$d^2 = T_M/(4T_A) < 1\,. \qquad (17.156)$$

In this often occurring case the machine responds with damped oscillations when excited (e.g., by a step function). Figure 17.50 shows an example of the reference action at a standarised rotating speed of h_1 and

armature current of h_2 after a step of the imposed armature voltage.

17.3.5 Fractional-Horsepower Motors

General Information

The power of fractional horsepower motors usually reaches 1 kW. These motors are used in large numbers in the consumer goods industry (household appliance, video and audio equipment, etc.), electrically driven tools, and as auxiliary drives in vehicles. Their professional use includes drives for data system technologies, office applications, and special drives for industry and scientific devices.

The construction of such motors mostly depends on their function, and not on standardized dimensions. The following types of motors are used in fractional-horsepower motors:

- Induction motors
- Synchronous motors
- Commutator machines

Small Induction Power Motors

In the following example asynchronous motors working with a one-phase system of 230 V and 50 Hz are considered. It is known that three-phase motors produce reduced torque when one phase is failing. However there is no start-up torque. External activation enables the motor to rotate in both directions. The mode of oper-

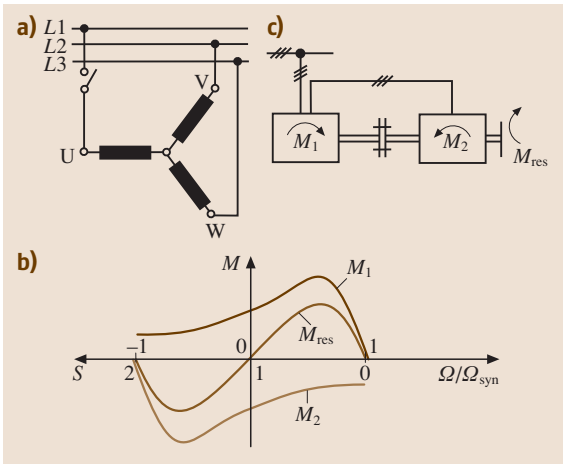

Fig. 17.51a–c One-phase operation of the machine because of phase breakdown. **(a)** Circuit; **(b)** characteristic of torsion; **(c)** equivalent system (two symmetrical machines for the negative- and positive-sequence system)

ation for a one-phase-fed motor can be explained using the symmetrical components theory (Fig. 17.10). The stator field features, in addition to the positive-sequence system, a negative-sequence system that works synchronously but in the opposite direction. Referring to the rotor the positive-sequence system rotates with a slip frequency of sf_1, whereas the negative-sequence system rotates with $(2-s)f_1$.

One-phase small power motors have a primary winding, a work winding, and an auxiliary winding. The current in the auxiliary winding produces an alternating field component that is shifted in position and time so that an incomplete rotating field is created. Figure 17.52 explains how the rotating field is produced, in which the positive-sequence system overbalances the negative-sequence system.

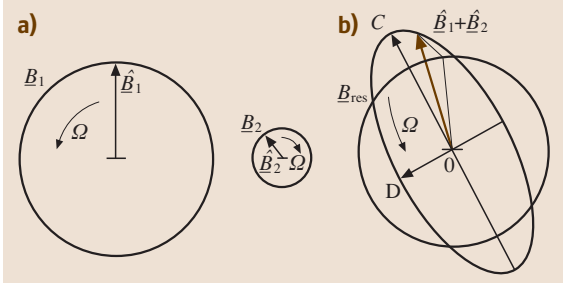

Fig. 17.52a,b Space vector for the creation of an elliptic rotational field. **(a)** Positive- and negative-sequence system; **(b)** superposition of both systems

Synchronous Small Power Motors for Network Operation

Three types of synchronous small power motors are in use:

- Permanent-magnet motors
- Hysteresis motors
- Reluctance motors

These motors can produce up to a few watts of power and can be used in switchgear equipment and me-

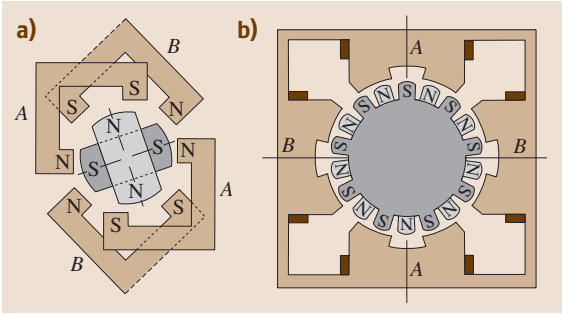

Fig. 17.54a,b Hybrid step motor (two phase). **(a)** Principle construction with two rotor plates ($z_r = 2$; $\alpha = 45°$); **(b)** construction with $z_r = 9$ and $\alpha = 10°$

chanical clocks. To produce a rotating (elliptical) field a capacitor-fed auxiliary phase as well as shaded pole windings can be used. For multipolar designs, claw pole constructions are favored.

Stepper Motors

Stepper motors may be thought of as polyphase synchronous motors fed with pulses produced by electronic controllers [17.13]. The name stepper comes from the feature that such a motor rotates only in defined steps (sectors of circle) for each pulse. Stepper motors can be excited permanently or by the principles of reluctance. In hybrid motors both principles are used to produce the torque. For large steps (e.g., 7.5−15°) claw pole machines are also applied. In order to realize very small steps (much smaller than 1°) polyphase hybrid motors are common. They are preferably equipped with high-grade magnets (e.g., cobalt-samarium).

The mode of operation can be explained using the example in Fig. 17.53, which depicts a two-phase stepper motor with a permanent-magnet rotor.

The drive is realized in a unipolar design through a four-transistor switch. At the default clock rate with the step frequency f_s the motor performs as shown in Fig. 17.53c. The hybrid motor contains an axial magnetized toric magnet in the rotor.

This magnet is placed between two magnetically soft rotor plates, which have z_r rims (Fig. 17.54). These plates are twisted against each other by half the width of the rims.

Electronic Commutated Motors

Generally speaking, these motors can be compared to synchronous machines. The rotor has a permanent excitation and the stator consists of multiple line windings and is controlled using an electronic controller. Unlike stepper motors, which are run in an open control chain, the drive for electronic commutation motors is dependent on the measured rotor position (e.g., using Hall sensors), as shown in Fig. 17.55. Usually the control of the rotational speed is realized as in DC current machines, which is why these motors are also called brushless DC motors.

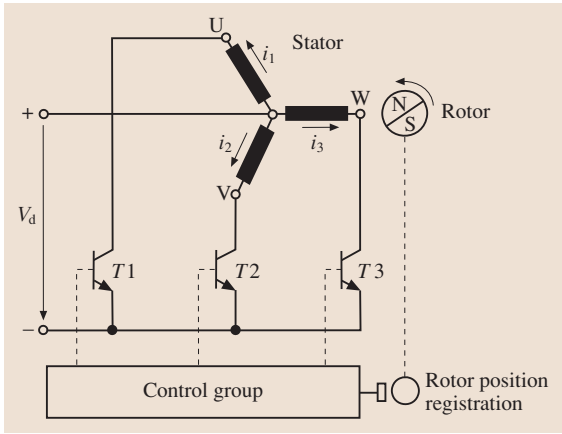

Fig. 17.55 Circuit of a brushless DC motor

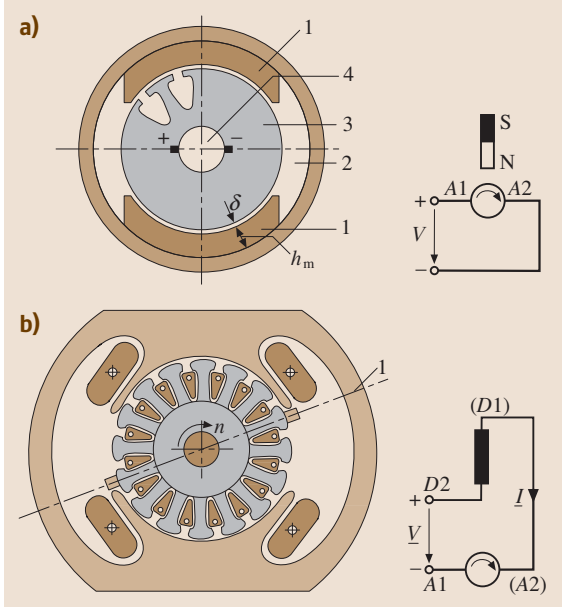

Fig. 17.56a,b Construction of **(a)** commutator small power motor ferromagnetic DC motor for 12 V: 1 – magnet part, 2 – iron interference, 3 – armature, 4 – commutator with brushes; **(b)** universal motor with movement of the brush axis: 1 – commutation axis

DC Small Power Motors

These kinds of motors are mostly used as auxiliary drives in vehicles and are supplied with a battery voltage of either 12 or 24 V. To produce low-cost motors only ferrite magnets are used. The high value of the temperature coefficient of the coercive field strength (about $+0.004\,\mathrm{K}^{-1}$) has to be considered as well as the deviation of the demagnetization characteristic in a high negative field strength; it has to be assured that at low ambient air temperature ($-20\,^{\circ}\mathrm{C}$) the start-up short-circuit current does not result in permanent demagnetization.

Universal Motors

These are motors which can work in both DC and AC systems. Nowadays they mostly use one-phase alternating current, especially in household appliances. The major advantage of these machines is that the rotating speed is not bound to the network frequency. For example, a vacuum cleaner that works at a rotating speed of up to $25\,000\,\mathrm{min}^{-1}$ can achieve a very high power-to-weight ratio. The universal motor is setup as shown in Fig. 17.56b.

The unloaded speed is limited by windage and friction. Because of their capability to operate at high speeds, universal motors of a given horsepower rating are significantly smaller than other kinds of AC motors operating at the same frequency.

Universal motors are ideal for home devices such as hand drills, hand grinders, food mixers, routers, and vacuum cleaners. Unfortunately the lifetime of such motors is limited by the lifetime of the brushes, which is about 2500 h.

17.4 Power Electronics

17.4.1 Basics of Power Electronics

Power Electronics is basically used to transform one electrical system into another. Major applications are variable-speed drives and power supplies. Configurations as follows are frequently met:

- Conversion DC → DC, e.g., to supply variable-speed DC drives from a constant-voltage DC line or as step-down DC–DC converters in decentralized power supplies
- Conversion AC → DC by a rectifier, e.g., to supply variable-speed DC drives or electronics – such as computers, communication equipment etc. – from AC mains
- Conversion DC → AC by an inverter, e.g., to feed energy generated from a DC source – such as a fuel cell or a photovoltaic generator – into AC mains
- Conversion AC → AC, e.g., to supply variable-speed AC motor drives by AC mains, or in generator mode to feed the generated electrical energy into mains

It is obvious that the voltage level and – in the case of AC – frequency are the subject of change in the transformation. The aforementioned conversion steps can of course also be cascaded, e.g., first rectifying mains AC into a DC system which is subsequently inverted again to supply a variable-speed AC drive.

Generally speaking, power electronics is used to transmit higher power than signal electronics, covering a range between some 100 W and several megawatts. Its operational principle can easily be derived based on following consideration, following the development of the control of variable-speed DC drives. A higher DC voltage u_1 can basically be reduced to a lower value $u_2 = R_1/(R_1+R_2)u_1 - R_1R_2/(R_1+R_2)i_2$ with a voltage divider circuit according to Fig. 17.57. It is however obvious that u_2 depends on the load current i_2; to keep the voltage u_2 constant for different loads, the voltage divider needs to be adapted. This can be achieved using controllable active devices instead of passive resistors. As an additional constraint power losses $p_V = (u_1-u_2)^2/R_1 + u_2^2/R_2$ in the circuit may become undesirably high and lead to low efficiency, especially in the case of a low ratio u_2/u_1. To avoid this, only ideally lossless passive devices, i. e., capacitors and inductors, should be used in power electronics along with digitally operated active devices.

Semiconductors are therefore used as switches according to Fig. 17.58a. They are either fully conductive, carrying a current $|i_S| \gg 0$ with negligible voltage drop $u_S \approx 0$, or fully blocking $|u_S| \gg 0$ with minimum leakage current $i_S \approx 0$; the transients between these steady states need to be short. Unless otherwise stated, the considerations of circuit theory in Sects. 17.4.2 and 17.4.3 therefore assume idealized behavior

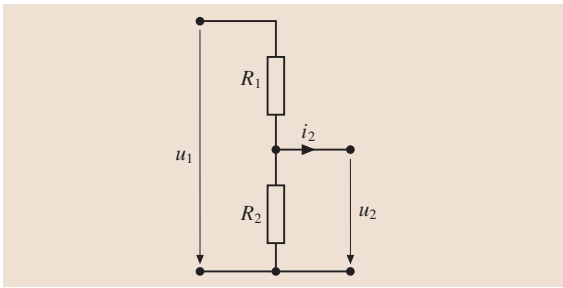

Fig. 17.57 Resistive voltage divider

of the basic power electronic switching components as follows:

- A insulated gate bipolar transistor (IGBT; Fig. 17.58b) carries a collector current $i_C \gg 0$ at ideally negligible saturation voltage $u_{CE} = u_{CEsat} \approx 0$ when turned on; when turned off, it will block a voltage $u_{CE} \gg 0$ at negligible leakage current $i_C \approx 0$. Control of the switching state is effected by the gate–emitter voltage u_{GE}.
- A metal oxide semiconductor field-effect transistor (MOSFET; Fig. 17.58c) behaves in a similar way. When turned off, it will block a voltage $u_{DS} \gg 0$ at negligible leakage current $i_D \approx 0$; it may however – like a diode, see below – conduct an inverse current $i_D \ll 0$. This also applies when turned on, where it will additionally conduct a drain current $i_D \gg 0$, both at ideally negligible voltage drop between the drain and source $u_{DS} \approx 0$. Control of the switching state is effected by the gate–source voltage u_{GS}.
- A diode (Fig. 17.58d) either carries a forward current $i_F \gg 0$ at an ideally negligible forward voltage $u_F = -u_R \approx 0$ or blocks a reverse voltage $u_R \gg 0$ at an ideally negligible reverse current $i_R = -i_F \approx 0$. Note that there is no separate control terminal: the switching state of a diode is thus simply defined by the mentioned voltage conditions in the power circuit.
- A thyristor (Fig. 17.58e) basically behaves similarly to a diode, however with additional means for control: after triggering with a gate current pulse $i_G > 0$ it can carry a forward current $i_T \gg 0$ at ideally negligible forward voltage $u_T = -u_R \approx 0$; this state is maintained until the forward current comes close to zero $i_T \to 0$ again, i. e., a thyristor device can be turned on via the gate control terminal but it will turn off only depending on the conditions in the power circuit. If not triggered, the thyristor will instead block a forward voltage $u_T = -u_R \gg 0$ at an ideally negligible forward leakage current $i_F \approx 0$ and will anyway block a reverse voltage $u_R \gg 0$, again at an ideally negligible reverse leakage current $i_R = -i_F \approx 0$ like a diode.

Transistors and diodes are relevant for the self-commutated circuits explained in Sect. 17.4.2, while diodes and thyristors are relevant for the externally commutated circuits described in Sect. 17.4.3. A more detailed description of these components with respect to their operation in these circuits is given in Sect. 17.4.4, which permits design issues for power electronics to be considered.

17.4.2 Basic Self-Commutated Circuits

DC Choppers

Stepping down a DC voltage u_Z to a lower value u_{1-} with $u_Z > u_{1-} > 0$ can be achieved with a buck chopper circuit as depicted in Fig. 17.59a operated according to Fig. 17.60a. When transistor T_1 is turned on and thus becomes conductive for $t_0 \le t < t_2$, the output voltage is $u_{L1-} = u_Z$. The voltage difference across the inductor

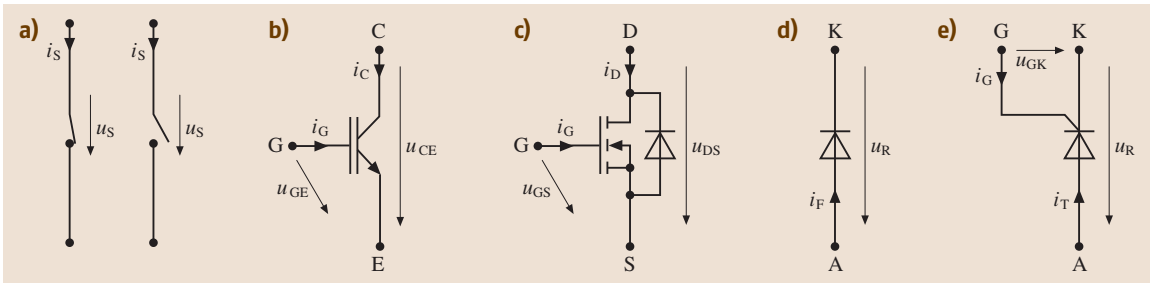

Fig. 17.58 **(a)** Switch turned on and off; **(b)** transistor (IGBT) with terminals C = collector, E = emitter, G = gate; **(c)** transistor (MOSFET) with terminals D = drain, S = source, G = gate; **(d)** diode with terminals A = anode, K = cathode; **(e)** thyristor with terminals A = anode, K = cathode, G = gate

L_{L1} determines the current change according to

$$L_{L1}\frac{di_{L1}}{dt} = u_{L1-} - u_{1-} \,. \tag{17.157}$$

Assuming that the DC link voltage and load voltage are constant $u_Z \equiv U_Z$, $u_{1-} \equiv U_{1-}$, the output current can be calculated to be

$$i_{L1}(t) = i_{L1}(t_0) + \frac{U_Z - U_{1-}}{L_{L1}}(t - t_0) \,, \tag{17.158}$$

which describes a linearly increasing waveform according to the aforementioned prerequisites. Because

$$i_{L1} = i_{S1} - i_{S2} \tag{17.159}$$

$i_{S1} = i_{L1}$ are identical while $i_{S2} = 0$ applies, because D_2 is the blocking reverse voltage.

After turning T_1 off at t_2, which leads to $i_{S1} = 0$, the inductor current can only be supplied via D_2 as $i_{S2} = -i_{L1}$. As long as this state lasts $u_{L1-} = 0$ applies, leading to an output current waveform starting at $i_{L1}(t_2)$ from (17.158) and changing according to (17.157)

$$i_{L1}(t) = i_{L1}(t_0) + \frac{U_Z}{L_{L1}}(t_2 - t_0) - \frac{U_{1-}}{L_{L1}}(t - t_0) \,. \tag{17.160}$$

The current will thus decrease linearly with a rate of change that depends on the load voltage U_{1-}. Because of the aforementioned device characteristics, with $i_{S1} \geq 0$ through transistor T_1 and $i_{S2} \leq 0$ through diode D_2, $i_{L1} \geq 0$ must apply. As long as $i_{L1} > 0$ flows continuously in the positive direction, the state described by (17.160) lasts until the cycle starts again at t_4, when T_1 is turned on again. If, on the other hand, $i_{L1} = 0$ becomes zero at $t_3 < t_4$, it will remain zero ($i_{L1} = 0$) with an output voltage determined by the load voltage $u_{L1-} = u_{1-}$ for $t_3 \leq t < t_4$ with both switches blocking; the current flow in this case is obviously discontinuous.

Both operational modes are depicted in Fig. 17.60a, calculated for the same DC link voltage U_Z; in the case of discontinuous operation U_{1-} has been set to a higher value than in the case of continuous operation, leading to a flatter increase of current according to (17.158) and a steeper decrease according to (17.160).

With respect to control, the symbols cycle duration $T_P = t_4 - t_0$ and switching frequency $f_T = 1/T_P$ are introduced together with the duty cycle

$$a = \frac{t_2 - t_0}{T_P} \,. \tag{17.161}$$

The latter represents the portion of the cycle during which T_1 is turned on; $0 \leq a \leq 1$ applies. The average output voltage can then be calculated to be

$$U_{L1-} = \frac{1}{T_P}\int_{t_0}^{t_4} u_{L1-}\,dt = aU_Z \,, \tag{17.162}$$

which is a linear transfer function of the variable average output voltage U_{L1-} versus the duty cycle a at constant DC link voltage U_Z. Considering the current, steady-state operation is achieved when $i_{L1}(t_0) = i_{L1}(t_4)$ applies: this is always the case in discontinuous operation with $i_{L1}(t_0) = i_{L1}(t_4) = 0$, while the condition for continuous operation can be derived from (17.160) to be $0 = (U_Z/L_{L1})(t_2 - t_0) - (U_{1-}/L_{L1})(t_4 - t_0)$, which is fulfilled for

$$a = \frac{U_{1-}}{U_Z} \,. \tag{17.163}$$

Considering (17.162) this means that the continuous current waveform in Fig. 17.60a does not change position when the average output voltage is adjusted to be equal to load voltage $U_{L1-} = U_{1-}$; the reason is that the average voltage across the inductor L_{L1} will then be zero.

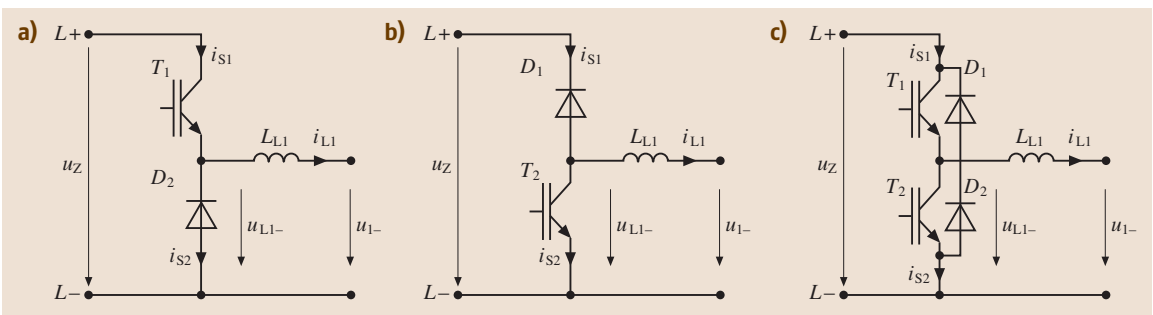

Fig. 17.59a–c Circuit diagrams of DC choppers with IGBTs and diodes: **(a)** buck chopper; **(b)** boost chopper; **(c)** phase leg

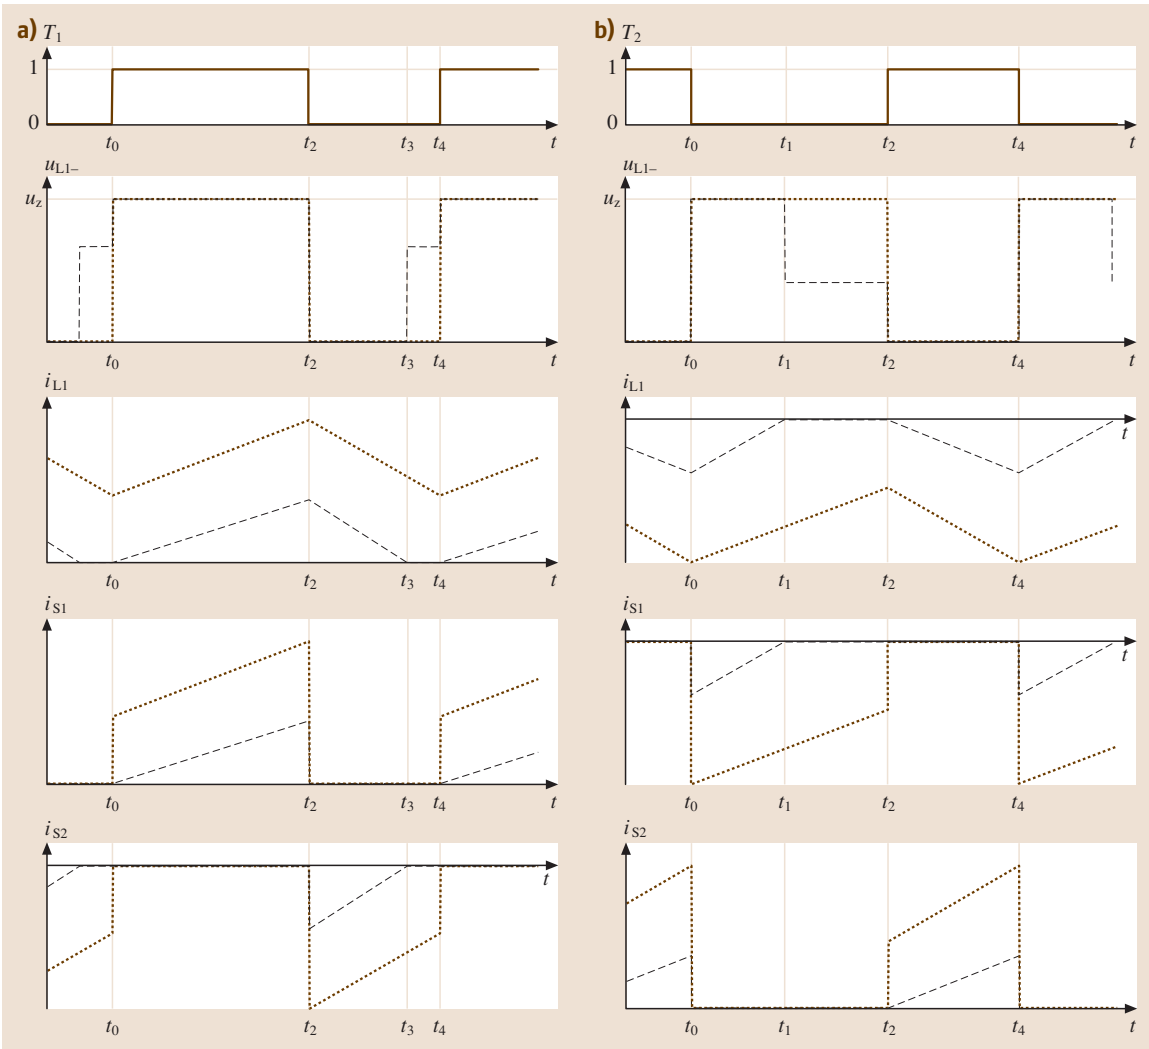

Fig. 17.60a,b Idealized waveforms of DC choppers in steady state – switching states of $T_1 - T_2$ (0 = off, 1 = on), output voltage u_{L1-} and current i_{L1}, switch currents $i_{S1} - i_{S2}$ of: **(a)** buck chopper and **(b)** boost chopper at continuous (*dotted*) and discontinuous (*dashed*) current flow

To transfer energy from a lower- to a higher-voltage source, the polarity of the current obviously needs to be inverted, which leads to the circuit diagram of the *boost chopper* in Fig. 17.59b with the corresponding waveforms in Fig. 17.60b. Here, D_1 permits a current flow $i_{S1} \leq 0$, T_1 $i_{S2} \geq 0$ and thus $i_{L1} = i_{S1} - i_{S2} \leq 0$.

To analyze the operation of this circuit it is assumed that T_2 will be turned on for $t_2 \leq t < t_4$. With $u_{L1-} = 0$, D_1 will then be blocking U_Z at $i_{S1} = 0$. Corresponding to the consideration of the buck chopper, (17.160) applies, i. e., $i_{L1} \leq 0$ will become more negative linearly in this time interval.

After T_2 has been turned off, leading to $i_{S2} = 0$, the output current $i_{L1} = -i_{S1} < 0$ will flow through D_1, making $u_{L1-} = u_Z$. As long as a current $i_{L1} < 0$ is flowing, (17.158) applies, meaning that i_{L1} becomes linearly more positive. Again corresponding to the above considerations, the current flow may be continuous, with $i_{L1} < 0$ not reaching zero for $t_0 \leq t < t_2$, or discontinuous with $i_{L1} < 0$ for $t_0 \leq t < t_1$ and $i_{L1} = 0$ for $t_1 \leq t < t_2$.

Due to the equivalent behavior of the boost and buck chopper, the derived control behavior – namely (17.162) and (17.163) – applies for both.

It is evident that combining the circuits of the buck and boost chopper according to Fig. 17.59a,b will permit bidirectional current flow and thus energy transfer from the higher- to the lower-voltage side and vice versa; the resulting *phase leg* circuit is depicted in Fig. 17.59c, and the corresponding waveforms are shown in Fig. 17.61. In the time interval $t_{10} \le t < t_{20}$ the circuit operates as a buck chopper, where the cycles $t_0 \le t < t_4$ according to Fig. 17.60a repeat with switching frequency f_T; the steady state with $i_{L1}(t_0) = i_{L1}(t_4)$ has been adjusted by choosing the duty cycle a according to (17.163). Correspondingly the DC–DC converter operates as a buck chopper in steady state for $t_{50} \le t < t_{60}$, as shown in Fig. 17.60b. In the time intervals $t_{20} \le t < t_{30}$ and $t_{40} \le t < t_{50}$ the average output voltage U_{L1-} is reduced according to (17.162) through a smaller duty cycle a; this is effected with shorter turn-on intervals of the transistor T_1 than in the steady state. The reduced average voltage U_{L1-} leads to a reduction of the average inductor current I_{L1}. The current is thus regulated by means of output voltage control through adjustment of the duty cycle a. Note that in the time interval $t_{30} \le t < t_{40}$ – where the steady state is adjusted again – the current plurally crosses the zero line. This is different to the operation of a pure buck or boost chopper as discussed before, where the current cannot change polarity and thus becomes intermittent. The reason is that the two transistors T_1 and T_2 of the phase leg are turned on alternately; thus paths for both polarities of current are open according to (17.159). Positive currents $i_{L1} > 0$ flow as $i_{S1} > 0$ or $i_{S2} < 0$ through T_1 or D_2, respectively, and negative currents $i_{L1} < 0$ as $i_{S2} > 0$ or $i_{S1} < 0$ through T_2 or D_1.

The considerations in this section can thus be summarized as follows. DC choppers are able to transfer energy from a higher- to a lower-voltage level $u_Z \ge u_{1-} \ge 0$, or vice versa. The average output voltage U_{L1-} is adjusted by the duty cycle a with a linear transfer function according to (17.161) and (17.162). During continuous current flow the average output current I_{L1} through the inductor will remain constant if (17.163) is met; for lower a it will decrease or become more negative, whereas for higher a it will increase or become more positive.

A typical application of such circuits is variable-speed drives, where a constant voltage U_Z is used to supply a DC machine with terminal voltage u_{1-}. With torque depending on current and speed on voltage, the drive is essentially in motor mode during buck chopper operation with $i_{L1} > 0$ and in generator mode during boost chopper operation with $i_{L1} < 0$; because $U_{1-} > 0$ these modes can be adjusted for one direction of rotation. To change to the other direction, the machine could be connected to L_1 and L_+ instead of L_-, which can be effected by using a relay in the case of low dynamic requirements or through a second phase leg as explained in the following.

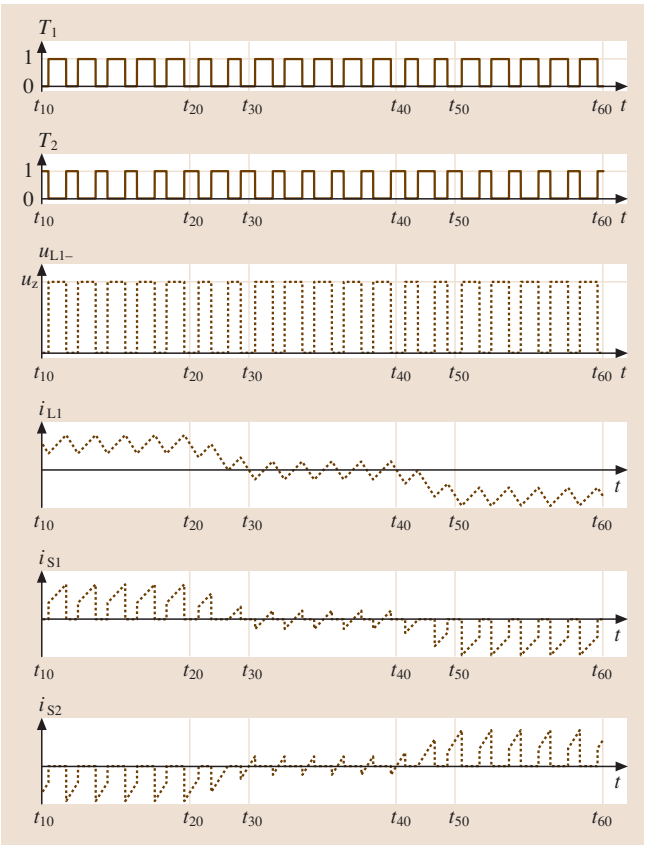

Fig. 17.61 Idealized waveforms of a two-quadrant DC chopper – phase leg: switching states of $T_1 - T_2$ (0 = off, 1 = on), output voltage u_{L1-} and current i_{L1}, switch currents $i_{S1} - i_{S2}$

Single- and Three-Phase Bridges

When combining two phase leg circuits according to Fig. 17.62a, the first consisting of T_1, D_1, T_2, and D_2 controlled by the duty cycle a_1 and the second consisting of T_3, D_3, T_4, and D_4 correspondingly by a_2, with

phase output voltages of

$$u_{\mathrm{L1M}} = \pm\frac{u_{\mathrm{Z}}}{2}\,,$$
$$u_{\mathrm{L2M}} = \pm\frac{u_{\mathrm{Z}}}{2}\,, \qquad (17.164)$$

which refer to a virtual center point M of the DC link, the resulting phase-to-phase output voltage will be

$$u_{\mathrm{L12}} = u_{\mathrm{L1M}} - u_{\mathrm{L2M}} = \begin{cases} \frac{u_{\mathrm{Z}}}{2} + \frac{u_{\mathrm{Z}}}{2} &= u_{\mathrm{Z}} \\ \frac{u_{\mathrm{Z}}}{2} - \frac{u_{\mathrm{Z}}}{2} &= 0 \\ -\frac{u_{\mathrm{Z}}}{2} - \frac{u_{\mathrm{Z}}}{2} &= -u_{\mathrm{Z}}\,. \end{cases} \qquad (17.165)$$

A calculation of the average values corresponding to (17.162) – assuming the same switching frequency f_{T} for both phase legs and a constant DC link voltage U_{Z} – yields

$$U_{\mathrm{L1M}} = \left(a_1 - \frac{1}{2}\right) U_{\mathrm{Z}}\,, \qquad (17.166)$$
$$U_{\mathrm{L2M}} = \left(a_2 - \frac{1}{2}\right) U_{\mathrm{Z}}\,. \qquad (17.167)$$

The difference is therefore

$$U_{\mathrm{L12}} = U_{\mathrm{L1M}} - U_{\mathrm{L2M}} = (a_1 - a_2)\, U_{\mathrm{Z}}\,, \qquad (17.168)$$

which covers the range $-U_{\mathrm{Z}} \le U_{\mathrm{L12}} \le U_{\mathrm{Z}}$ for the permissible values of a_1 and a_2 according to (17.161). This would fulfil the claim to provide both polarities of output voltage to supply a four-quadrant DC drive as stated at the end of last section.

The duty cycles a_1 and a_2 can be defined by several modulation schemes. A two-level modulation scheme is realized by switching the transistors in the diagonal of the bridge equally, i. e., T_1 and T_4 are on at the same time, leading to the first level of output voltage $u_{\mathrm{L12}} = u_{\mathrm{Z}}$, or T_2 and T_3 are on at the same time, leading to the second level $u_{\mathrm{L12}} = -u_{\mathrm{Z}}$, cf. the solid waveforms in Fig. 17.63a. The duty cycles are then $a_2 = 1 - a_1$, leading to an average output voltage of $U_{\mathrm{L12}} = (2a_1 - 1)\, U_{\mathrm{Z}}$ according to (17.168). In an alternative three-level modulation scheme independent duty cycles a_1 and a_2 can be adjusted, which makes all three levels of output voltage according to (17.165) occur, as depicted with dotted lines. Note that the average output voltage for the two different pulse patterns shown in Fig. 17.63a is the same: $U_{\mathrm{L12}} = -U_{\mathrm{Z}}/2$. The special case of a phase shift is illustrated in Fig. 17.63b. Both phase legs are operated with the same duty cycle, however the pulse patterns are shifted with respect to each other. Because $a_1 = a_2$, (17.168) yields an average output voltage of $U_{\mathrm{L12}} = 0$; it is thus a pure AC voltage. Its RMS value can be adjusted by using the phase shift, as is obvious from a comparison of the two displayed waveforms u_{L12}. The phase shift is commonly characterized by indicating the angle $2\pi\, f_{\mathrm{T}} t$. In

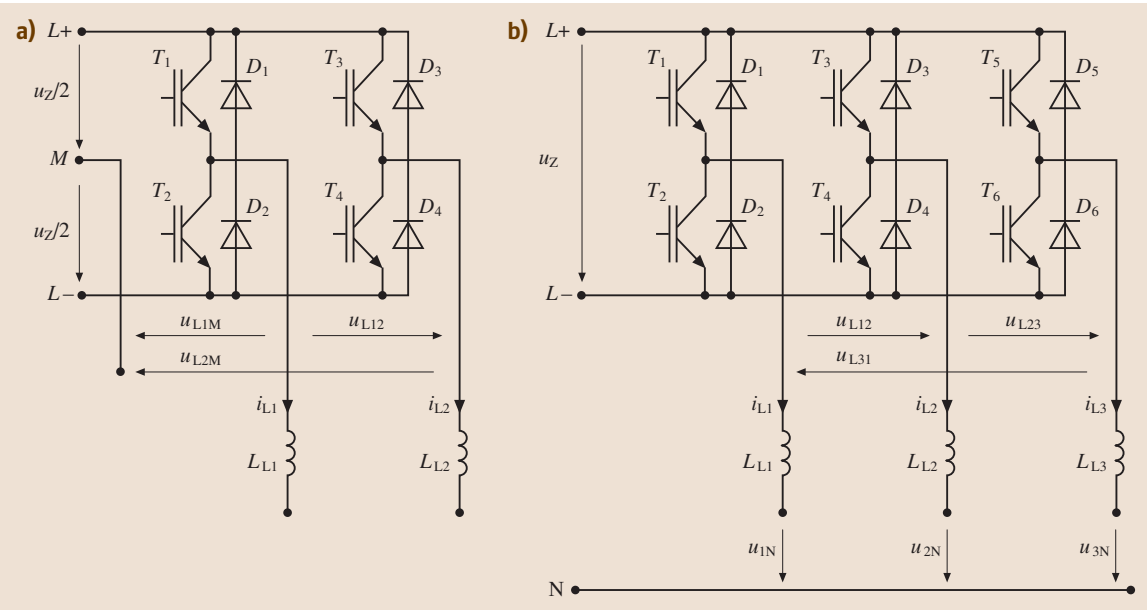

Fig. 17.62a,b Circuit diagrams of (a) single and (b) three-phase bridges with IGBTs and diodes

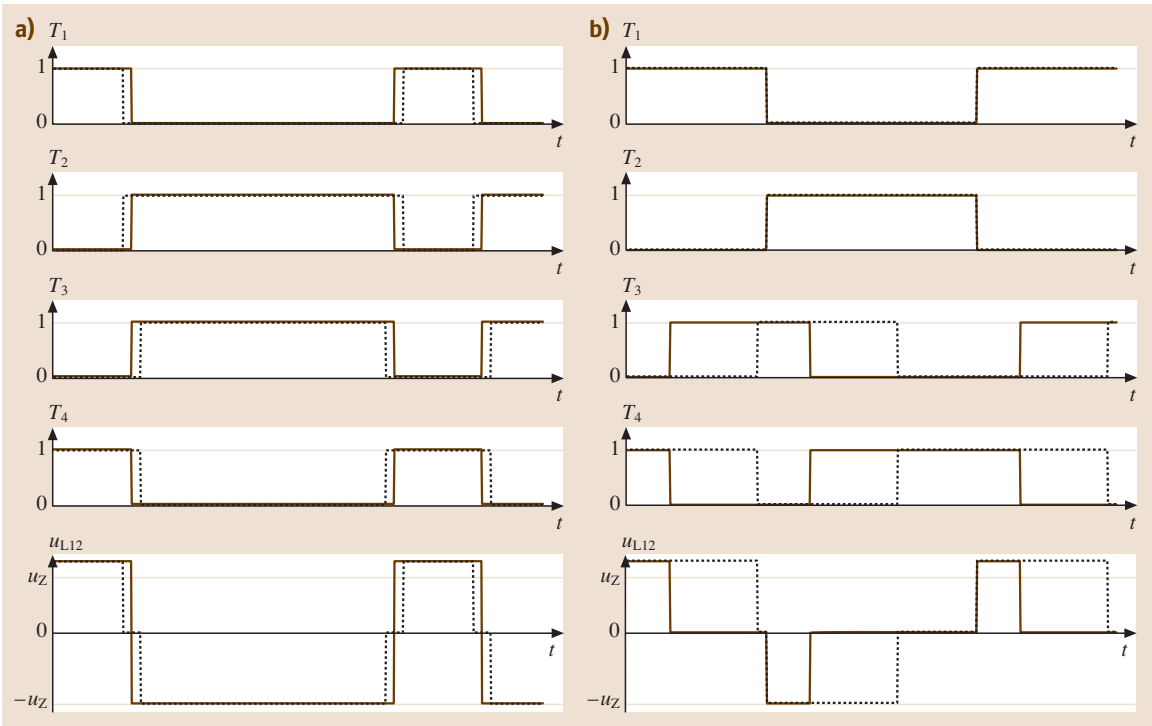

Fig. 17.63a,b Modulation schemes of a single-phase bridge – switching states of $T_1 - T_4$ (0 = off, 1 = on) and output voltage u_{L12}: **(a)** two-level (*solid*) and three-level (*dotted*) modulation scheme; **(b)** phase shift: 45° (*solid*) and 135° (*dotted*)

this way, the circuit can be used as a controllable source for a rectangular AC voltage, which is suitable, e.g., to feed a transformer. Consequently, the single-phase bridge under consideration is a key element of many switched-mode power supplies, where a DC voltage is inverted, then transformed to another voltage level with galvanic isolation and finally rectified.

A rectangular voltage shape can be divided up into a fundamental oscillation and harmonics; because of the latter however it is not well suited to the supply of electric machines with a rotating field or to feed electrical energy into an AC grid. Ideally, the converter would instead behave like a source of sinusoidal voltage. When the switching period of the converter is much shorter than the period of the desired output voltage $T_P \ll T_n$, this can be approximated by varying the duty cycle of the converter during each output cycle and in this way producing a sequence of average voltages over one switching period according to (17.168) which follows the sine wave on the output in a stepwise fashion. It is thus required to introduce pulse-width modulation [17.14]. This is frequently implemented by comparing a carrier signal u_T with switching frequency f_T to a control signal u_{St} with output frequency $1/T_n$, in this case a sine wave; if the control signal u_{St} is higher than the carrier u_T, one switching state of the respective phase leg or the bridge is applied, otherwise the other is applied. An example is shown in Fig. 17.64a, where a two-level modulation scheme has been implemented: it is obvious that the pulse lengths for which the transistors T_1 to T_4 are turned on vary during the displayed output cycle. In fact, the output voltage u_{L12} is mainly positive at the maximum of control signal u_{St}, mainly negative at its minimum, with a gradual change of the pulse widths in between; thus an average output voltage U_{L12} during one switching cycle is achieved. This emulation of a sine wave consequently leads to an output current i_{L1} with the typical ripple, but which basically follows a sine wave. Note that the output current i_{L1} depends on the voltage difference between the converter output voltage u_{L12} and the outer counter-voltage u_{12}, which in turn has been assumed to be sinusoidal. For one of the depicted counter-voltages, the converter will feed energy into the external AC source and thus oper-

ates in inverter mode; in the case of the other voltage, it takes energy from the source and thus operates as a rectifier. At a given external counter-voltage the current – including its phase angle with respect to the voltage, which determines the power factor $\cos\varphi$ – is determined by adjustment of the converter output voltage u_{L12}. It can therefore be concluded that the considered converter is not only suitable to transform one DC system into another but also to transform DC to AC as an inverter, and vice versa as a rectifier. It thus accomplishes several of the tasks outlined in Sect. 17.4.1. Single-phase bridges are frequently used as an interface between AC mains and a DC link: as inverters they may, e.g., feed electrical energy generated by renewable sources such as photovoltaic cells into the grid; as rectifiers, they may feed a DC link for power supplies. The harmonic content of the current – which needs to be limited in the case of mains connection [17.15] – can be controlled to be low.

Three-phase AC machines such as common induction or synchronous machines can be supplied with a corresponding three-phase converter circuit which is obtained when adding a third phase leg to the single-phase bridge, cf. Fig. 17.62b. Corresponding considerations then apply. Figure 17.64b exemplarily shows the generation of a three-phase system of output voltages u_{L12}, u_{L23}, and u_{L31}. Note that the odd number of phases requires the introduction of a three-level modulation scheme which may be implemented with one control voltage u_{St1}, u_{St2}, u_{St3} per phase. Three-phase converters of this kind are a key component of modern variable-speed drives: the machines can be supplied and thus controlled by three-phase AC systems with variable amplitude and frequency. Motor and generator operation of the machine are possible in inverter and rectifier mode of the converter, which is also able to supply the required reactive power. The direction of rotation is defined by the phase sequence of the converter output voltages, depending on the control voltages u_{St1}, u_{St2}, and u_{St3}. Consequently full four-quadrant operation of the drive can be achieved.

17.4.3 Basic Circuits with External Commutation

Uncontrolled Bridges

Although the circuits considered so far can be used as rectifiers, the conventional topology of rectifier bridges is often preferred. The reason is that it is simpler and needs no control, as is obvious from the schematics shown in Fig. 17.65.

Fig. 17.64a,b Idealized waveforms of pulse width modulated **(a)** single-phase bridge: from *top* to *bottom* – triangular carrier u_T (*solid*) and sinusoidal control signal u_{St} (*dotted*) – switching states of $T_1 - T_4$ (0 = off, 1 = on) – output voltage u_{L12} (*solid*) together with two different load voltages u_{12} (*dashed*) – output currents i_{L1} at these output voltages (*long dashed*: inverter operation, *short dashed*: rectifier operation); **(b)** three-phase bridge: from *top* to *bottom* – triangular carrier u_T (*solid*) and sinusoidal control signals $u_{St1/2/3}$ (*dotted and dashed*) – switching states of $T_1 - \overline{T}_6$ (noninverted 0 = off, 1 = on) – output voltages u_{L12}, u_{L23}, and u_{L31} ▶

To characterize their behavior when connected to the mains, mains voltages are defined to be

$$u_n = \hat{U}_n \sin(\omega t) \tag{17.169}$$

for the single-phase circuit or

$$u_{L1N} = \hat{U}_n \sin(\omega t)\,, \tag{17.170}$$

$$u_{L2N} = \hat{U}_n \sin\left(\omega t - \frac{2\pi}{3}\right)\,, \tag{17.171}$$

$$u_{L3N} = \hat{U}_n \sin\left(\omega t - \frac{4\pi}{3}\right)\,, \tag{17.172}$$

for the three-phase circuit, using the angular frequency of the mains $\omega = 2\pi/T_n$ with cycle duration T_n of one mains period. The RMS value of the single-phase or star voltages is therefore $U_{n,RMS} = \hat{U}_n/\sqrt{2}$. Unless otherwise stated, a constant DC current $i_d = I_d$ is further assumed.

Regarding the single-phase circuit it is obvious that in the upper half of the bridge the diode with the highest potential of anode, i. e., D_1 or D_3, will conduct i_d while the other is blocking $|u_n|$; correspondingly in the lower half of the bridge the diode with the lowest potential of cathode, i. e., D_2 or D_4, will conduct i_d while the other again blocks $|u_n|$. Consequently the switching states described in Table 17.4 occur. The corresponding waveforms are depicted in Fig. 17.66a: the output voltage u_{di} consists of two sinusoidal half waves $u_{di} = |u_n|$ per mains period T_n, which is why the circuit is called a two-pulse bridge connection, abbreviated to B2. Its average value can be calculated from (17.169) to be

$$U_{di0} = \int_{T_n} u_{di}(t)\mathrm{d}t = \frac{2}{\pi}\hat{U}_n = \frac{2\sqrt{2}}{\pi}U_{n,RMS}\,. \tag{17.173}$$

The input current i_n is rectangular. Note that a rectangular waveform can be expressed as the sum of

a fundamental oscillation and harmonics; the occurrence of the latter in mains current is undesirable.

As stated, this basic consideration applies for the idealized circuit in Fig. 17.66a, comprising no inductances and being loaded with a constant DC current $i_d = I_d$. Frequently, the circuit is loaded by a buffer capacitor connected to the output terminals – which as a kind of voltage source might supply a self-commutated bridge as explained in Sect. 17.4.2, while inductors in the DC path are minimized. The shape of the current i_d then changes to pulses, as shown in Fig. 17.67b; their amplitude may be quite high compared to the load current, especially in the case of power-on when the previously discharged capacitor is charged. Note also that the shape of the DC voltage u_{di} is different, because all the diodes are blocking while $|u_n| < u_{di}$, which is buffered by the capacitor; the distribution of blocking voltages $u_{R1} + u_{R2} = u_{di}$ is not well defined by the circuit itself in this time interval.

The three-phase bridge shown in Fig. 17.65b behaves correspondingly to the described single-phase bridge. Again, the diode in the upper half of the bridge, i. e., D_1, D_3 or D_5, with the highest anode potential will be conducting, as will the diode in the lower half of the bridge, i. e., D_2, D_4 or D_6 with the lowest cathode potential, while the others are blocking. The six resulting states are summarized in Table 17.5 and illustrated in Fig. 17.67a. In this case the output waveform is composed of six pulses per mains period T_n, where the maximum of the noninverted and inverted line-to-line voltages is applied as the output voltage $u_{di} = \max\{u_{L12}, -u_{L12}, u_{L23}, -u_{L23}, u_{L31}, -u_{L31}\}$. Consequently the circuit is called a six-pulse bridge connection, abbreviated to B6. The average output voltage can be calculated to be

$$U_{di0} = \int_{T_n} u_{di}(t)\,dt = \frac{3\sqrt{3}}{\pi}\hat{U}_n = \frac{3\sqrt{6}}{\pi}U_{n,RMS}\,. \qquad (17.174)$$

Note that the line current waveforms of the B6 bridge consist of three levels including $i_{L1/2/3} = 0$.

To summarize it should be stated that the uncontrolled single- or three-phase diode bridges are only usable as rectifiers because the power $U_{di0} i_d \geq 0$ is exclusively transferred from the mains AC side to the DC side. The moment of current commutation from one diode to another is determined by the time values of the mains voltages. This is why the output voltage of the uncontrolled bridge – which is proportional to the mains voltage according to (17.173) or (17.174) – cannot be controlled. The inherently rectangular shape of the mains currents in the case of a constant DC load

or the occurrence of pulse shapes is disadvantageous. Because of their simplicity and ruggedness these circuits are widely used for mains rectification, e.g., to supply drive converters or as input stages of power supplies.

Controlled Bridges

A means to control the output voltage is frequently desirable. Basically maintaining the previously discussed bridge circuits, this can be achieved by controlling the timing of current commutation through the use of thyristors, which behave similarly to diode but need to be triggered by a gate pulse (Fig. 17.58). The corresponding circuit diagrams are depicted in Fig. 17.68. The principle of operation of a single-phase thyristor bridge is illustrated in Fig. 17.66c. At $\omega t \to \pi$ the current will flow through T_1 and T_4, which is the state characterized in the middle column of Table 17.4; the input current is thus $i_n = i_d$ and the output voltage is $u_{di} = u_n$. In a diode bridge, the current would commutate to the other pair of diodes at $\omega t = \pi$; in a thyristor bridge this cannot happen before the respective thyristors are triggered. This means that the previous switching state is maintained until triggering is applied, at the firing angle $\omega t = \alpha$. The correspondent waveforms are shown in Fig. 17.66c for $\alpha = \pi/4$; the output voltage continues to follow the sine wave $u_{di} = u_n$ in its negative half wave. The average value thus becomes lower; depending on the firing angle α it can be calculated to be

$$U_{di\alpha} = \int_{T_n} u_{di}(t)\mathrm{d}t = \frac{2}{\pi}\hat{U}_n \cos\alpha$$
$$= \frac{2\sqrt{2}}{\pi} U_{n,RMS} \cos\alpha = U_{di0} \cos\alpha \,. \qquad (17.175)$$

Compared to the uncontrolled bridge the trigger delay by α thus leads to a reduction of the average bridge output voltage by a factor of $U_{di\alpha}/U_{di0} = \cos\alpha$. Note that, for $\alpha > \pi/2$, $U_{di\alpha}$ can in this way become negative; a corresponding example with $\alpha = 3\pi/4$ is depicted in Fig. 17.66d. Here, however, consideration of the thyristor blocking voltages – see u_{R1} and u_{R2} – becomes important: because $u_n < 0$, $u_{R1} = -u_n > 0$ will, for example, apply for $\pi < \alpha < 2\pi$ when T_3 is conducting, cf. also Table 17.4. As stated in Sect. 17.4.1, a thyristor with forward current flowing cannot be actively turned off to take over a forward blocking voltage, but it will block a reverse voltage $u_R > 0$ like a diode. It is thus necessary to trigger T_3 sufficiently long before $\alpha = \pi$ to guarantee that a positive reverse voltage $u_{R1} > 0$ will be applied to T_1; if this is not the case, T_1 and T_3 might conduct at the same time, leading to a potentially destructive short circuit, also called through conduction. If this is observed, the thyristor bridge will operate as an inverter, transferring power $U_{di\alpha} i_d < 0$ from the DC side to the mains for $\pi/2 < \alpha \ll \pi$, while it remains a rectifier transferring power $U_{di\alpha} i_d \geq 0$ from the mains to

the DC side for $0 \le \alpha \le \pi/2$. The shape of the current waveform is also rectangular, as analyzed previously; however it should be noted that the current waveform is shifted by the firing angle α as marked by the arrows in Fig. 17.66c and d. The occurrence of a phase angle between the mains voltage and current is equivalent to undesirable consumption of reactive power from the mains when voltage control is applied through $\alpha > 0$.

Again the three-phase circuit according to Fig. 17.68b behaves equivalently as depicted in Fig. 17.67b: thyristor triggering is delayed from the instant of natural commutation (where a diode would start to conduct) by the firing angle α. Consequently the output voltage follows the sine waves according to Table 17.5 in a delayed interval, again reducing the average value with respect to the uncontrolled bridge (17.174)

$$
\begin{aligned}
U_{\mathrm{di}\alpha} &= \int_{T_\mathrm{n}} u_\mathrm{di}(t)\mathrm{d}t = \frac{3\sqrt{3}}{\pi}\hat{U}_\mathrm{n}\cos\alpha \\
&= \frac{3\sqrt{6}}{\pi}U_{\mathrm{n,RMS}}\cos\alpha \\
&= U_{\mathrm{di}0}\cos\alpha\,. \qquad (17.176)
\end{aligned}
$$

The circuit can thus correspondingly be used as a controlled rectifier transferring power $U_{\mathrm{di}\alpha} i_\mathrm{d} \ge 0$ from the mains to the DC side for $0 \le \alpha \le \pi/2$, or as a controlled inverter, transferring power $U_{\mathrm{di}\alpha} i_\mathrm{d} < 0$ from the DC side to the mains for $\pi/2 < \alpha \ll \pi$. The above findings regarding the required safety margin $\alpha \ll \pi$ to avoid through conduction and regarding the shape and phase angle of the input current waveforms $i_{\mathrm{L}1}$, $i_{\mathrm{L}2}$, and $i_{\mathrm{L}3}$ apply for the three-phase bridge as well.

In conclusion, the considered thyristor bridges permit the control of the output voltage, which can be varied by the factor $\cos\alpha$ by using the firing angle $0 \le \alpha \ll \pi$. However, operation at $\alpha > 0$ leads to undesirable consumption of first-harmonic reactive power from mains, while the additional harmonic content of the input currents is the same as for uncontrolled bridges. This voltage control method permits the use of these circuits as rectifiers and inverters. They are thus suitable to supply DC machines from the mains; because the considered bridge is suitable only for one polarity of current, i. e., a two-quadrant drive, it must be further complemented to create two-way rectifiers enabling four-quadrant operation. Due to the replacement of DC by AC drives and the availability of self-commutated converters over a wide power range the use of fully controlled thyristor bridges has decreased. An alternative is half-controlled bridges, where half of the

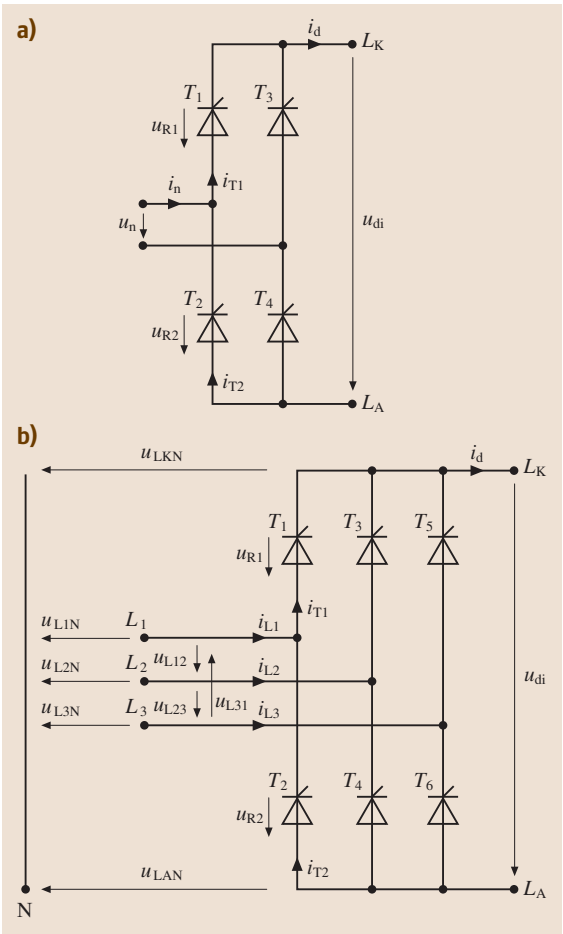

Fig. 17.68a,b Circuit diagrams of (a) single- and (b) three-phase controlled bridges

switches are diodes and half are thyristors. The operational principle of these circuits can be derived with the methods applied in this section. As a result, they constitute controllable rectifiers, being especially useful to limit inrush currents at power-on when charging a large capacitor in the DC link, as explained with reference to Fig. 17.66b.

AC Controllers

The direct conversion from one AC system to another, mentioned in Sect. 17.1, can be effected by combining a rectifier and an inverter as described in Sect. 17.4.2. In some cases a significantly simpler circuit is sufficient, i. e., an AC controller as depicted as a single-phase version in Fig. 17.69a. If the thyristor T_1 is conductive, a mains and load current $i_\mathrm{n} > 0$ can flow; if T_2 is con-

ductive, the same applies for $i_n < 0$. If a current $i_n \neq 0$ is flowing, the output voltage u_L is equal to the mains voltage u_n. The corresponding waveforms are depicted in Fig. 17.69b for an input voltage according to (17.169), a firing angle of $\alpha = \pi/4$, and a resistive load of R_L; without the AC controller, the mains current would be proportional to the voltage $i_n = u_n/R_L$. Using a firing angle of $0 < \alpha < \pi$, no current will flow before triggering the corresponding thyristor, while the current will follow the part of the sine wave after triggering. With a resistive load, i_n becomes zero again at the next zero crossing of u_n; the thyristor then blocks the reverse voltage, where possible trigger pulses have no effect. The intervals with $i_n = 0$ have two consequences. First, the AC controller reduces the RMS current in the load, which is its purpose. Second, it consumes reactive power from mains, in this case because of the phase angle between the fundamental oscillation of the mains current i_n and the voltage u_n, and harmonics due to the current shape which in total is nonsinusoidal; this again is undesirable. Note that the control behavior needs to be considered in a corresponding way, but separately for capacitive or inductive loads, causing a phase angle between the load current i_n and voltage u_L. The described behavior in principle also applies for three-phase AC controllers.

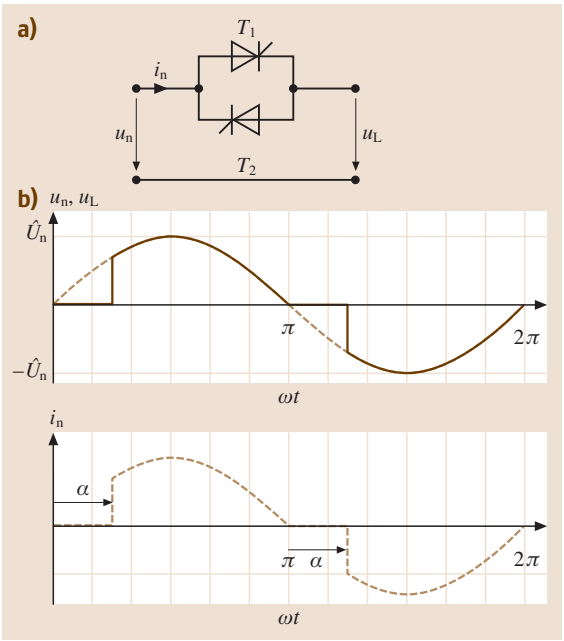

Fig. 17.69 **(a)** Circuit of a single-phase AC controller; **(b)** idealized waveforms at firing angle $\alpha = \pi/4$ with resistive load: from *top* to *bottom* – line voltage u_n (*dotted*) and output voltage u_L (*solid*) – line current i_n with label of firing angle α

Light dimmers are a typical application of AC controllers: the higher the firing angle $0 \leq \alpha < \pi$, the darker a bulb will be. The output frequency is equal to the input frequency and the nonsinusoidal shape of the output voltage u_L is no constraint in this application. Heaters can be controlled in this way as well: sometimes multicycle control is applied, where the controller is triggered with $\alpha = 0$ for several mains cycles T_n, followed by an interval without triggering. The average temperature remains smooth due to the thermal time constant of the device; no phase angle between the mains current i_n and voltage u_n occurs, however subharmonics are present in the current. In the low-power range, the pair of thyristors displayed in Fig. 17.69a may economically be replaced by one triode alternating current switch (TRIAC) with the same functionality but only one gate terminal.

17.4.4 Design Considerations

For the consideration of circuit and control theory in Sects. 17.4.2 and 17.4.3 ideal components have been assumed as stated in Sect. 17.4.1. More details need to be taken into account regarding circuit design. For this purpose, power semiconductor devices as explained with a strong physical background in [17.16] are characterized according to standards such as [17.11, 17–23]. Power losses belong to the important parameters:

- A voltage drop across the device when it is conducting leads to the following conduction losses

$$p_{VD} = u_S i_S = \begin{cases} u_{CEsat}\ i_C & \text{for IGBTs} \\ u_{DS}\ i_d = R_{DSon}\ i_D^2 & \text{for MOSFETs} \\ u_F\ i_F = -u_R\ i_F & \text{for diodes} \\ u_T\ i_T = -u_R\ i_T & \text{for thyristors} \end{cases} . \quad (17.177)$$

The conduction behavior of all bipolar devices, i. e., IGBTs, diodes, and thyristors, corresponds to diode characteristic – cf. Fig. 17.70a – while the MOSFET conducts with an almost linear on-state resistance R_{DSon} when turned on. Note that many semiconductor properties typically have a temperature dependence; the operating temperature therefore needs to be considered for the balance of losses.
An IGBT is typically in the on-state at $u_{GE} = 15\,V$,

a MOSFET at $5\,\mathrm{V} \le u_{GS} \le 10\,\mathrm{V}$, and a thyristor after a specified trigger pulse $i_G \ge I_{GT}$.

- Blocking losses

$$p_{VS} = u_S i_S \tag{17.178}$$

are often negligible. It is however essential to choose devices with rated blocking voltages higher than the applied voltage, i. e.,

$$u_Z < \begin{cases} U_{CES} & \text{for IGBTs} \\ U_{DSS} & \text{for MOSFETs} \\ U_{RRM} & \text{for diodes} \\ U_{RRM}, U_{DRM} & \text{for thyristors} \end{cases} . \tag{17.179}$$

A sufficient safety margin needs to be provided to avoid destruction by overvoltages, which may be caused by parasitic inductances in self-commutated circuits – which need to be minimized – or by voltage peaks in the mains.

An IGBT is typically in the off-state at $-15\,\mathrm{V} \le u_{GE} \le 0\,\mathrm{V}$, a MOSFET at $u_{GS} = 0\,\mathrm{V}$, and a thyristor after current has fallen below a specified limit $i_T < I_H$, unless a forward blocking voltage $u_R < 0$ is applied too early or too quickly.

- Switching losses play an important role in self-commutated circuits. Their origin can be recognized in Fig. 17.70b, where the instant t_2 when turning off the transistor T_1 of the buck chopper – cf. Fig. 17.60a – has been magnified: as stated, turn-off is effected by lowering the gate–emitter voltage. The IGBT will consequently start to desaturate and take over an increasing voltage $u_{CE} \to u_Z$ after t_{21}. Because $u_{CE} + u_R = u_Z$, the diode blocking voltage decays correspondingly. When u_{CE} reaches the DC link voltage u_Z at t_{22}, the diode voltage is consequently $u_R = 0$ and the diode can begin to conduct $i_F > 0$. When the IGBT pinches off further, the diode will thus take over the current $i_{L1}(t_2)$, which has been assumed to be virtually constant in the considered short commutation interval because of the inductance L_{L1} in the current path. At t_{23} the commutation ends with the full load current flowing through the diode $i_F = i_{L1}$. It is obvious that current is flowing through the transistor while voltage is also applied, which leads to power dissipation $u_{CE} i_C$. In the time interval $t_{21} \le t < t_{23}$ an amount of energy $E_{off} = \int_{t_{21}}^{t_{23}} u_{CE} i_C \mathrm{d}t$ is dissipated in the transistor. While the power levels may be considerable, the time intervals are typically rather short, in the range of tens of nanoseconds to few microseconds.

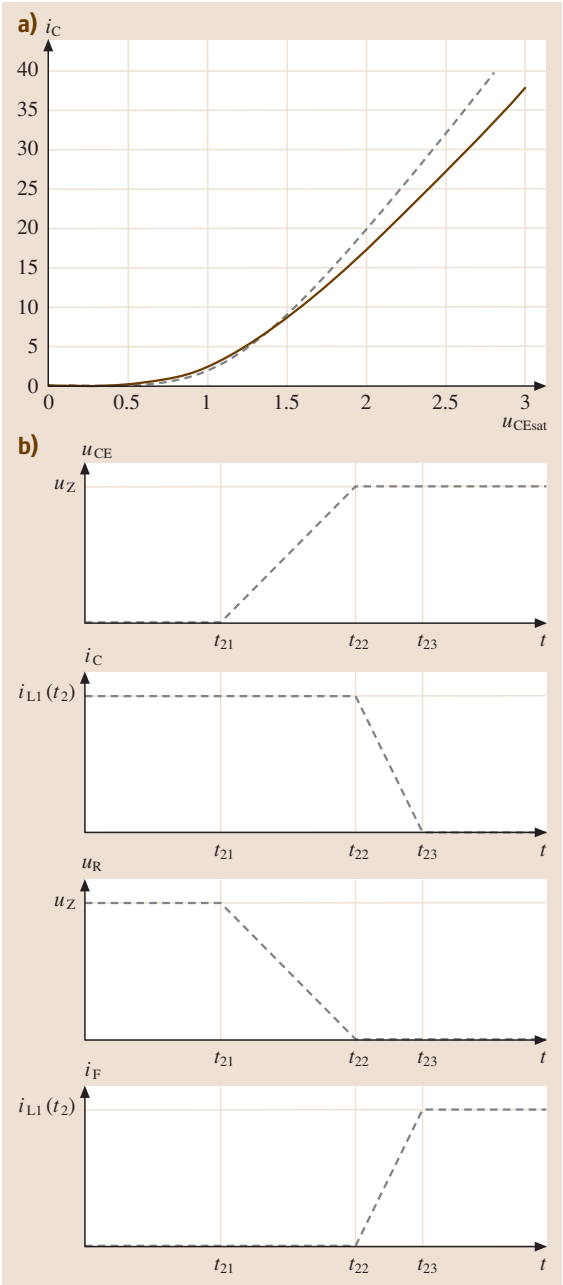

Fig. 17.70 **(a)** Exemplary conduction characteristic of an IGBT at gate–emitter voltage $u_{GE=15\,V}$ and junction temperatures $T_J = 25\,°C$ (*dotted*) and $T_J = 125\,°C$ (*solid*); **(b)** simplified waveforms of commutation in a buck chopper: from top to bottom – collector–emitter voltage u_{CE} and collector current i_C of IGBT – reverse voltage u_R and forward current i_F of the diode

The turn-on energy E_{on} of the transistor can be determined in a corresponding way. It is strongly influenced by the related diode turn-off, which is delayed by the reverse recovery effect. This is the reason why there is a variety of power semiconductor diodes with different switching characteristics; fast-recovery diodes are required in self-commutated choppers.

The fact that device switching times are not infinitesimal will in practice require the introduction of a delay between the turn-off of one and the turn-on of the other transistor in a phase leg (Fig. 17.61) thereby securely avoiding the short circuit of the bridge.

Note that besides the considered case – called hard switching – soft switching may apply, where the voltage across or the current through the device is kept at zero during switching operation; this can be achieved with resonant loads or suitable snubber networks such as in [17.24].

Assuming that the thermal time constant is much longer than the period T_P, losses can be averaged over one switching period

$$P_V = \frac{1}{T_P}\left(\int_{T_P} (p_{VD} + p_{VS})\,dt + E_{on} + E_{off}\right) . \tag{17.180}$$

Power losses, i. e., heat, need to be dissipated to ambient. For this purpose power semiconductor devices are often assembled on a heat sink, which in most cases is accessible and grounded, therefore requiring electrical isolation from the power circuit. Power semiconductor modules will include isolation while conventional discrete devices need to be isolated externally, e.g., with an insulator pad. The thermal path consequently comprises thermal resistances; it is convenient to summarize all of them between the junction (where the heat is generated) and the case as R_{thJC}, between the case and the heat sink as R_{thCS}, and between the heat sink and the ambient (where the heat will be dissipated) as R_{thSA}. Heat flow can then be modeled with an equivalent circuit according to Fig. 17.71 which permits one to derive

$$T_J = (R_{thJC} + R_{thCS} + R_{thSA})\,P_V + T_A , \tag{17.181}$$

$$T_J = (R_{thJC} + R_{thCS})\,P_V + T_S , \tag{17.182}$$

$$T_J = R_{thJC}\,P_V + T_C , \tag{17.183}$$

optionally also using the alternative indication of thermal resistance from the junction to the heat sink

$$R_{thJS} = R_{thJC} + R_{thCS} . \tag{17.184}$$

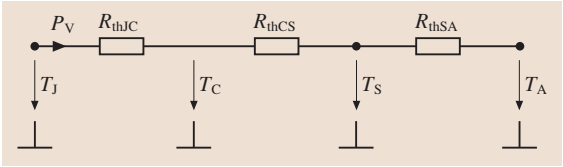

Fig. 17.71 Thermal equivalent circuit of the heat path with power P_V being transferred from the junction at temperature T_J via the case at T_C and the heat sink at T_S to ambient at T_A through thermal resistances R_{th}

With the power losses according to (17.180), (17.181–17.183) permit the evaluation of the junction temperature T_J depending on the boundary conditions T_A, T_S, or T_C; this may not exceed the rated value

$$T_J \le T_{Jmax} \tag{17.185}$$

and in some cases it should be further restricted for reliability reasons. In this way it is possible to check whether a proposed design of a power section is suitable for a particular application demanding certain current and voltage ratings of the converter.

Generally speaking, the following solutions turn out to be expedient:

- Switching losses of unipolar power MOSFETs are typically lower than those of comparable bipolar IGBTs. However, the on-state resistance R_{DSon} increases exponentially with the rated blocking voltage, saturation voltage u_{CEsat} only about linearly. This makes power MOSFETs preferable for applications with a low DC link voltage up to some $u_Z \le 100 \ldots 200$ V, e.g., in vehicle electrical distribution systems, or when high switching frequencies f_T of several tens to more than a hundred kilohertz are required, e.g., to minimize transformer size in a switched-mode power supply. Care needs to be taken that the reverse diode of the MOSFET has a reasonable switching behavior if it is used. In many other applications – in particular variable-speed drives supplied by rectified mains with a DC link voltage $u_Z \ge 300$ V and moderate switching frequency $f_T \le 20$ kHz – IGBTs in combination with appropriate fast-recovery diodes have become established.
- Complementary rectifier diodes or phase-control thyristors will be used for rectification at mains frequency. While switching losses are secondary, the insertion of inductances between the mains and a B2 or B6 bridge is recommendable at higher power ratings to limit the rate of change of cur-

rent during commutation and thus the related mains disturbance. Device surge current ratings may be important for power-on and the occurrence of mains voltage peaks.

The aforementioned control algorithms can be implemented in various ways. Some of them, e.g., for light dimmers according to Sect. 17.4.3, have been realized in integrated circuits; more complex algorithms are frequently programmed in microcontrollers or even digital signal processors. Interfaces between the power section and the control unit need to be defined: typically measurement and status signals are transferred to the control unit whereas logic levels indicating the switching states of the transistors are transmitted to the power section. The interfaces often include potential separation: while thyristors can be triggered with small transformers, the control of IGBTs or MOSFETs is mainly realized with integrated or discrete driver circuits to charge and discharge their gates; a separate power supply may be required for this purpose. Note that the potential difference between the emitters of T_1 and T_2 in the phase leg of Fig. 17.59c will vary between virtually zero (when T_2 or D_2 are conducting) and u_Z (when T_1 or D_1 are on). Because of this kind of fast transients, electromagnetic compatibility including conducted and radiated emissions should already be considered in the design phase.

17.5 Electric Drives

17.5.1 General Information

Electric drives deliver the required form of mechanical energy needed to conduct certain technical processes [17.25,26]. These drives are applied in a wide variety of industrial processes and are mainly used in:

- Machine tools
- Lifts and crane devices
- Pumps and ventilators
- Roller mills and calanders
- Valves and gate valves
- Positioning facilities and robots

Additionally, they are used in vehicles, particularly railed vehicles.

Electrical drives have the following functions:

- Control of torque (forces) and angular speed (speeds) to be compatible with machine operation and technological processes
- Optimization of machine operation to achieve technical criteria
- Insurance of minimal power losses during energy conversion

Rotating electrical machines such as induction, synchronous, direct-current machines, and their improved forms are used in these drives. For some purposes, a linear motor can also be used.

The drive device structures are addressed to technological processes:

- The electrical machine can be connected directly to the power supply for operation at fixed frequency and voltage.
- If control and regulation are required, controllable energy supply units must be used. These units mainly consist of power electronics.
- For speed, position, or torque control with closed-loop schemes the principles of cybernetics are applied.

It is therefore obvious that the field of electric drives is multidisciplinary (Fig. 17.72).

Steady-State Operation

In steady-state operation, the drive device produces a constant torque at a constant angular speed [17.26]. The intersection point between the drive characteristic and load characteristic must ensure stability for the whole drive system.

The various characteristics for these machines are often approximated by an ideal constant or quadratic, and rarely linear, relation between the torque produced M_L and the angular speed $\Omega = 2\pi n/60$ (with n in rpm). In the starting range of the machine there are usually particular variations from the ideal characteristics which mainly result from the breakaway torque. Examples of the torque characteristic for working machines and drive devices are presented in Fig. 17.73.

At constant voltage drive devices can be described by three typical characteristics in relation to $M(\Omega)$ (Fig. 17.73b):

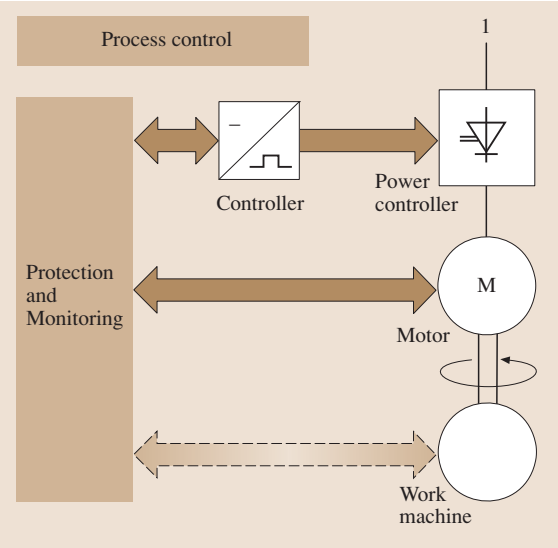

Fig. 17.72 Control schema for drive devices: 1 – power supply [17.1]

- The synchronous characteristic (for synchronous machines)
- The shunt-wound characteristic (for direct-current motors with constant flux or asynchronous machines)
- The series characteristic (for series commutator motors for DC and AC currents)

In some drives, alternating moments can additionally appear. For example, a single-phase motor can produce alternating torque at twice the fundamental frequency. When the drives are supplied through a thyristor converter, the alternating torque has a frequency based on the pulse number p of the converter. When designing a drive device, resonance phenomena produced by these types of torques must also be taken into account.

Starting Period

Usually asynchronous machines with a short-circuit rotor are switched on directly to the power supply. The short-circuit current of large three-phase machines can be reduced by using the star or delta start-up method. In the star circuit the voltage is $1/\sqrt{3}$ times the voltage in the delta circuit. Therefore, the current flowing through the branches is also $1/\sqrt{3}$ times the current flowing in delta circuit. As a result the values of the consumed power, the line currents, and the torque of the machine are reduced by 1/3 compared to the delta connection. In

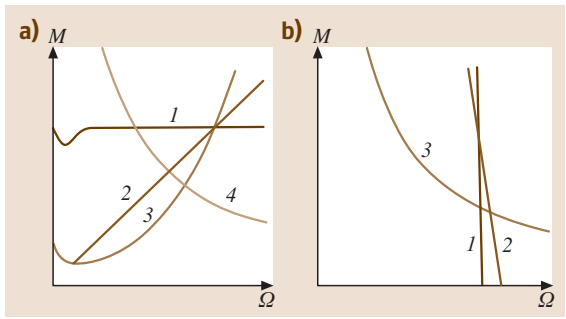

Fig. 17.73a,b Angular speed – torque characteristics of **(a)** working machines, 1 – M_L = constant; 2 – $M_L \sim \Omega$, 3 – $M_L \sim \Omega^2$, 4 – $M_L \sim 1/\Omega$, PL = const and **(b)** drive devices 1– synchronous characteristic, 2 – shunt-wound characteristic, and 3 – series-wound characteristic [17.1]

some cases, the machine can be started with the help of a starting transformer, which allows the voltage level to be increased until the machine has run up completely (Fig. 17.74).

For low-power electric machines the so-called soft-start techniques are used. These methods are applied in order to protect shafts and gears from torque surges. For three-phase rotating machines a converter that generates a linearly variable magnitude and frequency of the voltage at the clamps of the drive is used. A soft start can also be realized by the parallel connection of several resistance levels with the rotor of the machine. Changes in the resistance levels cause the machine to start-up stepwise. Instead of resistances, electronic valves can also be used.

Generally, synchronous machines are designed for asynchronous starting. Therefore, they need a start-up

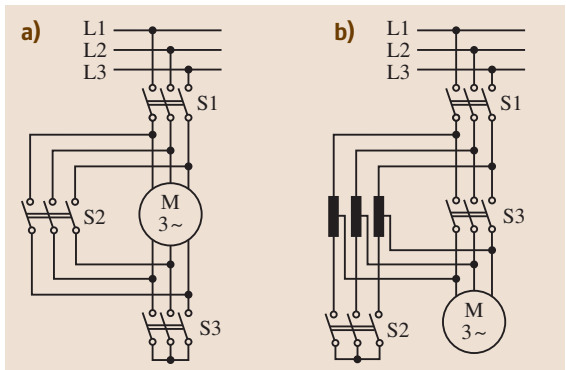

Fig. 17.74a,b Starting examples for induction machines: **(a)** star delta starting and **(b)** starting with the help of a start-up transformer

cage in the form of a damper cage. The exciting winding is shorted out with a resistance. When the rotor reaches the synchronization speed, the cage is switched off and the exciting system is switched on. Synchronization can be achieved by the use of a converter with linear frequency and magnitude control.

For DC machines, the classic starting method is the stepwise changing of a resistance at constant voltage. To reduce resistance losses during start-up, the current-leading method is mainly used. In this case, the DC machine is run up with the help of a controllable converter, which ensures maximal performance by running permanently at the current limit. This start-up system is characterized by high dynamic.

Speed Control

In controlled and regulated drive systems the angular speed is changeable with the help of a controller. There are various ways in which such systems can operate:

1. DC machines. The angular speed is controlled by suitable armature voltage regulation. By appropriate settings of the actuator, operation in all four quadrants of the coordinate system $M(\Omega)$ is possible. At speeds above the nominal speed, field control (flux control) is also used, although in this case the controlled speed range is limited. Speed control via resistance changes is also possible but it also has a lossy character. Figure 17.75 presents all of the regulation methods for DC drive devices.
2. Induction machines. The simplest method to regulate the speed of an induction machine is by changing the voltage at the clamps of the machine. This is realized with the help of a three-phase controller (Sect. 17.4.2). In this case, the idle speed is not adjustable. Because the relation between the voltage and the produced torque ($M \sim V^2$) and due to the high losses resulting from higher harmonics, this method is not suitable for high powers and wide control ranges. Thus it is only applied to ventilators with low power.
   The frequency control method is a low-loss method. In this case, the idle angular speed is adjustable. For this method the voltage needs to be adjusted as proportionally to the frequency $V \sim f(V/f)$. The breakdown torque has a constant value in the range up to the nominal voltage. If the resistance of the stator windings are taken into account, the voltage must be additionally increased for lower frequencies. If the controller is set to maximum gain, the voltage cannot be increased anymore. The frequency, typically the nominal frequency f_N of the machine, at this point is called the cut-off frequency. For further regulation the frequency is increased above the nominal frequency $f_1 > f_N$, and the machine works in the field-weakening range, which leads to a decrease of the breakdown torque. These characteristics are shown in Fig. 17.76.
   There is another conventional method for regulating the speed. By changing the number of poles the speed can be adjusted in fixed steps. The pole number of a Dahlander motor, for example, can be changed in a ratio of 1 : 2. In this case, the three-phase winding consists of six winding parts, which can work at variable pole numbers.
3. Synchronous machines. For synchronous machines, the angular speed control can only be realized through variation of the frequency and simultaneous adjustment of the voltage. The power performance of the drive device is restricted by current and voltage limitations. The speed control in the range of $0 \leq \Omega \leq \Omega_{max}$ is broken down into three general areas, see the corresponding numbers in Fig. 17.77:
   a) *Constant value of the current and flux*: linear increasing the voltage $V \sim \Omega$; from this relation the power also increases linearly $P \sim \Omega$.
   b) *Field-weakening range*: at constant voltage and current; the power level is maintained as the torque decreases.
   c) *Minimal flux* Φ_{min}: both the current and power are decreased.

Torsional Vibrations

Torsional vibrations can arise due to variable moments, rapid load changes, and short circuits. Due to possible resonances in the electromechanical system, a lot of undesirable effects can appear. In order to investigate the dynamic requirements for shafts, couplings, and gears, computational methods are used in the design stage. For this purpose, the mechanical part of the system is simulated as a multiple-mass system.

If necessary the effects of the mechanical alternating torque on the electromagnetic moment need to be taken into account.

Electric Braking

In electric drive devices, electrical as well as mechanical braking is possible. To achieve this, a reverse torque is produced by operation in the second quadrant of

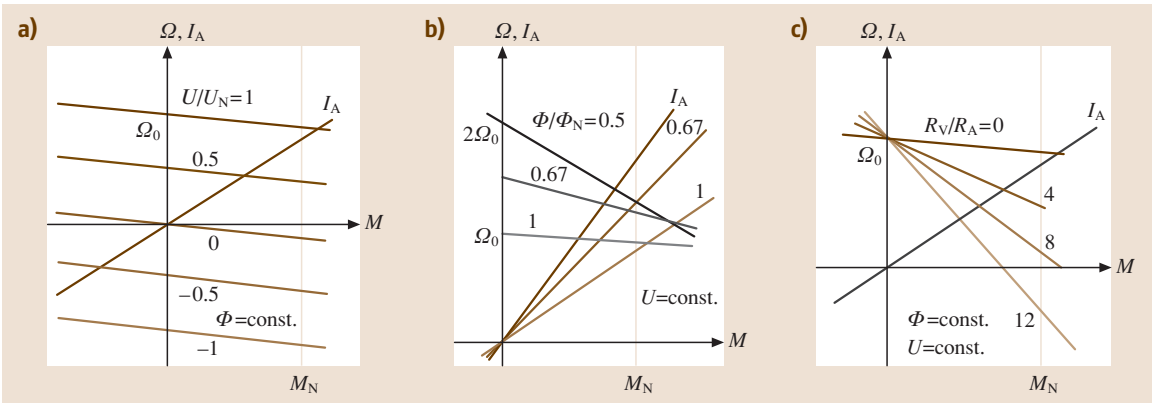

Fig. 17.75a–c Control characteristics for DC machines: **(a)** armature voltage regulation; **(b)** flux control; **(c)** resistance control

the $\Omega(M)$ characteristic. There are various methods to brake a machine:

- Regenerative brake. The braking energy flows into the network. If suitable controllers are available this is a beneficial method, which can be applied to DC (for example with self-excitation) and asynchronous machines.
- Resistance braking. During a separation from the supply system, the drive can be braked by switching certain levels of resistances to the drive. This is a classical braking method and is used mainly for DC machines. However, this method does not brake the drive all the way down to zero speed. In order to do that, either mechanical or magnetic braking is needed.
- Reverse current braking. In this case, the supply voltage is redirected, and as a result the motor tries to change the direction of rotation. If the machine is not stopped by switching off the supply voltage, the working point of the drive device will go into the third quadrant of the $\Omega(M)$ characteristic. This type of braking is used for DC current and asynchronous machines with the help of additional resistance connected to the machine. It is characterized by high energy losses because not only the braking energy but also the energy taken from the grid is converted into heat at the resistances.
- Constant-current braking. This is a special braking method used for three-phase machines. The machine in this case acts as a generator feeding a resistive load. To realize constant-current braking, the windings of the AC motor are excited with a constant current.

17.5.2 Direct-Current Machine Drives

Drives with Line Commutated Converters

In Fig. 17.78a a common structure for a DC-current converter is illustrated. This structure makes it possi-

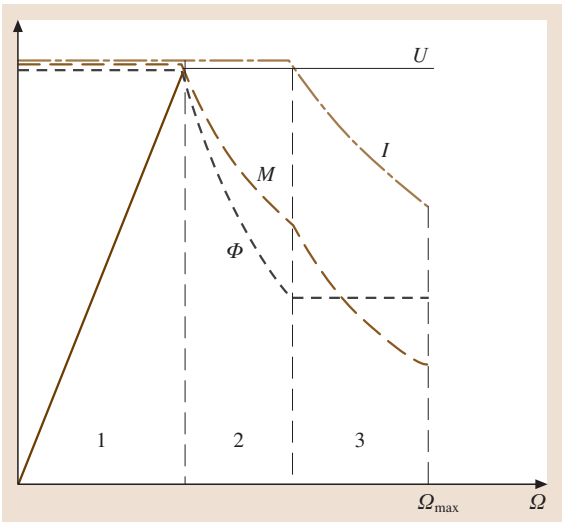

Fig. 17.77 Operation area for drive devices

ble to operate the device in two quadrants (the first and fourth). In the first quadrant the motor serves to drive the machine, and in the fourth quadrant the motor brakes the machine. An advantage in terms of reactive power compensation can be achieved by two series-connected converters (Fig. 17.78b). The equivalent circuit (Fig. 17.78c) is only valid for the continuous current mode. In this circuit, the supply system consists of the DC component, containing higher harmonics. The drive is interpreted as a DC voltage source (V_d) connected with linear inductance and resistance (L_{AM} and R_{AM}, respectively).

If a machine works in the impulse current mode this equivalent circuit is no longer valid. In this case the inductance and resistance have to be replaced by a fictitious much higher resistance. During the transition to the impulse current mode the system changes its structure. Therefore only adaptive methods can help to achieve suitable working conditions for a controlled drive device.

In steady-state operation at constant flux, the $\Omega(M)$ characteristics are similar to the load characteristics of rectifiers and inverters.

By using reverse drives, the device can be operated in all four quadrants. In order to change the drive direction, a reverse current in the armature circuit or reverse flux direction is needed. Due to the relatively long time constant of the magnetic flux, control based on changes in the current direction is preferred. To realize reverse operation of the machine a reverse converter is employed.

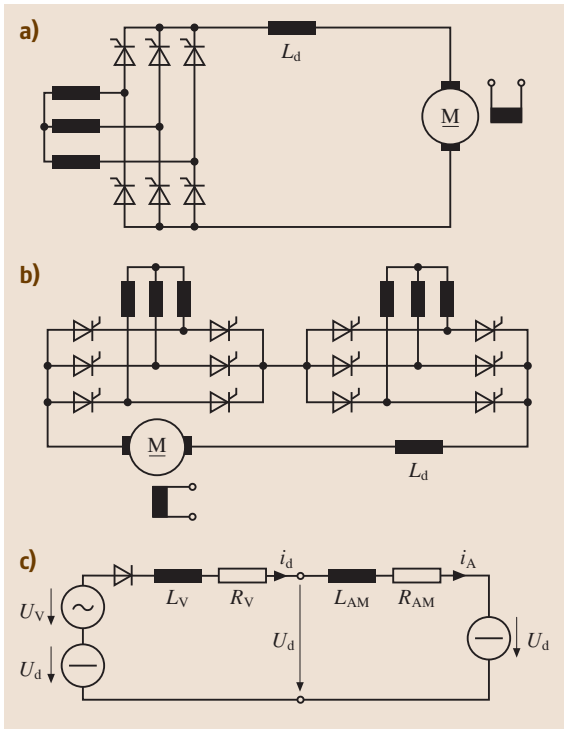

Fig. 17.78a–c DC drive device for two-quadrant operation: **(a)** circuit with current converter; **(b)** circuit with two current converters; **(c)** equivalent circuit

The commonly used structure for four-quadrant operations is two antiparallel-connected traditional controlled converters. There are two main versions to achieve reverse operation: cross-connection circuits and circuits with no DC-link current. When one converter operates as a rectifier, the second must work as an inverter. In this case the DC voltage must be higher than or equal to the voltage supplied by the second converter.

Drive Control

In drive engineering the application of control theory is indispensable [17.27]. There are two main operating principles for control systems: continuous control, which is based on analogue signals, and discrete control, which is related to digital control systems. Because of the recent progress in the field of microprocessor technologies it can be assumed that all new control systems will be based on digital processing.

To design the control system of the drive device, the following steps must be taken.

- *Modeling and system analysis*. The drive device can be described with the help of differential equations or equivalent block structures. To simplify the description and solution methods, the Laplace transformation is often used for linear time-invariant systems. The Laplace transformation makes it possible to describe the system in the form of transmittance functions in which all connections between the input and output signals are reflected in algebraic form. By using the transmittance function the relation between the signals in the frequency domain in which the dynamical properties are illustrated can be presented (Bode diagram). Time-discrete systems are described in the z-domain.
- *The controller design*. For this purpose the frequency response and root locus method are executed. The study of the stability of the system plays a very important role. For controller synthesis, a suitable parameterization is performed on the basis of optimization procedures.

If the control is based on comparison of the variance a state regulator is used. In some cases the actual value of the controlled parameter is not accessible, which is why an observer-based controller is deployed.

In many applications controllers with cascade structures are used. Therefore each controlled parameter has its own control loop. The loops are brought together in a prioritized order where the higher priorities are superposed on the lower ones.

Speed Control

The control variable of a speed control is the angular speed, which has to follow the command variable [17.28]. The control path consists of the actuator (converter), the motor, and the load. As the disturbance variable, the load torque appears. The control system is characterized by a closed-loop structure, where the control deviation, the difference between the reference and actual value, affects the control path. In terms of speed control there is another quantity to regulate, namely the current.

The dynamic properties of the controlled system are evaluated based on the transient behavior after a stepwise change of the command variable. Figure 17.79a illustrates the step response of the controlled value. It shows that the actual value has damped characteristics and exceeds the tolerance range. The rise time t_r specifies the time the control variable needs to reach the tolerance area W_T for the first time. After the transient time t_t is reached, the control variable does not leave the tolerance range again. Another characteristic term is the maximal overshoot Δ_O of the controlled variable during the transient response.

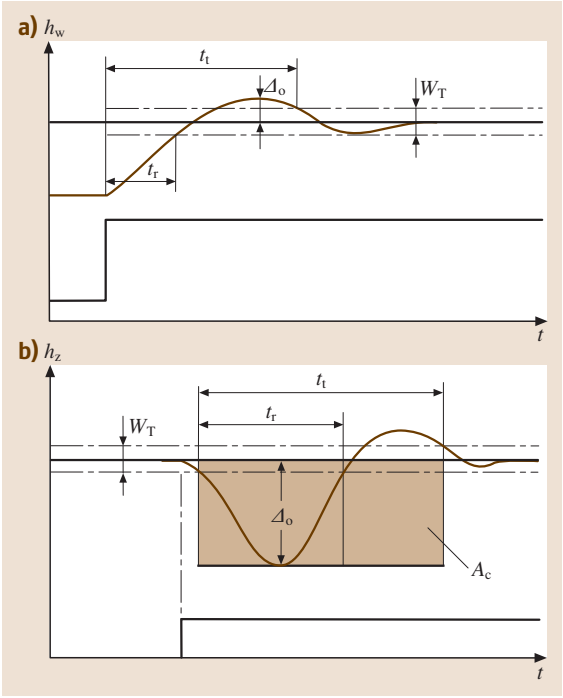

Fig. 17.79a,b Behavior of the regulated quantity by **(a)** command action; **(b)** disturbance action

A common performance index of the speed control is the quadratic form which is the integration of the quadratic control deviation. Occasionally the control area A_C, as shown in Fig. 17.79b for the disturbance variable, is used as well.

The continuous angular speed control of a DC drive is the classical representative of a cascade structure. In this case the speed control loop is subordinated by a current control loop. If necessary a position control loop can be overlaid on the speed control loop.

In Fig. 17.80, the DC machine is described by blocks 1–4. The input variables are the armature voltage v and the load torque m_L. Armature circuit 1 is simulated by a first-order time-delay element with time constant T_A. If the flux has a fixed value, the torque produced is proportional to the armature current 2 (the proportional element). The angular speed ω arises from integration 3 of the acceleration torque m_b with mechanical time

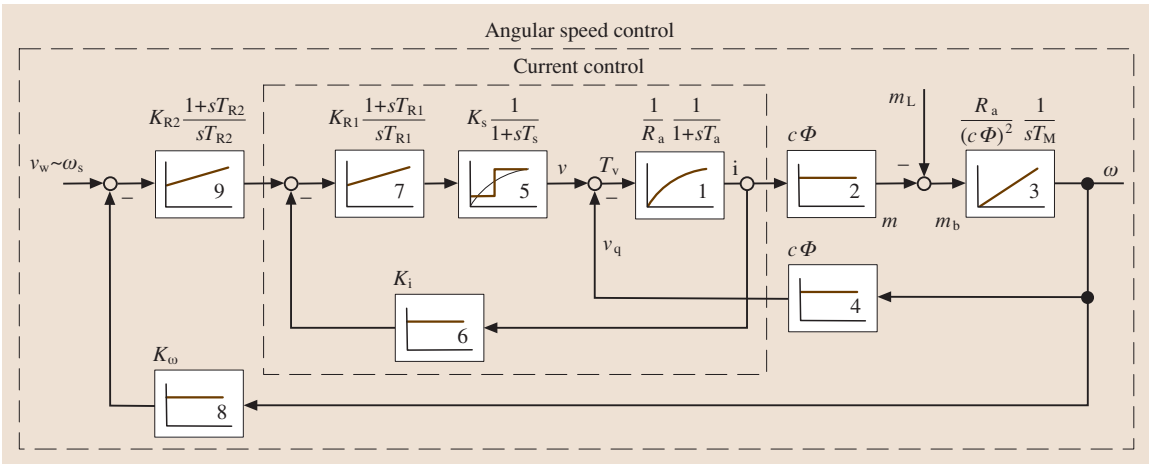

Fig. 17.80 Control loop for a DC drive device [17.1]

constant T_M. The rotating voltage v_q is created by the proportional element 4 and fed back into block 1.

The converter is reflected by an amplifying dead time element 5, which for simplification can be treated as a first-order time-delay element. Blocks 6 and 8 represent measurement equipment for angular speed and armature current, and have proportional character. The drive exhibits an angular speed control with a subordinated current control. In such a controller PID or PI controllers are usually applied. In this example, two PI controllers (blocks 7 and 9) are included in the design. The input variable for the speed controller is the control deviation $(\omega_s - \omega)$. The output value is the command variable of the current controller. The output from the controller is often limited in order to eliminate operation overload.

The required parameters of the PI controller can be set with the help of certain rules [17.1]. These procedures are explained for the given example. First, the current loop is optimized and then the overlaid controller is adjusted. In these two stages each control loop is summarized into a control block as shown in Fig. 17.81 and expressed as its step response $F_k(s)$.

In order to achieve an optimized command action of the controller the absolute value of the frequency response is required to be approximately 1, preferably for a high frequency range. This optimization is called the amplitude optimum. In this case the current control loop is optimized for the command action. By disregarding the reaction of the angular speed on the armature circuit, the transfer function of the opened loop can be expressed as follows

$$F_{k1}(s) = K_{R1}\frac{(1+sT_{R1})}{sT_{R1}}\frac{K_s}{1+sT_s}\frac{1/R_A}{1+sT_A}K_i\,. \tag{17.186}$$

The algorithms of the amplitude optimum lead to the following rules for the controller

$$T_{R1} = T_A; \quad K_{res} = K_{R1}K_S K_i 1 R_A = \frac{1}{2}\frac{T_A}{T_s}\,. \tag{17.187}$$

It becomes clear that the time constant T_A is compensated by T_{R1}, which is why the following transfer function for the closed control loop can be assumed

$$F_{w1}(s) = \frac{1}{K_i}\frac{1}{\left(1+s2T_s+s^2 2T_s^2\right)} \approx \frac{1}{K_i}\frac{1}{(1+s2T_s)}\,. \tag{17.188}$$

The last approximated transfer function is used to obtain the controller parameter for the speed control loop.

For this purpose the following function of the open loop can be applied

$$F_{k2}(s) = K_{R2}\frac{1+sT_{R1}}{sT_{R2}}\frac{1}{K_i}\frac{1}{1+sT_\Sigma}\frac{R_A}{(c\Phi)}\frac{K_\omega}{(sT_M)}\,, \tag{17.189}$$

where $T_\Sigma = 2T_s$.

The control system shown in Fig. 17.80 is generally adjusted to five a symmetrical optimum, which simultaneously gives an optimized disturbance response and short rise times after a stepwise change in the command

Table 17.6 Parameters of second-order control loop [17.1]

Methods	Amplitude optimum	Symmetric optimum	
		Without smoothing	With smoothing
Rise time t_r/T_s	4.7	3.1	7.6
Transient time t_t/T_s	11.0	11.0	14.0
Overshooting Δ_0	0.043	0.434	0.08

variable. The symmetrical optimum leads to the rules

$$T_{R2} = 4T_\Sigma,\ K_{res} = K_{R2}\frac{K_\omega}{K_i}\frac{R_A}{c\Phi} = \frac{1}{2}\frac{T_M}{T_\Sigma}\ . \quad (17.190)$$

As a result of the above approach the following transfer function is obtained

$$F_{w2}(s) = \frac{1}{K_\omega}\frac{1+s4T_\Sigma}{\left(1+s4T_\Sigma+s^2 8T_\Sigma^2+s^3 8T_\Sigma^3\right)}\ . \quad (17.191)$$

In the given example, the DC drive is considered a time-invariant system and the control system is designed continuously.

In practice, to avoid overshooting, additional smoothing of the command variable is carried out.

From (17.186–17.189) the step responses after voltage surges (command action) and torque steps (disturbance action) are determined. The characteristic values of the step responses are the rise time, the transient time, and the transient overshoot (Fig. 17.79). These values are shown in Table 17.6 for a second-order PI controller.

17.5.3 Three-Phase Drives

Drives with Three-Phase Current Controllers

An asynchronous drive with a connected current converter is adjustable within a certain angular speed range. The effective value of the voltage at the clamps of the motor is controlled by phase-angle modulation. In order to achieve a stable working point within an acceptable speed range, it is preferred to use an asynchronous machine with a resistance rotor.

The working range is limited by the maximum allowable current. The high slip values cause high rotor losses which can barely be dissipated through the self-cooling mechanism at low motor speeds. Compared to operation with a sinusoidal voltage supply the motor

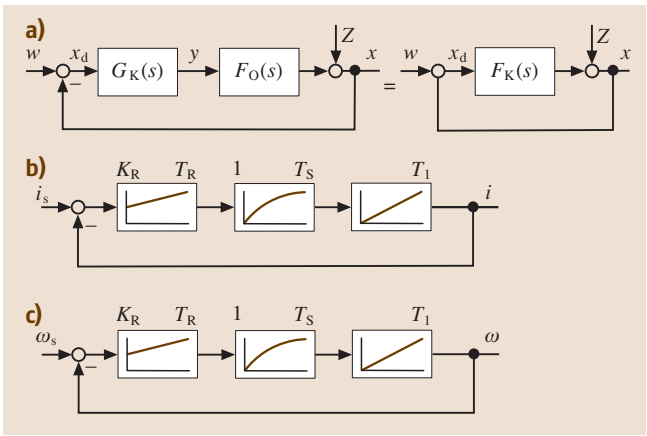

Fig. 17.81a–c Structure for controller modeling: (a) standard loop; (b) current loop; (c) angular speed loop [17.1]

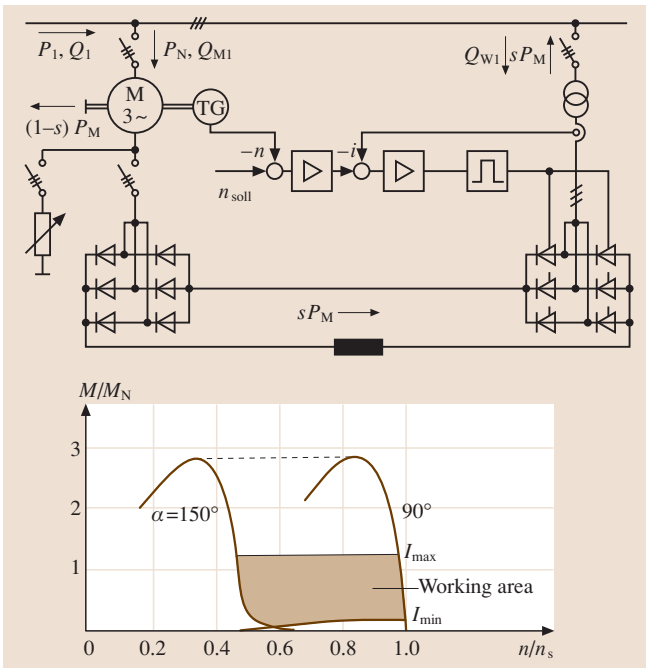

Fig. 17.82 Subsynchronous current cascade

produces additional losses due to the higher harmonics. Because of these disadvantages, this type of drive system is only used for low-power systems.

Subsynchronous Static Kraemer System

For large drive devices with a limited angular speed range of up to 2 : 1 a subsynchronous static Kraemer system can be used.

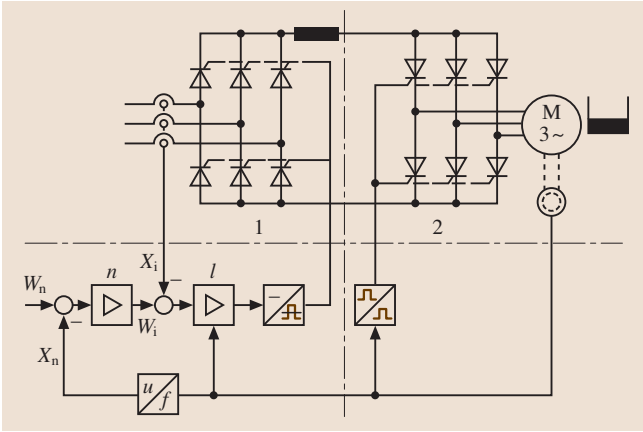

Fig. 17.83 Electrical machine with a current converter

In Fig. 17.82 the schema for a Kraemer system is shown. To realize such systems induction motors with slip-ring rotors are employed. The slip power of the rotor is fed into the power network by an indirect converter. The stator side of the motor is directly connected to the network. Disregarding the losses, the system can be analyzed in the following way:

- Real power. The electric machine consumes the power P_{M1} from the network. If the drive runs with slip s, than the mechanical power output is expressed as $P_{M2} = (1-s)P_{M1}$. The rest of the energy is given off as slip power through the indirect converter which is regulated in an angle range of $90° \leq \alpha \leq 150°$. In such a case, the power taken from the network is only $P_1 = (1-s)P_{M1}$.
- Reactive power. The machine needs reactive power Q_{M1} to operate. In addition, the inverter needs reactive power as well. The required reactive power is expressed as $Q_{W1} = V_{di} I_d \sin\alpha$ for the fundamental frequency. As a result the network has to supply the reactive power $Q_1 = Q_{M1} + Q_{W1}$.

It can be seen that the $\cos\varphi_1$ value of the drive becomes smaller as the rated power of the inverter becomes bigger; it is dependent on $P_{smax} = s_{max} P_{M1}$ and therefore also on the regulation range. Consequently, the subsynchronous system is not attractive for a wide regulation range.

Converter-Fed Motor

Common converter-fed motors are synchronous machines which are supplied by an indirect converter. The controlled rectifier ensures a suitable current level; this converter is commutated by the network voltages. The inverter forms the current waveform for the machine. Here, commutation takes place with the help of the induced machine voltages (Fig. 17.83)

Converter-fed motors are designed for power in the range of 1000 kW–20 MW.

During start-up (rotational speed up to 5–8% of the rated speed) the machine cannot ensure the commutation voltage for the inverter. In this case, additional methods are needed. The most common method is known as link-circuit pulsing. The link current is pulsed by the rectifier and provided cyclically to the machine winding by the inverter.

Control of Three-Phase Drives

In compensated DC machines, the excitation flux and armature do not influence each other. In induction machines, however, the flux produced by the stator and flux generated by the rotor are coupled. Voltage changes at the clamps of the stator cause changes in both components of the current, the flux-creating and the torque-producing component.

In DC machines, the excitation flux (d axis) is always perpendicular to the armature flux (q axis). In asynchronous machines, the flux is produced by the magnetization components of the stator current. The flux phasor exhibits an angle φ_s with reference to the static α–β coordinate system. Decoupling is achieved when the rotating system is linked to the synchronous rotating flux phasor. Now a rotating l–m coordinate system is created. This practice is called field orientation. In this system the stator current phasor exhibits the components i_m, i_l which are denoted as the flux- and moment-creating components, respectively. The torque is proportional to the product of Ψ_r and i_l. Control with the help of the field-orientating method gives good results in terms of the dynamic properties, as is known from DC machines. In order to estimate the control parameters for such drive devices, the measurable parameters are applied to partial models of the machine and transformed to the rotating coordinate system.

17.6 Electric Power Transmission and Distribution

17.6.1 General Information

Electric energy is produced in power plants and consumed by customers located at various distances from the plants. Power networks and related equipment are needed for the transmission and distribution of electric energy from the plant to the customer. Thus the following devices are used:

- Overhead lines and power cables
- Transformers
- Switching stations

These devices also include measuring transformers, protection units, and relays. Power networks are distinguished according to their purpose, with different voltage levels and structures.

The usual nominal voltages of transmission systems are high voltages of 110, 220, and 380 kV. In special cases the three-phase current is transmitted at an extra high-voltage level of up to 765 kV. Distribution systems are operated at medium voltages of either 10 or 60 kV, while low-voltage supply grids usually work at nominal voltages below 1 kV, i. e., 230 V (single phase) or 400 V (three phase).

The related operating frequency for all voltage levels is generally 50 Hz in Europe and 60 Hz in North America and Japan. Other frequencies are also used for special applications such as railway supply systems in Germany, Austria, and Switzerland, which operate at $16\frac{2}{3}$ Hz.

When choosing which basic voltage to use technical and economical factors have to be considered. In the case of long-distance energy transmission voltage stability plays an important role. Additionally, the isolation of the network components must always be able to bear the short-circuit current.

Another possibility for the transmission of electric energy is the use of the high-voltage direct-current transmission system (HVDC) at a few hundred kV. This technology is applied either for long distances or for the coupling of two systems with different frequencies and decoupling the short-circuit power of both systems to protect network components in the case of faults.

Figure 17.84 shows an example of an urban electric power network structure. The voltage levels for transmission are 380 kV and 110 kV, connected as closed loops. This voltage is then stepped down in transformer stations from 110 kV to the distribution level of 10 kV. This medium-voltage network is connected in open-loop circuits. This is advantageous in the case of faults within the medium-voltage network because the sectioning point can easily be moved within the ring and the customers are quickly reconnected to the grid.

If the number of customers connected to a given grid increases, more energy will be transmitted. Therefore, the network capacity must be increased. By increasing the network capacity and the amount of network interconnections the short-circuit power also increases. Ideally, the short-circuit power is the product of the short-circuit current and the rated voltage. This value does not appear in reality but is used for the dimensioning of network components. An increased short-circuit power can be dangerous for network components if a fault occurs because dynamic and thermal effects lead to their destruction. To limit the short-circuit power several actions have to take place. Some of these concern the neutral-point treatment, which has an influence on the resulting short-circuit current.

Networks are generally distinguished according to the neutral-point treatment of the transformers. There are isolated neutral points, impedance grounding, and direct grounding. (Figs. 17.85–17.87). When faults occur – especially single-phase faults – some neutral-point structures can continue operation, whereas some others have to be disconnected immediately. Which structures can be used and which must be disconnected depends on the type of neutral-point treatment deployed.

The fault-to-earth current is determined mainly by the earth capacitance and must not be higher than 35 A to self-extinguish. During a fault, the network can continue to operate when an isolated neutral point is used. (Fig. 17.85). The isolated neutral point can be applied to small networks with voltages below 30 kV.

By using a specific type of impedance grounding (Fig. 17.86) (e.g., an *arc suppression coil* or *neutral grounding reactor*), in the case of a phase-to-ground fault, the capacitive components failure current will be compensated by the reactor (*Petersen coil*). As a result, the residual current of the arc will be small enough to self-extinguish if it has a value below 100 A. The voltages in the faultless phases are multiplied by the factor $\sqrt{3}$ during the fault in one phase. Like the isolated neutral-point network, this type of network can also continue to operate during a fault.

Impedance grounding is used for networks with voltages below 110 kV.

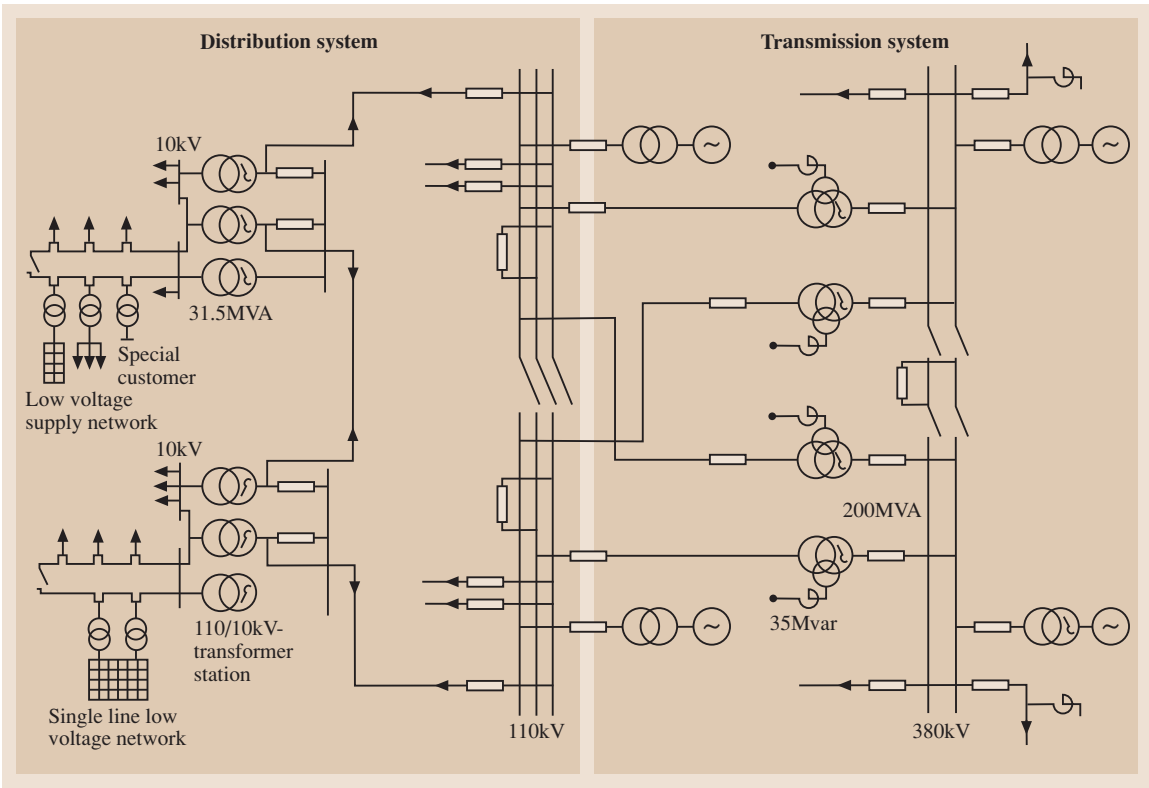

Fig. 17.84 Example of an electric power network structure

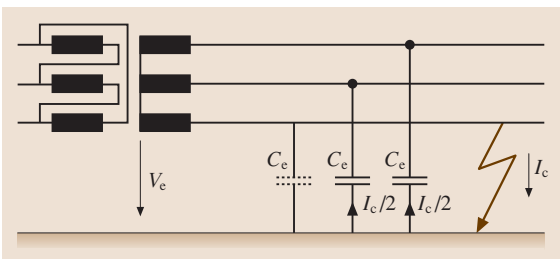

Fig. 17.85 Isolated neutral point

Direct grounding is mainly used in HV networks operating at higher than 110 kV (Fig. 17.87). Here an automatic protection system is necessary because the self-fault-clearing of the short-circuit arc cannot be ensured. Due to the small impedance of the neutral point the fault-to-earth current is a short-circuit current and therefore has to be cut off immediately. The overvoltages resulting from a fault in a direct-grounded system are a lot smaller than in the other structures mentioned above.

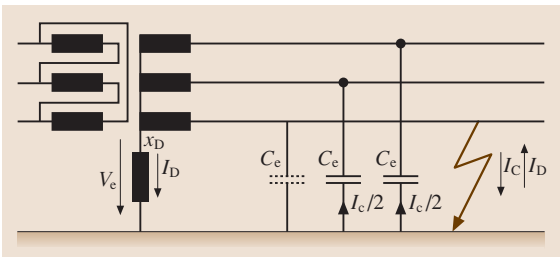

Fig. 17.86 Impedance grounding

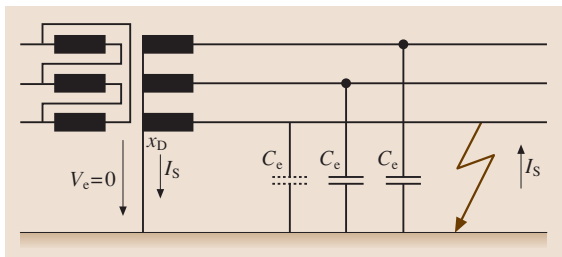

Fig. 17.87 Direct grounding

17.6.2 Cables and Lines

Electrical energy is conducted from the generator to the customer through either cables or lines. The relative losses per phase of a three-phase line can be defined as

$$\frac{\left(P_\mathrm{v}/l\right)}{S} = \frac{S}{\left(V_\mathrm{L}^2 \kappa A\right)} , \qquad (17.192)$$

where κ is the electrical conductance, A is the cross-section per phase, l is the length, S isthe apparent power and V_L is the line voltage.

This equation reveals why a high voltage is advantageous for transmitting a definite apparent power – the higher the voltage, the smaller the losses. For economical and technical reasons mainly overhead lines are used in high-voltage systems (110–380 kV) instead of cables. Cables are used up to a voltage of 110 kV (in special cases up to 380 kV) in densely populated areas, and sometimes even outside cities due to visible impact.

Line Parameters

The one-phase equivalent circuit shown in Fig. 17.88 can be used for both cables and overhead lines.

Due to their construction three-phase cables have symmetric characteristics. The three phases of an overhead line have to be twisted within a certain distance to achieve this quality.

The active resistance R depends on the length l, the cross-section A, the electrical conductance κ as well as on temperature ϑ

$$R = \frac{1}{\kappa A(1+\alpha\Delta\vartheta)} . \qquad (17.193)$$

The operating inductance L_b of a phase line can be expressed as

$$L_\mathrm{b} = \frac{\mu_0 l}{2\pi}\left(\ln\frac{d_\mathrm{m}}{r} + \frac{1}{4}\right) . \qquad (17.194)$$

where d_m is the average conductor distance and r is the conductor radius.

The operating capacitance C_b consists of the capacitance to earth C_e and the capacitance C_g between phases, which is converted from a star connection to a delta connection Fig. 17.89

$$C_\mathrm{b} = C_\mathrm{e} + 3C_\mathrm{g} = \frac{(2\pi\epsilon_0 l)/\ln d_\mathrm{m}}{r} . \qquad (17.195)$$

Cables have a remarkably higher capacitance per length C' than overhead lines. This has an effect on the charging current which is 25–40 times higher for cables, and on the earth fault current, which is more capacitive in cable networks and has to be compensated.

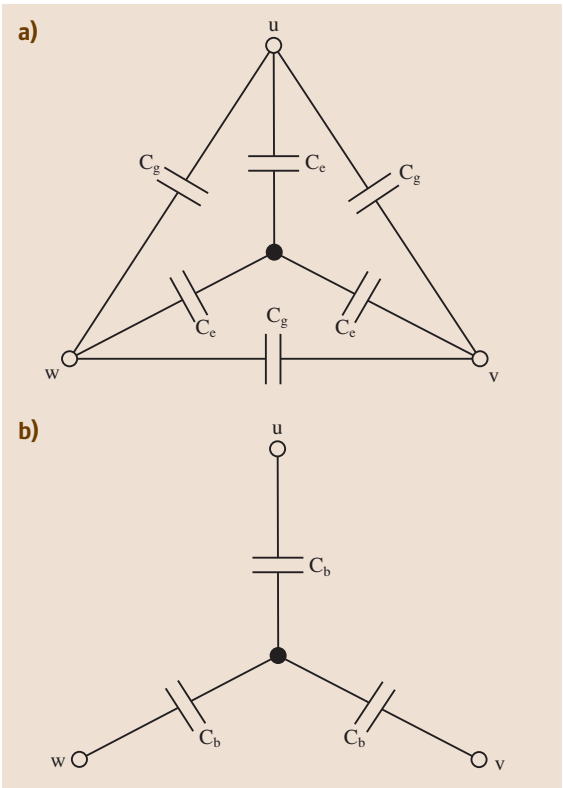

Fig. 17.88a,b Three-phase system capacitance: **(a)** part capacitance; **(b)** operation capacitance

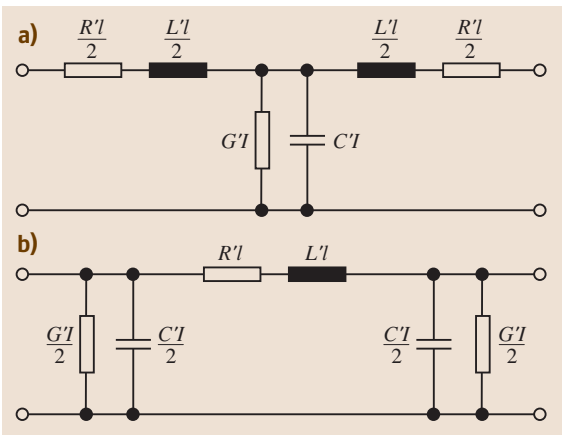

Fig. 17.89a,b Equivalent circuit of a line: **(a)** T-circuit; **(b)** Π-circuit

The specific values for resistance, inductance, and capacitance per length of a line are minimally dependent on the voltage if the operating voltage is changed

$$I_c = \frac{V_l \omega C_b}{\sqrt{3}} \,. \tag{17.196}$$

Line Simulation

Figure 17.89 shows an equivalent circuit for one line. A line can be described using:

- The resistance per unit length R'
- The inductance per unit length L'
- The capacitance per unit length C'
- The conductance per unit length G'

The equivalent circuits can have either a T or Π form.

In most cases the conductance per length G' can be neglected because $G' \ll \omega C'$.

The line operation can be described using line theory, which helps to determine the voltage and current at each position of a line. Therefore, the line impedance is needed. The impedance is generally identified as the characteristic wave impedance Z_W

$$\underline{Z}_W = \sqrt{\frac{R' + j\omega L'}{G' + j'\omega C'}} \,. \tag{17.197}$$

For a lossless line this can be reduced to a resistive value

$$\underline{Z}_W = Z_W = \sqrt{\frac{L'}{C'}} \,. \tag{17.198}$$

The current and voltage along a line can be represented as a superposition of a forward-running wave (w_f) and one reflected, backward-running wave (w_b). The voltage at the end of a line v_2 can be calculated by the summation of both waves

$$v_2 = w_f + w_b \,. \tag{17.199}$$

The current can be calculated by the difference between w_f and w_b, divided by the wave impedance

$$i = \frac{1}{Z_W} (w_f - w_b) \,. \tag{17.200}$$

The relation between the backward and forward components of the voltage is expressed as a reflection coefficient r, which depends on the terminating impedance $\underline{Z}_a$ of the line and the wave resistance $\underline{Z}_W$

$$\underline{r} = \frac{\underline{w}_f}{\underline{w}_b} = \frac{\underline{Z}_t - \underline{Z}_w}{\underline{Z}_t + \underline{Z}_w} \,. \tag{17.201}$$

The reflection coefficient for unloaded operation ($\underline{Z}_t = \infty$) is $\underline{r} = 1$ and for short-circuit operation ($\underline{Z}_t = 0$) it is $\underline{r} = -1$.

This results in a voltage of $v_2 = 2w_b$ for unloaded operation and $v_2 = 0$ for a short circuit.

The reflection coefficient is $\underline{r} = 0$ for $\underline{Z}_t = \underline{Z}_w$, in the case of complete adjustment of the terminating impedance. In this case there are no backward-running waves and as a result, the voltage at the end of the line is the same as at the beginning ($v_2 = w_f$). At this point the transmission of maximal power P_n with minimal losses is possible

$$P_n = \frac{V_L^2}{Z_W} \,. \tag{17.202}$$

This active power P_n is called the *natural power*. For 380 kV overhead lines it has a value of about 450 MW.

17.6.3 Switchgear

Switching Stations

Switchgear is a general term covering switching devices and their combination with associated control, measuring, protective, and regulating equipment. Switching stations are needed to collect and distribute electric energy.

High-voltage switching stations up to 110 kV are usually located within buildings; higher voltages require outdoor switching stations or special encapsulated switching stations based on SF_6 gas technology. Due to its electric strength it can be used in places where insulation with air would take too much space.

High-Voltage Switchgear

The three types of switchgear, each with a different purpose, are:

- A *circuit breaker* is intended to switch both load and short-circuit currents. The switching power can be calculated as a product of the rated voltage and the switching current. It is dimensioned to avoid damage due to the short-circuit current's dynamic and thermal effects on generators, transformers, switching stations, and lines. It restores quickly after a short circuit and is the most effective but also expensive form of switchgear. It

is not primarily intended for frequent operation, although newer vacuum and SF_6 circuit breakers are more suited to load-switching duties than older switchgear types.

- An *on-load switch* is intended for switching loads under normal and overloaded conditions. It is designed for frequent operation but has a limited short-circuit current-carrying and switching capability. It is therefore often backed up by fuses or a circuit breaker.
- An *air-break disconnector* provides a visible isolating distance in the open position. It has nearly no current-switching capability and is used for security of personnel, to show that a circuit is open. It is usually connected in series with a circuit breaker or an on-load switch.

In Fig. 17.90 an equivalent circuit of a circuit breaker is shown, to explain the basic principle of switching. The circuit contains the source impedance $R_s + j\omega L_s$, the switch, followed by the circuit breaker's downstream impedance $R_L + j\omega L_L$, and the fault. The shunt impedance can be neglected as it is several orders of magnitude smaller than the other series impedances involved. Initially, the circuit breaker is closed and carries the fault current $i_s(t)$. The relay protection notices a fault and initiates the opening of the circuit breaker. Figure 17.91 shows the behavior of the short-circuit current $i_s(t)$, through the circuit breaker and the voltage across the circuit breaker $v_{cb}(t)$. At time t_1, the circuit breaker contacts begin to separate and an arc ignites across the contacts. The arc is then extinguished by the particularly used arc-quenching mechanisms, which can differ between different types of circuit breakers. This involves stretching the arc and its intense rapid cooling.

The duration of the arc is rather short (≈ 10 ms) and is coupled with a low arc voltage. The characteristic waveform of the recovery voltage is also shown in Fig. 17.91. A high frequent voltage oscillation, also known as the transient recovery voltage, appears as soon as the short-circuit current passes the zero line and is cleared at time t_2. The behavior of this voltage is determined by the specific circuit parameters.

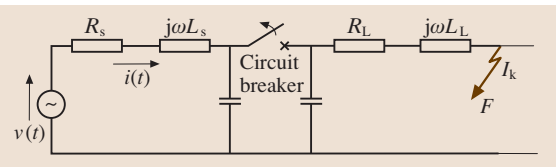

Fig. 17.90 Circuit breaker

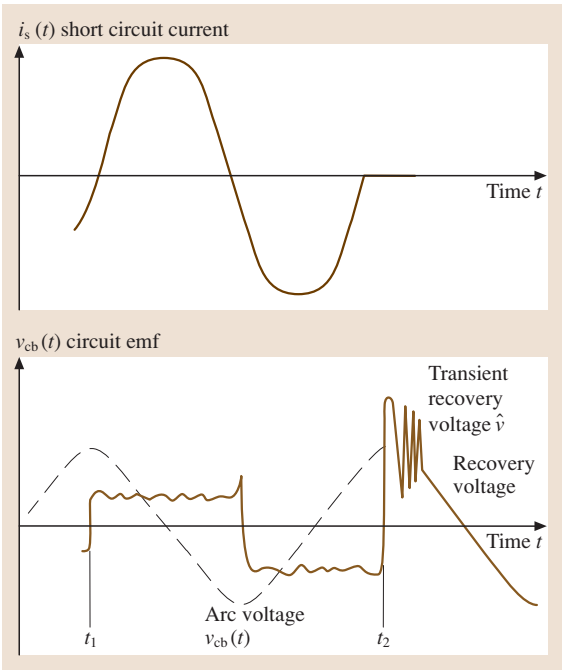

Fig. 17.91 Behavior of the short-circuit current and recovery voltage

Low-Voltage Switchgear

In low-voltage systems below 1000 V many different types of switchgear exist. They can be distinguished according to the:

1. Type of activation:
   - Manually controlled switch
   - Impulse controlled switch
   - Air-gap switch
2. Switch ability:
   - Disconnector
   - On-load switch
   - Circuit breaker
   - Motor switch
3. Intended use:
   - Control switch
   - Limit switch
   - Disconnecting switch
   - Protection switch

17.6.4 System Protection

Short-Circuit Current Protection

To rapidly clear short circuits either power circuit breakers with magnetic tripping devices or melting fuses

are mainly used. Rapid clearance is important because the short-circuit current is much higher than the nominal current and can seriously damage power system devices.

Protection Switches

In low-voltage networks the protection function is often taken over by the switch gear. When a fault occurs, e.g., an overcurrent or voltage sags, the switch gear is able to switch off the endangered part of the system. *Key switches* release the energy that was stored in a latch mechanism and use it for tripping. Other switches are moved into their starting position by a resetting force which is activated by the omission of the driving force. *Contactors* are switches whose contacts are kept in the turn-on position using a current-carrying magnet coil. Contacts within the control circuit of the contactor are responsible for tripping because their control current is interrupted. Contactors are mainly used as a motor protection switch combined with thermal overcurrent relays and instantaneous magnetic tripping, see Fig. 17.92. Tripping devices and relays can be arranged in different ways for instantaneous, delayed or time-selective cutoff of power circuit breakers.

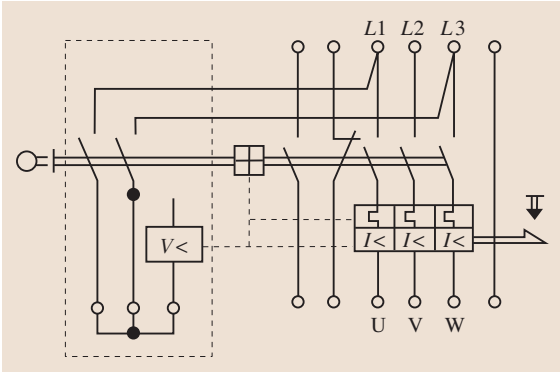

Fig. 17.92 Circuit for motor switch protection

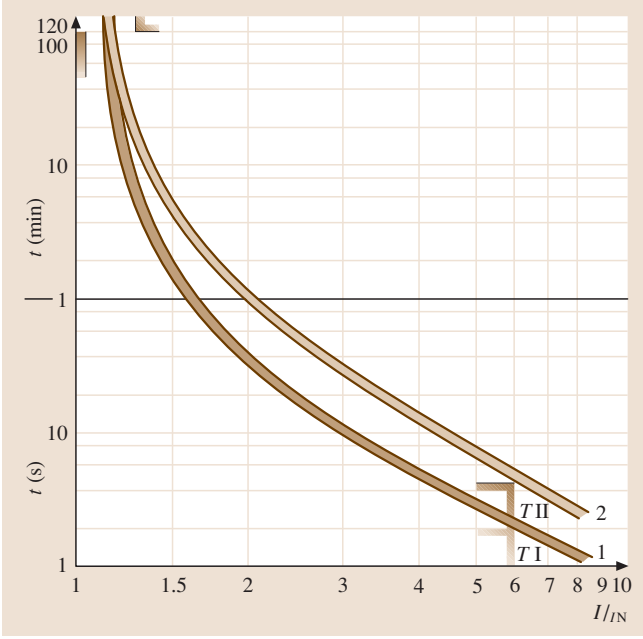

Fig. 17.93 Breakdown characteristics of overcurrent relays

Thermal Overload Protection

Conventional protection devices are bimetal tripping devices and relays. Their operation is based on the behavior of belts composed of two materials with different expansion coefficients. Bending of the bimetal is caused by internal tension due to warming as a result of current flow (Fig. 17.93).

Short-Circuit Current

When choosing devices and equipment, the dynamic and thermal demands appearing during short circuits have to be considered. Thus, and also because of possible unallowed high contact voltages, the highest possible short-circuit current has to be calculated during the design process. Also the smallest possible short-circuit current is important for the dimensioning of the protection system.

In three-phase systems several kinds of short circuits can be distinguished:

- Three-phase short circuit. This is a symmetrical short circuit, with alternating short-circuit currents depending only on the impedance of the positive-sequence system and forming a symmetrical three-phase system. This results in the highest thermal stress and dynamic operational demand for the network components.
- Nonsymmetrical short circuits. This category includes two-phase short circuits with and without contact to ground, one-phase line-to-ground short circuits, and the double-earth fault. The short-circuit currents are defined by the impedances of the positive- as well as of the negative-sequence system and possibly the impedance of the zero-sequence system.

To determine the short-circuit currents the applied voltages and short-circuit impedances have to be known.

In a simple network with one three-phase generator which is transferred into symmetrical components the subtransient voltage E'' determines the initial short-circuit current I''_s. The subtransient voltages of the generator are $\underline{E}''_1 = \underline{E}''$, $\underline{E}''_2 = 0$, and $\underline{E}''_0 = 0$, given in symmetrical components. The generator only produces a positive-sequence voltage. The impedance between the generator and the fault location is composed of impedances in symmetrical components $\underline{Z}_1$, $\underline{Z}_2$, and $\underline{Z}_0$, which are mainly inductive, so often $\underline{X}_1$, $\underline{X}_2$, and $\underline{X}_0$ are used (Fig. 17.95).

Below, the three most important cases are described:

- The maximum initial short-circuit alternating current I''_s (starting current) can be calculated using

$$\underline{I}''_{s3} = \frac{\underline{E}''}{\underline{Z}_1} \,. \tag{17.203}$$

- The initial short-circuit alternating current I''_k in a two-phase short circuit without earth contact (line-to-line fault between phase V and W) will be

$$\underline{I}''_{s2} = \frac{\sqrt{3}\underline{E}''}{(\underline{Z}_1 + \underline{Z}_2)} \tag{17.204}$$

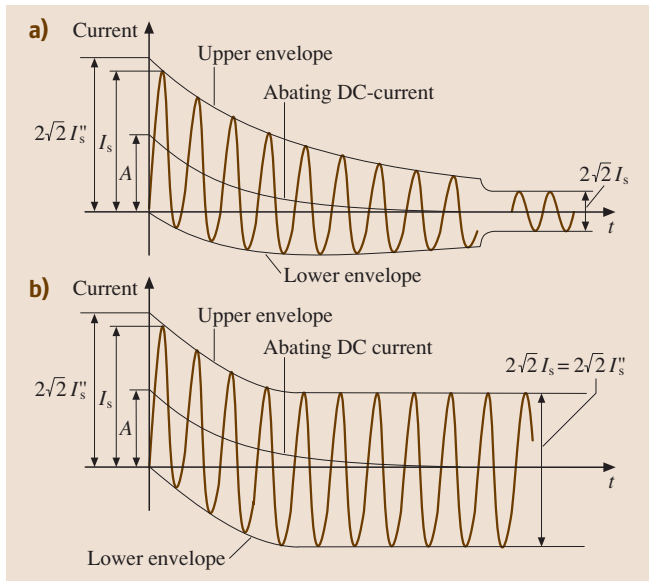

Fig. 17.94a,b Characteristic of a short circuit: **(a)** close to the generator; **(b)** far from the generator

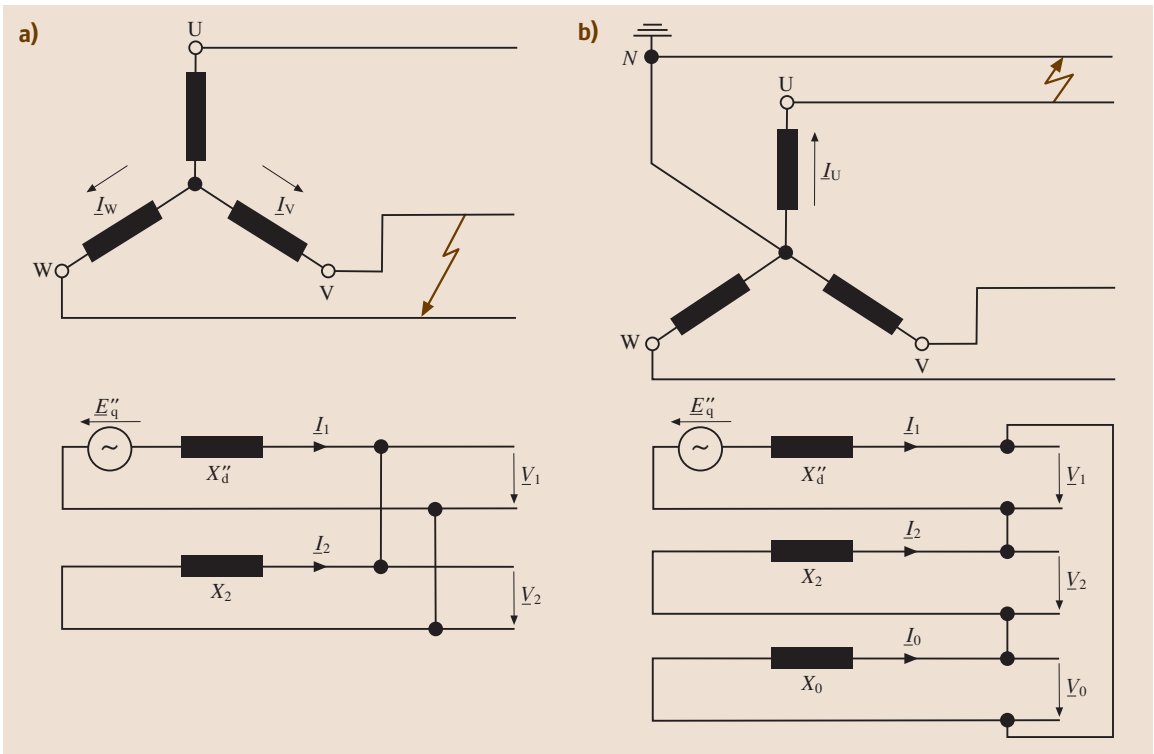

Fig. 17.95a,b Unsymmetrical generator short circuits: **(a)** two phase and **(b)** single phase

considering the fault conditions

$$\underline{I}_U = 0;\ \underline{I}_W = -\underline{I}_V;\ \underline{V}_V - \underline{V}_W = 0\,. \qquad (17.205)$$

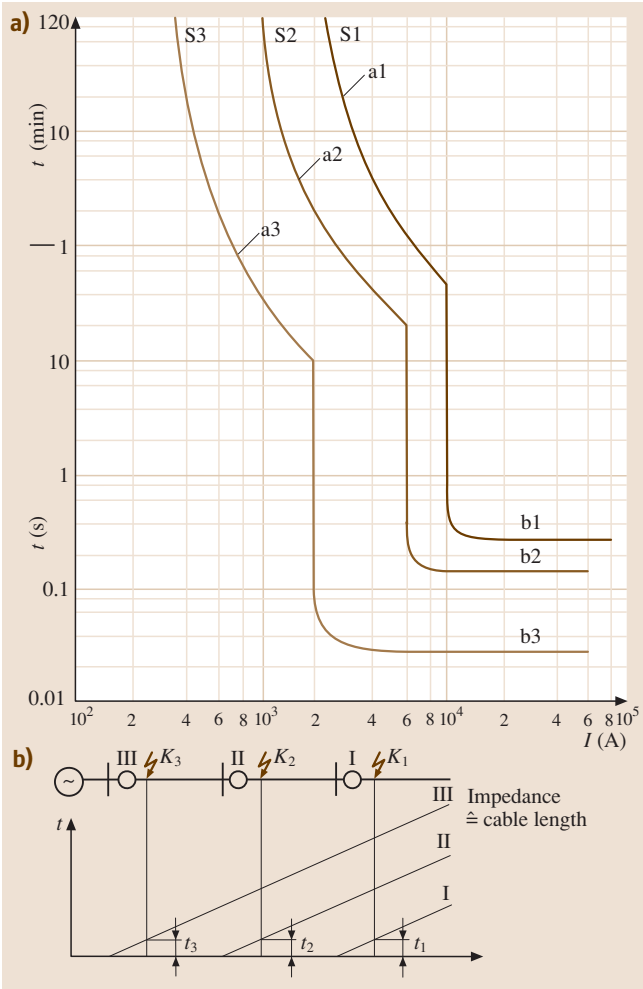
- The initial short-circuit alternating current I''_k for a phase-to-ground fault of phase U will be

$$\underline{I}''_{s1} = \frac{3\underline{E}''}{(\underline{Z}_1 + \underline{Z}_2 + \underline{Z}_0)} \qquad (17.206)$$

considering the fault conditions

$$I_V = I_W = 0 \quad \text{and} \quad V_U = 0\,. \qquad (17.207)$$

Figure 17.95 shows examples of two kinds of non-symmetrical short circuits, represented by means of symmetrical components.



The standard DIN VDE 102 defines the calculation method for any kind of short circuit using an equivalent voltage source $(cV_h)/\sqrt{3}$ implemented at the fault location, with V_h being the line-to-line voltage and $c = 1.1$ for high-voltage networks. For low-voltage networks $c = 0.95$ for the calculation of the smallest possible short-circuit current.

If the initial short-circuit alternating current I''_k is known, the peak short-circuit current can be determined using $I_S = \kappa\sqrt{2}I''_k$, with κ taking values between 1 and 2 depending on the relation R_k/X_k of the short-circuit loop.

In more complicated networks the short-circuit analysis requires the use of special software or, in former times, special analogue network models. Thus, dynamic processes can also be investigated.

Selective Network Protection

If a short circuit occurs, only the affected parts of the network should be cut off. Thus selective network protection has to be achieved, which is possible by using time grading for radial networks. This means that the time delay of a circuit breaker located closer to the fault should be smaller than the time delay of the next circuit breaker and not dependent on the current. Between several power circuit breakers connected in series, a time delay of about 60 ms is used.

Figure 17.96 shows an example of the tripping characteristics for three selective time-graded switches. The selectivity within an intermeshed network is achieved using distance protection.

At the power switch location, currents and voltages are measured and the network impedance is calculated. The tripping time increases with increasing network impedance, thus the switches which are closest to the short-circuit area will open first (Fig. 17.96b).

Alternatively, a selective high-speed switch used for automatic rapid reclosing can be used. In the case of a short circuit all switches in a current-carrying path are turned off simultaneously after 10 ms. If the short circuit only consists of an arc it is feasible for it to self-extinguish. After a rapid reclosing of 700 ms the switches will turn on again. If the short-circuit current still flows, they will open again.

For the parts of the energy system not containing generators or loads the difference protection system

Fig. 17.96a,b Selective network protection: **(a)** tripping characteristic of selective time-graded power circuit breakers; **(b)** tripping characteristics of distance protection with tripping time depending on fault location◀

can be employed. Difference protection is based on the comparison of the input and output currents, if necessary considering the related transformer ratio; failures are thereby identified and the appropriate circuit is shut off.

Oil transformers are additionally equipped with Buchholz relay protection, which responds to gas production within the transformer due to a fault.

Electric Shock Protection

Electric shock protection is necessary to prevent persons from touching voltage-carrying parts. According to IEC 61557 (DIN VDE 0100) the acceptable limit of touchable voltage is 65 V. Protection arrangements should prevent related parts of a system from carrying higher voltages under normal operation conditions as well as in the case of faults.

There are various forms of protection, including:

- *Protection by low voltage*: a maximum operating voltage of 42 V is required for devices operating at protection low voltage.
- *Protective insulation* is used to prevent too high contact voltages from bridging; this requires additional insulation.
- *Protective separation* uses an isolation transformer to disconnect the load circuit from the supplying network and therefore avoids a contact voltage between the equipment and earth in the case of body contact.

The purpose of further protection techniques is to ensure switching off the respective device in the case of isolation faults; thus an unallowable contact voltage will not appear.

These devices need to have a protective grounding conductor for:

- *Protective grounding*, in which the device's case is either connected to the earth or to grounded parts.
- *Neutral grounding* requires a connection between the device's case and a directly grounded wire, e.g., a grounded neutral wire.
- In a *protective conductor system* all respective devices of the electric system are connected to each other as well as to conducting parts of the building, the piping, and grounding electrode.
- *Voltage-operated earth-leakage protection* is able to disconnect all phase conductors within 0.2 s in the case of high contact voltages.
- The *current-operated earth-leakage circuit breaker* is able to disconnect within 0.2 s in the case of a fault current (e.g., 60 mA), thus there will not be any contact voltage at the devices. The operating currents, which usually sum up to zero, pass through a summation current transformer whose secondary winding is guided to an overcurrent relay.

Figure 17.97 shows examples of protection techniques.

17.6.5 Energy Storage

Storage Power Stations

Electric energy cannot be stored in its original form. Nevertheless, in electric energy systems the possibility of storing exists by using reservoir power stations. During periods of weak load water is pumped upstream into a reservoir and during peak load periods the potential

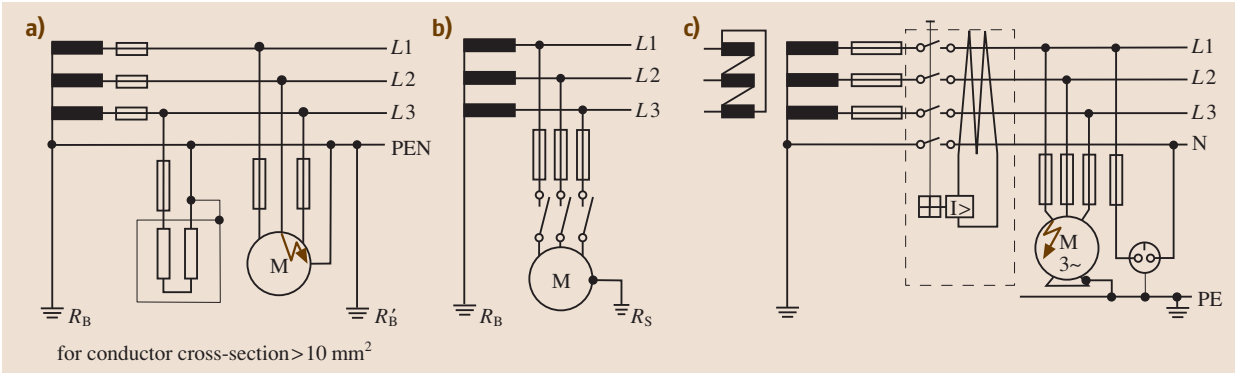


Fig. 17.97a–c Examples of protection techniques: **(a)** grounding without a special grounding conductor; **(b)** protective grounding; **(c)** current-operated earth-leakage circuit breaker, N – neutral conductor, PE – protective grounding conductor (grounded), PEN – zero conductor

energy of this water is used to produce electrical energy again.

For this type of storage system, synchronous machines are used. The synchronous machine is mechanically connected to a water turbine and a pump. A technical variant is the use of only one hydraulic machine, which has to be suitable for turbine as well as pump operation. In this case the operation mode is given by the rotational direction of the machine. The synchronous machine has to be able to start as a motor during pump operation. Reservoir power stations have a total efficiency of energy conversion of about 0.6–0.65.

Batteries

Batteries work according to the basic principle that electrical energy is converted into chemical energy during charging periods, whereas during discharging periods the chemical energy is converted back into electrical energy.

Lead-Acid Storage Battery. These batteries are used for stationary equipment as well as for traction purposes and as starting batteries in vehicles.

Different types of lead-acid battery exist, for example, grid plate accumulators or armor-plate accumulators. The active material is made of lead, lead oxide, and other additives. It is produced in the form of a malleable mass and the solid-lead plates are coated with it. The electrolyte is sulfuric acid with a concentration of about 5 mol/l, and an according density of 1.28 g/cm^3. The concentration decreases during discharging, but should not drop below 1.05 g/cm^3. The total reaction in the cell can be described using the chemical equation

$$\underset{\text{(charging)}}{\mathrm{Pb} + 2\mathrm{H_2SO_4} + \mathrm{PbO_2}} \quad \leftrightarrow \quad \underset{\text{(discharging)}}{2\mathrm{PbSO_4} + 2\mathrm{H_2O}} \,. \tag{17.208}$$

The nominal voltage per cell is defined to be 2.0 V for lead-acid accumulators. The battery's capacity is given in Ah and depends on the type of lead-acid battery used. The charging process can be seen in Fig. 17.98. The electrolyte gas starts to appear at above 2.4 V and charging should be stopped at 2.65 V per cell.

During discharging the minimal voltage should not be below the cutoff voltage of 1.8 V. The useable capacity is a function of the discharge current. Figure 17.98b shows the discharge time as a function of the current for a single cell, using a logarithmic scale. The discharge characteristics of a single cell as a function of the discharge rate with the discharge current as a parameter is presented in Fig. 17.98c. Lead-acid storage batteries are sometimes used as storage devices in the field of electricity supply. Then the battery is used for load leveling, frequency control, provision of instantaneous reserve or voltage control. One example of a 17 MW 14.4 MW h plant was installed and successfully operated in Berlin between 1987 and 1994. A 10 MW 40 MW h plant was used in the Southern California Edison Co. During the

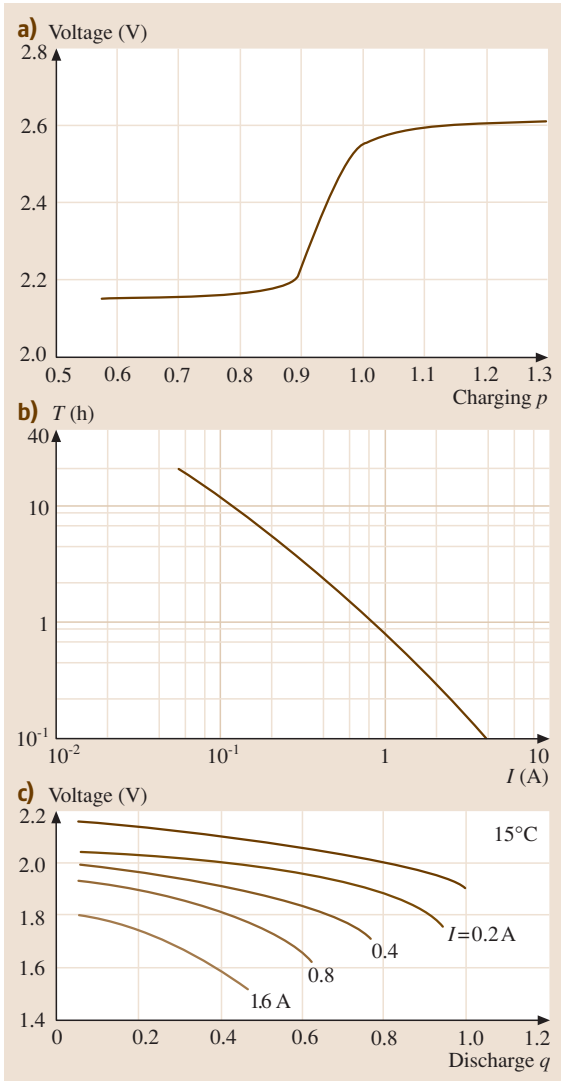

Fig. 17.98a–c Characteristic of lead-acid batteries: **(a)** charge process; **(b)** discharge time of one cell related to discharge current; **(c)** discharge characteristic of a cell at 15 °C

1990s several plants were installed worldwide showing that the economical operation of this system is possible. Developments caused by the liberalization of the energy market may promote this technology.

Other Accumulators. Cadmium and nickel batteries are accumulators with an alkaline electrolyte; they are rechargeable and are produced as button cells with a capacity between 10 mA h and 25 A h. The use of electric drives in vehicles depends considerably on the capability to produce storage batteries with a high energy density. However, the lead-acid accumulator with a specific capacity of 30–40 W h/kg, assuming a 2 h discharging time, cannot entirely fulfil these requirements. A promising development is the sodium/sulphur battery with a ceramic electrolyte and liquid sodium and sulphur. An energy density of about 120 W h/kg is achieved with this technology. The sodium/sulphur battery requires a minimum operating temperature of 285 °C.

Other Energy Storage Methods

Future development is addressing the possibility of storage of magnetic energy in superconducting coils, in which the current can flow nearly without losses. The coupling in and coupling out of electrical energy is realized by an electronic power converter. Other methods involve the unconventional charging processes with switches, which are converted from a superconducting state into a normal state.

A different approach is the use of flywheel storage, which is charged by an electric source and can be discharged depending on the demand for electricity.

17.6.6 Electric Energy from Renewable Energy Sources

Renewable energy is sometimes called *green energy* because it is – in contrast to fossil energy like coal, oil, and gas – not finite. Renewable energy sources are based on regenerating natural primary energy sources (biomass, biogas) or infinite primary energy sources (sun, wind, water). The transformation process into electrical energy has no or only a small effect on the environment and does not contribute to the greenhouse effect and global warming like the conventional burning of fossil sources. The five most common renewable sources – which are finally all solar sources – are hydropower, wind energy, solar energy (thermal as well as photovoltaic), geothermal energy and biomass. Sometimes using fuel cells for the transforming process into electrical energy is also referred to as using a renewable energy source, but this depends on the primary energy – the *fuel* being used. Some of them will now be briefly discussed.

Solar Energy

Solar energy from the sun is the most abundant energy form on the planet. The sun provides energy in two forms – light and heat [17.8]. The thermal energy can be used either for heating (homes, offices, swimming pools etc.) or to power a conventional turbine to produce electricity (a solar thermal power plant). The light energy can be converted into electrical energy directly by using photovoltaic systems.

Photovoltaic Energy Systems. Photovoltaic (PV) energy systems transform light directly into electricity. They use daylight to supply ordinary electrical equipment, for example, household appliances, computers, and lighting.

A PV cell consists of two or more thin layers of semiconducting material, most commonly silicon (for the different types of PV see Table 17.7). When the silicon is exposed to light, electric charge carriers are generated and an electric potential develops between the two layers of the material. To balance this potential a charge transport is necessary, which is conducted via metal contacts on both sides of the cell. If an electrical load is connected to the contacts a direct current (DC) will flow.

To achieve a higher voltage and power level single cells are connected electrically. For mechanical stability and outdoor use these cells are then encapsulated, usually behind glass, to form a module. The connection of several modules is called a panel or string.

The PV module is the principle building block of a PV system and any number of modules can be connected to give the required power with a suitable current and voltage output.

Typical modules have a rated power output of around 75–200 W peak (W_p) each. A typical domestic system of 1.5–2 kW_p may therefore contain about 10–24 modules covering an area of 12–40 m^2. The actual power output is dependent on the technology used and the orientation of the array with respect to the sun. An inverter (see Sect. 17.4) is used to convert the comparatively low DC voltage to a compliant AC voltage.

The solar generators are suitable for autonomous distributed energy supplies as well for feeding into public networks. Figure 17.100 shows an example of a 10 kW_p photovoltaic system.

Table 17.7 Types of PV cells

Type of PV cell	Specification
Monocrystalline silicon cells	• Made from a single cylindrical crystal of silicon • High efficiencies, typically around 15% • Manufacturing process is complicated, resulting in slightly higher costs than other technologies
Multicrystalline silicon cells	• Made from an ingot of melted and recrystallized silicon • Multicrystalline cells are cheaper to produce than monocrystalline cells • Efficiency around 12% • Creating a granular texture
Thick-film silicon	• Another multicrystalline technology • Encapsulated in a transparent insulating polymer with a tempered glass cover • Bound into a strong aluminum frame
Amorphous silicon	• Composed of silicon atoms in a thin homogenous layer • Thinner because of more effective light absorption • Flexible for curved modules • Typical efficiencies of around 6% • Cheaper to produce

PV equipment has no moving parts and as a result requires minimal maintenance. It generates electricity without emitting any greenhouse or other gases, and its operation is silent.

Photovoltaic power is the same technology that supplies certain calculators and watches. It is also used for remote telephones in some regional areas.

Solar Thermal Energy Systems. This type of energy occurs when energy from the sun is absorbed and used to heat liquids such as water or oil. The hot water can either be used directly or via a heat exchanger or to create steam and drive a small turbine to generate electricity.

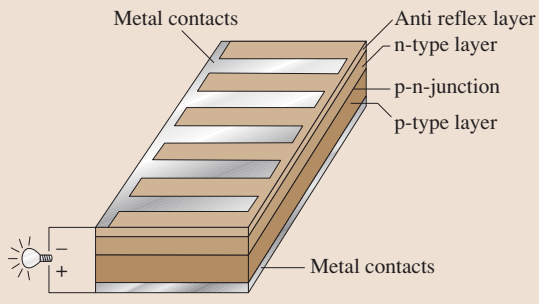

Fig. 17.99 PV cell schematic construction

Advantages of using solar energy:

- Solar energy is infinite and always available.
- It is useful for remote areas that are not connected to the main electricity grid.
- No output of greenhouse gas.

Disadvantages of using solar energy:

- It is weather dependent.
- It is expensive.
- Due to its efficiency it requires a lot of space.

Wind Energy

Wind is moving air that results from different temperature zones created by solar energy. By using wind turbines, kinetic wind energy can be used to generate electrical energy [17.29, 30].

Wind turbines consist of numerous components, including the blades, a shaft, a generator, and a tower. The shaft is connected to the blades, and rotates as the blades are turned by the wind (Fig. 17.101). It can either be connected directly or via a gear box to the generator, which converts the kinetic energy into electrical energy.

The power P of a wind energy converter is proportional to the coating area of the rotor blades A and the cube of the wind speed v^3. The maximal theoretic aerodynamic efficiency of an ideal wind turbine is

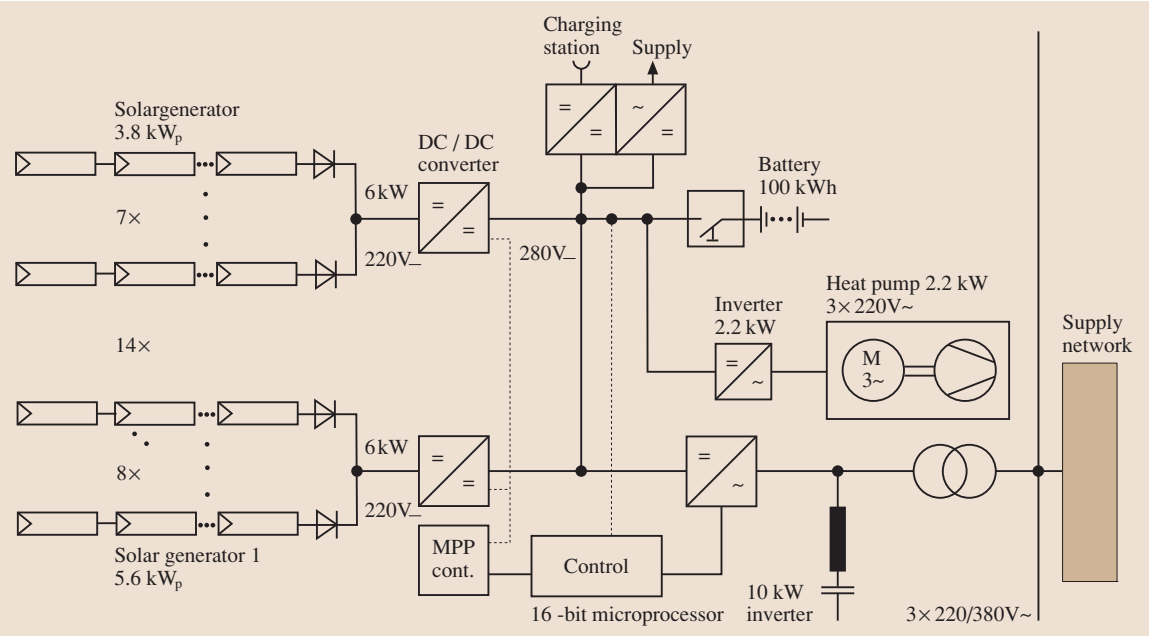

Fig. 17.100 PV system

59.3% [17.31]. Today efficiencies are 38–50% depending on the technology used.

The nominal power of a wind turbine ranges from a few watts up to 7 MW (2008).

Figure 17.103 shows a typical power characteristic as a function of the rotational speed and for different wind speeds. The maximum power point moves to a higher rotation speed with increasing wind speed v. If the generators are connected to a network with constant frequency they have to be adapted to the grid frequency because they cannot work at any wind speed at their maximum power point. This can be solved by applying, for example a link converter between the generator and the three-phase network.

Today four types of machines are used within wind turbines: asynchronous machines, synchronous machines, double-fed induction machines, and full converter machines.

The double-fed induction generator (DFIG) makes it possible to operate the turbine at variable speed. Thereby the utilization even at low wind speeds is enhanced. The present option of choice is based on full AC–DC–AC conversion with a gearless mechanical implementation.

There are various methods for connecting wind turbines to an electrical network:

- A cyclo- or matrix converter
- A converter with a DC link
- A converter with an AC link

The type of connection chosen depends on the kind of wind turbine used and the network parameters (voltage, current, frequency, harmonics, etc.).

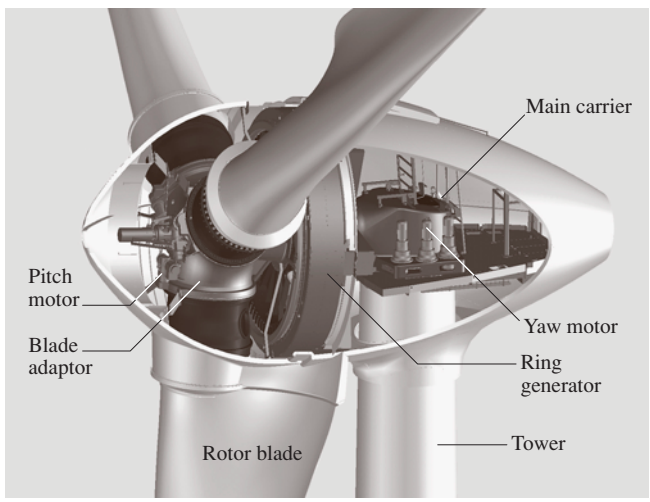

Fig. 17.101 Wind generator (Enercon)

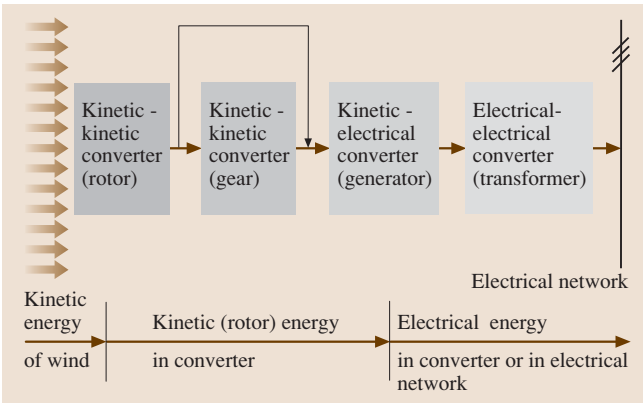

Fig. 17.102 Electrical conversion chain of a wind turbine

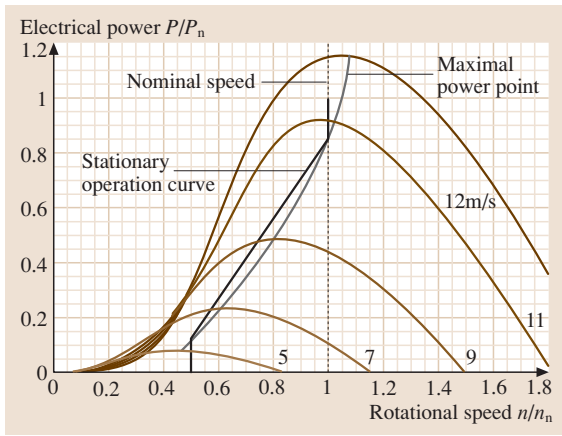

Fig. 17.103 Characteristic of output power against rotational speed and wind speed in per unit (p.u.)

Wind turbines can differ depending on:

- The setting of the rotor axis (horizontal or vertical)
- The number of rotor blades (1–4)
- The tip speed ratio (slow or fast)
- The possibility of power control (pitch or stall)
- The possibility of wind storm security
- The type of generator (synchronous, asynchronous, DFIG or full converter machine),
- The type of network connection (direct or via a DC link)

Advantages of using wind energy:

- Energy from the wind is infinite and always available.
- It is very useful for remote regions that are not connected to the main electricity grid.
- It is environmentally safe.
- Land for wind farms can usually be used for other things as well (farming).

Disadvantages of using energy from the wind:

- Wind speed is variable.
- It creates noise, so turbines should not be built near houses.

Hydropower

The fall and flow of water is part of a continuous natural cycle. The sun draws moisture up from the oceans and rivers, and the moisture then condenses into clouds in the atmosphere. This moisture falls as rain or snow, replenishing the oceans and rivers. Gravity drives the water, turning ist potential energy into kinetic energy, which can be quite high.

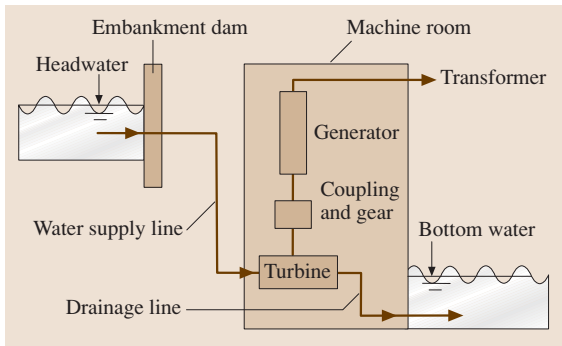

Fig. 17.104 Hydropower station – physical principles

An advantage of hydropower is its operating costs – it is less expensive than mining fossil fuels. Also, unlike other renewable sources like the sun or wind, water can be stored, which makes it interesting for generating electricity.

Rivers, dams, and waterfalls can be used to generate electricity. Today the exploitation of wave energy and tidal power plants are also being developed.

Hydroelectric power stations are built where water is running. The most common location is at dams, where water is stored. To produce hydroelectric power, water from rain or melting snow is collected and stored in a natural or artificial sea. The flow of this water can be controlled by the opening and closing of gates or pipes. The dam wall can also create a high water level, which creates a higher pressure in the pipes to the turbine. A large pipe carries the water from the dam to the turbine. The pressure of the water pushes against the blades and turns the turbines.

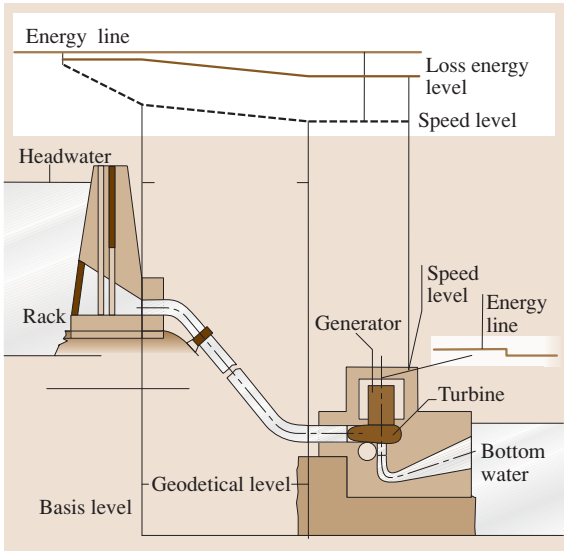

Fig. 17.105 Scheme of a hydropower station

The theoretical power of water is defined as

$$P_{\mathrm{WAth}} = \rho_{\mathrm{WA}} g q_{\mathrm{WA}} (h_{\mathrm{HW}} - h_{\mathrm{BW}}) \,, \qquad (17.209)$$

where ρ_{WA} is the water density, g is the gravitational constant, q_{WA} is the flow rate through hydropower system, h_{HW} is the geodetical level of head water surface, and h_{BW} is the geodetical level of the lower water surface.

The construction of a typical hydropower station is illustrated in Fig. 17.105. It consists of:

- The turbine, a hydraulic machine that transforms the kinetic water energy to rotary motion (it can be a Pelton, Francis, propeller, Kaplan or Straflo turbine).
- Coupling and gear (via direct coupling for small stations or via gears for large units).
- The generator (synchronous or asynchronous generator).
- The transformer (voltage adjustment).
- The embankment dam (responsible for continuous water charge).
- The water supply line (water can flow to the turbine either directly or through a gear canal).

Pumped Storage Systems. Some hydro plants also use pumped storage systems. A pumped storage system operates much as a public fountain does. The same water is used again and again. At a pumped storage hydro plant, flowing water is used to generate electricity and is then stored in a lower pool. Depending on how much electricity during a certain period is needed, the water is pumped back to the upper pool. Pumping water to the upper pool requires electricity, thus this pumping procedure is done during low load periods, when the electricity price is lower than during peak load hours, when selling this energy is beneficial. Pumped storage systems are used when there is a high demand for peak load electricity and the geographical prerequisites are fulfilled as well.

For a long time hydropower has been the leading renewable energy source. Worldwide, hydropower provides more than 90% of all electrical energy produced from renewable sources. All other renewable sources produce only about 10% of the renewable energy (status 2001). In Germany the share of hydropower refering to the electricity consumption was overtaken by wind energy in 2004, while other power systems like e.g. the Norwegian system are mainly based on hydro power.

Advantages of hydropower:

- It is a renewable source
- Hydroelectricity produces no gas emissions or waste.
- It is more reliable than solar and wind power because water can be stored.
- Hydroelectric stations are inexpensive to operate.

Disadvantages of hydropower:

- Large dams take up large areas of land and can cause fish and other animals to relocate.
- The durability of the plant can be affected by a change in water quality.

Fuel Cells as an Alternative Energy Source

In principle, a fuel cell operates like a battery [17.32, 33]. However, unlike a battery, fuel cells do not run down or require recharging. Rather they deliver electricity and heat as long as fuel is supplied. A fuel cell

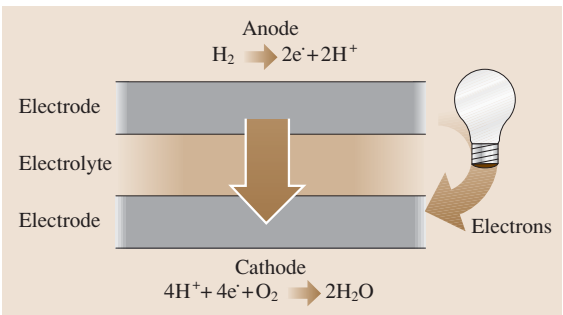

Fig. 17.106 Principles of a fuel cell

consists of two electrodes with an electrolyte between. The most well developed fuel cell is the polymer electrolyte fuel cell (PEMFC) [17.34]. Oxygen passes over one electrode and hydrogen over the other, generating electricity, water, and heat (Fig. 17.106). Hydrogen fuel is fed into the *anode* of the fuel cell. Oxygen (or air) enters the fuel cell through the cathode. With the help of a catalyst, the hydrogen atom splits into a proton and an electron, which take different paths to the cathode. The proton passes through the electrolyte, while the electron creates a separate current that can be utilized before returning to the cathode, to be reunited with the hydrogen and oxygen in a molecule of water. This DC current is transformed into an AC current using a DC–AC converter. Afterwards it will be supplied to the electrical network. For fuel cells the DC–AC converters have to satisfy specific requirements, for example, wide DC voltage range. There are many kinds of DC–AC converters and choosing the suitable one also depends on the circuit and network parameters.

A fuel cell system which includes a *fuel reformer* can utilize the hydrogen from any hydrocarbon or alcohol fuel: natural gas, ethanol, methanol, propane, and even gasoline or diesel. Hydrogen can be extracted from novel feed stocks such as landfill gas or anaerobic digester gas from wastewater treatment plants, from biomass technologies, or from hydrogen compounds containing no carbon, such as ammonia or borohydrides. Hydrogen can also be produced from electricity from conventional, nuclear or renewable sources. Electrolysis uses an electric current to extract hydrogen from water. Fuel cell in combination with solar or wind power, or any renewable source of electricity can contribute to zero-emission energy system that requires no fossil fuels and is not limited by variations of sunlight or wind. The hydrogen from the electrolysis can supply energy for power needs and for transportation.

Fuel cells differ from one another in terms of operation temperature, electrolyte, fuel, kind of application, etc.

Application possibilities suchas the provision of backup power to a grid-connected customer, in case the grid should fail are possible by special configuration. A configuration to provide completely grid-independent power is possible as well, then the grid can be used as a backup system. Modular installation (the installation of several identical units to provide a desired quantity of electricity) provides high reliability, which is crucial to an economy that depends on increasingly sensitive computers, medical equipment, and machines.

Since the fuel cell relies on chemistry and not on combustion, emissions from this type of a system are much smaller than emissions from today's cleanest fuel combustion processes, while also being, fundamentally more efficient than combustion systems:

- Fuel cell power generation systems in operation today achieve 40% fuel-to-electricity efficiency utilizing hydrocarbon fuels.
- Systems fueled by hydrogen consistently provide 50% efficiency. Even more efficient systems are under development.
- In combination with a turbine, electrical efficiencies can exceed 60%.
- If waste heat is put to use for heating and cooling, overall system efficiencies exceed 85%.

17.6.7 Power Quality

Fundamental Terms

The term *power quality* covers a lot of issues which are related to description, analyses, monitoring, and elimination of undesirable phenomena appearing in power systems. Interest in power quality increases due to the changes of the network operation conditions over the last years [17.35].

The significant increase of power demand and the appearance of nonlinearity of loads have resulted in a situation where network elements are overloaded and required to work at their upper load limits. Such properties contribute to unstable network operation,

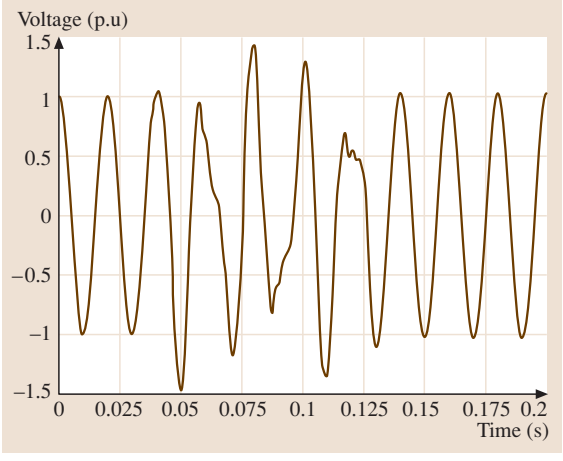

Fig. 17.107 Example of flicker caused by arc furnace operation

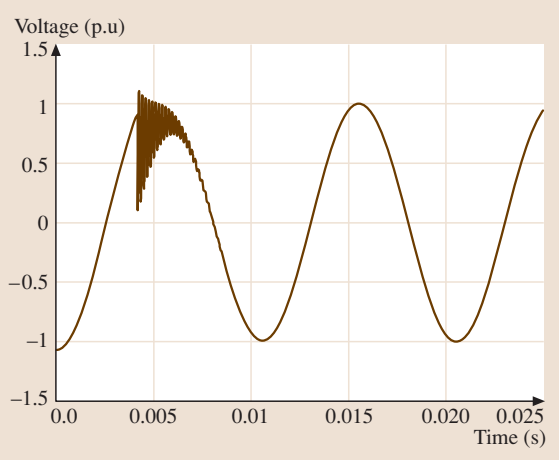

Fig. 17.108 Low-frequency oscillatory transient caused by capacitor bank energization

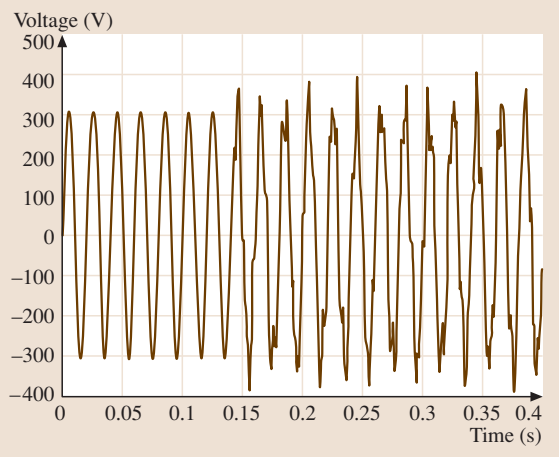

Fig. 17.109 Low-frequency oscillatory transient caused by ferroresonance of an unloaded transformer

known as power quality phenomena (see Figs. 17.107–17.109), which can be classified into the following groups:

- Transients: momentary events. They can be subdivided into two groups: impulsive and oscillatory transients. Impulsive transients are sudden changes in the steady-state condition of voltage or current. The polarity of the impulsive transient is either positive or negative. The oscillatory transient has sudden changes as well, but the polarity has both positive and negative values.
- Long-duration voltage variations: variations of the voltage or current at the power frequency lasting longer than 1 min. These can be divided into several subgroups: overvoltages, which are changes in the RMS AC voltage to more than 110% of the normalized value; and undervoltages, which are decreases of the voltage to less than 90% of the normalized value.
- Short-duration voltage variations: phenomena that last for less than 1 min. The following event types can be distinguished: interruptions appearing when the voltage or current decreases to less than 10%. Sags (dips) are variations at the power frequency in the range between 10–90% in RMS value. Swells are phenomena defined as an increase of the voltage or current in the range 110–180%.
- Blackouts. A black-out is a sustained power outage over a relatively wide area. Usually the pre-stage of a black-out is a so called brown-out. The brown-out leads to a black-out, when the system cannot recover so the outage area grows.
- Voltage imbalances, which arise when the three-phase supply system operates with unsymmetrical voltages.
- Waveform distortions, defined as steady-state deviations from an ideal sine wave. Such events can be divided into the following groups:
  - Harmonics, which are sinusoidal voltages and currents that are integer multiples of the fundamental frequency.
  - Interharmonics, which differ from harmonics in that they have a noninteger relation to the fundamental frequency.
  - Notchings, which are periodic disturbances resulting from the operation of power electronic elements. Noise and DC offset can also be classified into this group of phenomena.

The Power Quality Description

In order to evaluate and analyze power quality, some mathematical definitions need to be introduced. The whole power quality analysis is based mainly on voltage and current studies in the frequency domain. Some specific numerical tools are used, like the discrete Fourier transformation (DFT) and fast Fourier transformation (FFT), which assess the energy quality based on comparative analyses. These analyses can be applied to both impulsive and steady-state phenomena. In order to evaluate the higher harmonic and interharmonic content in the steady state, the total harmonic distortion (THD) is

defined

$$\mathrm{THD} = \frac{\sqrt{\sum_{h>1}^{h_{\max}} G_{\mathrm{h}}^2}}{G_1} , \tag{17.210}$$

where G_{h} is the individual RMS value of the quantity G. It can be seen that THD is referred to as the fundamental harmonic. To measure the distortions produced by nonlinear loads of mainly large power networks the total demand distortion (TDD) is introduced

$$\mathrm{TDD} = \frac{\sqrt{\sum_{h>1}^{h_{\max}} I_{\mathrm{h}}^2}}{I_{\mathrm{L}}} , \tag{17.211}$$

where I_{L} is the peak, or maximum, demand load current at the fundamental frequency. For power quality evaluation the individual harmonic components can be analyzed separately as well. In this case the magnitude of the harmonic cannot exceed the prescribed values that are introduced by standards and norms.

Not only harmonics are evaluated in terms of the power quality. Power analysis is also conducted when the current or voltage occurs as a harmonic signal. In such cases the apparent power S is divided into three components

$$S = \sqrt{P^2 + Q^2 + D^2} , \tag{17.212}$$

where P is the active power at each harmonic, Q is the reactive power at each harmonic, and D is called the distortion power, reflecting the relationship between the different harmonic elements.

The general relationship between the active power (needed to operate equipment) and the apparent power is

$$\mathrm{PF} = \frac{P}{S} , \tag{17.213}$$

the power factor. The best conditions for network operation are obtained when this parameter is equal to 1.

Power Quality Improvement

A lot of methods are used to improve the power quality. These methods are distinguished in terms of phenomena that need to be compensated. Harmonic mitigation, for example, requires the use of filters. Two main groups of filters can be distinguished: passive and active. Passive filters are constructed by a suitable connection of inductances and capacitances. They are designed to reduce individual harmonics (mainly the fifth) or narrow frequency ranges. Over the last few years, active filters have begun to play an important role in the improvement of network operation in terms of harmonics. These elements are based on semiconductor components and a storage system (battery, supercapacitor, superconductor). By applying suitable switching techniques of the valves in active filters the higher harmonics can be limited.

The reactive power in a distribution system has turned out to be an important problem as well. The reactive flow power results in additional losses. To reduce this, capacitor banks are used to compensate the prevailing inductive load.

Furthermore, short circuits are another important issue in network operation. A high short-circuit current can contribute to the destruction of distribution elements (wires, transformers). To avoid short circuits, relaying systems are applied.

Sudden changes in current can induce current in other wires and also cause the aggravation of the power quality. To limit this type of phenomena shielded cables are utilized.

In order to improve the reliability of the network, the designing approach of the power system plays a very important role. Using new numerical techniques, the network can be designed to have more stable operation, and can be monitored to find the distortion source and eliminate it.

17.7 Electric Heating

In resistances electric power is converted into heat [17.1, 36]. This process is described by the simple formula

$$P_{\mathrm{w}} = UI\cos\varphi = I^2 R = U^2/R . \tag{17.214}$$

The different electric heating procedures vary in terms of the kind of resistance and the nature of the energy source and include resistance, arc, inductive, and dielectric heating. For a smelting furnace, the first three principles, shown in Fig. 17.110, are used.

For the techniques illustrated in Fig. 17.110a,e,f, the heated material itself acts as the resistance, and for the examples shown in Fig. 17.110a,d the heating source is arc plasma.

The only practical application of Fig. 17.110c is the arc-heating steel furnace. Most reduction furnaces, for

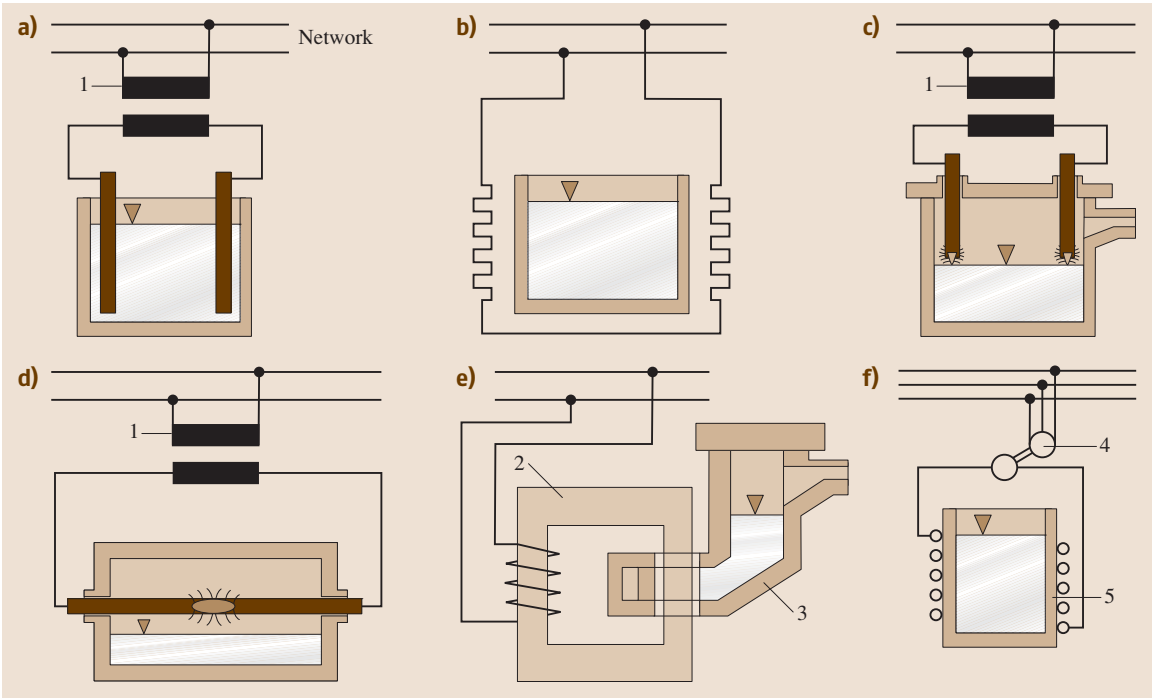

Fig. 17.110a–f Examples of electric heating: **(a)** direct resistance heating; **(b)** indirect resistance heating; **(c)** direct electric arc-heating; **(d)** indirect arc-heating; **(e)** low-frequency induction heating; **(f)** middle-frequency induction heating: 1 – transformer, 2 – iron core, 3 – smelting chamber, 4 – middle-frequency converter, 5 – induction coil with water cooling [17.36]

example, for the production of carbide, ferrosilicon, and aluminum, are hybrid forms of (a) and (c).

17.7.1 Resistance Heating

Figure 17.111 shows examples of direct resistance heating. Such devices are characterized by high current demand at relatively low voltages.

For indirect resistance heating, heating conductors that meet the relevant thermal, chemical, and mechanical demands are needed [17.37]. The heating conductors differ from each other greatly in terms of the temperature dependency of their conductivity. Depending on the temperature range, the following metals can be used: molybdenum, molybdenum compounds, tantalum, and in special cases platinum or ceramic (mainly silicon carbide) and graphite.

Metallic heating conductors are produced in different forms, e.g., wires or bands, whereas the other heating conductor forms are confined to pipe or slat forms. Liquid glass can be used as a heating conductor as well. The heating conductors are mounted on ceramics or other temperature resistant isolators.

17.7.2 Electric Arc Heating

As well as in steel furnaces arcs are also applied in the arc welding process. These arcs can be described as resistances that are dependent not only on their length but also on the current. The relationship between the arc voltage and current is nonlinear (Fig. 17.112).

Arc Furnaces

Large arc furnaces are low resistance loads (a few mΩ and currents of more than 10 000 A at voltages of a few hundred V). The three-phase current that feeds the arc is fed through a graphite electrode. The current is regulated by changing the arc impedance by controlling the distance between the electrodes. In addition, the input voltage at the clamps of the furnaces is changeable to achieve a suitable current level. In order to adjust the voltage, a regulating transformer is used

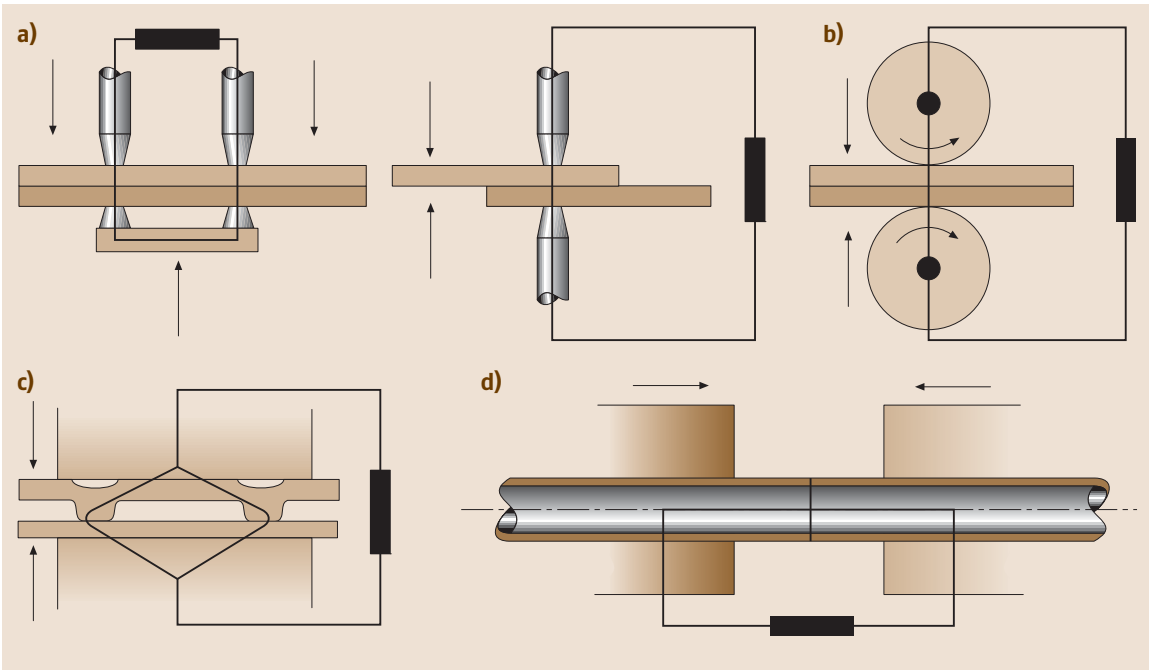

Fig. 17.111a–d Materials and electrode position of resistance welding: **(a)** point welding; **(b)** continues rolling welding; **(c)** projection welding; **(d)** butt welding [17.36]

which has winding taps on the high-voltage side of the transformer, because the high-current (secondary) side consists of only one or a few windings. Thus the furnace voltage is changed through the magnetic flux in the transformer.

The strongly varying magnetic fields on the secondary side evoke high inductive voltage drops that limit the short-circuit current and the maximum voltage on the secondary side. They can also be responsible for an unsymmetrical network load.

The electrodes can be controlled hydraulically or with the help of electric machines. The control variable is the arc impedance, which can only be measured with the help of specific methods; otherwise measurement errors occur due to the magnetic fields generated by the high-current circuit. The voltage v_{0M} in Fig. 17.113 is the error occurring in the normal measurement method.

The inductances L_1, L_2, and L_3 are the real mutual inductances of the high-current loop, namely

$$L_1 = M_{12,13}\frac{\mathrm{d}i_1}{\mathrm{d}t} + M_{23,21}\frac{\mathrm{d}i_2}{\mathrm{d}t} + M_{31,32}\frac{\mathrm{d}i_3}{\mathrm{d}t} \,. \tag{17.215}$$

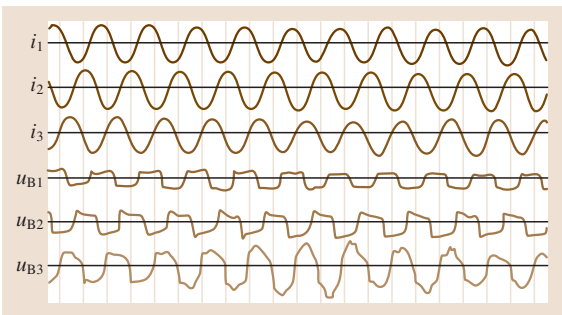

Fig. 17.112 Current and arc voltage of an arc furnace

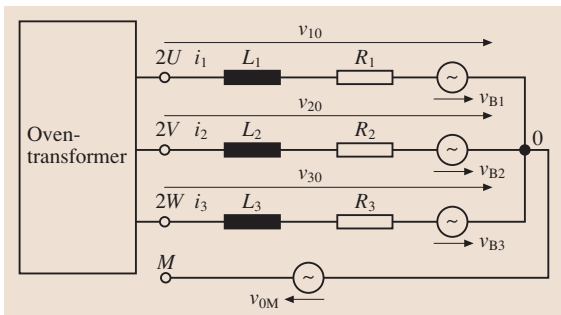

Fig. 17.113 Equivalent circuit for an arc furnace

The error voltage in the star point of the circuit results from the expression

$$V_{0M} = M_{2M,M3}\frac{di_1}{dt} + M_{3M,M1}\frac{di_2}{dt} + M_{1M,M2}\frac{di_3}{dt}\,. \tag{17.216}$$

where v_{B1}, v_{B2}, and v_{B3} are the arc voltages and R_1, R_2, and R_3 are the resistances of the high-current circuit (Fig. 17.113).

Arc Welding

Arc welding requires voltages of up to 40 V, which are not dangerous values for manual welding. The DC or AC voltage source is connected to the workpiece with one pole and to the electrode (welding rod) with the other pole (for DC sources mainly the negative pole). In order to melt the material properly, a suitable arc feeding current and voltage level must be maintained. Therefore, the voltage source must match the characteristics of the arc.

17.7.3 Induction Heating

For inductive heating, the transformer principle is employed to transfer the power to the workpiece, which has the function of the short circuit secondary winding. In crucible furnaces (Fig. 17.110f) the secondary winding has a massive cylindrical form, in contrast to the ring form in trench furnaces (Fig. 17.110e). Therefore an iron core is not used in a crucible furnace.

Due to the iron losses in trench furnaces, they are only used for frequencies of 50–60 Hz. The crucible furnace, on the other hand, can operate in a frequency range up to 10 kHz.

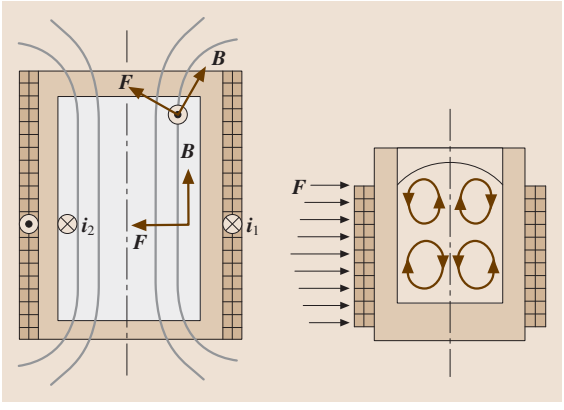

Fig. 17.114 Field concentration in a crucible furnace

Skin Effect, Depth of Penetration

The skin effect of the eddy current (secondary current) causes the current density to be higher in places that lie near to the induction coil. The depth of penetration δ is the depth x measured from the surface nearest to the primary coil for which the current density S has a value of S_0/e, where S_0 is the current density at the surface and e is the Euler number (≈ 2.716).

The following equation is valid for the current density

$$S(x,t) = \hat{S}_0 \exp(-x/\delta)\cos(\omega t - x/\delta) \tag{17.217}$$

and, for the depth of penetration

$$\delta = \sqrt{\frac{2}{\omega\mu\kappa}} = 503\sqrt{m/\Omega s}\,\frac{1}{\sqrt{f\mu_r\kappa}}\,. \tag{17.218}$$

δ is thus inversely proportional to the root of the frequency, the permeability, and the conductance of the

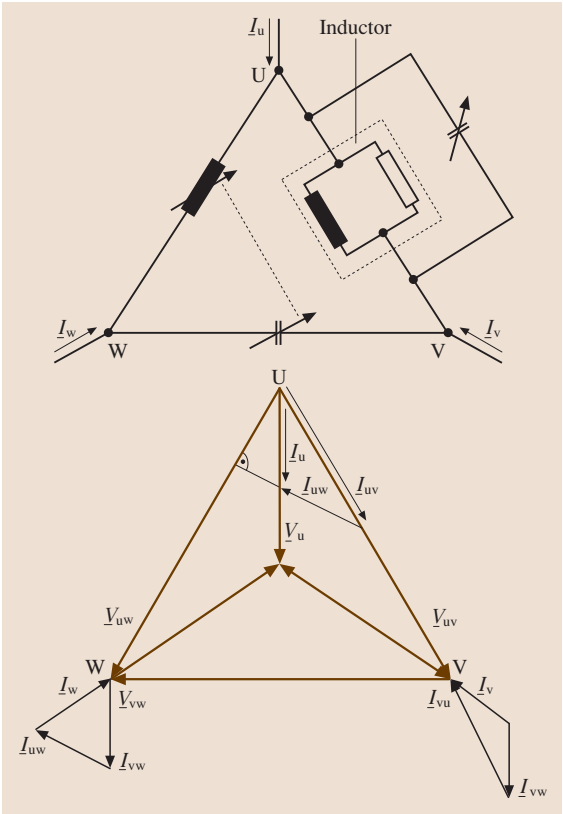

Fig. 17.115 Method to compensate the unsymmetrical and reactive power load of an inductive heating facility

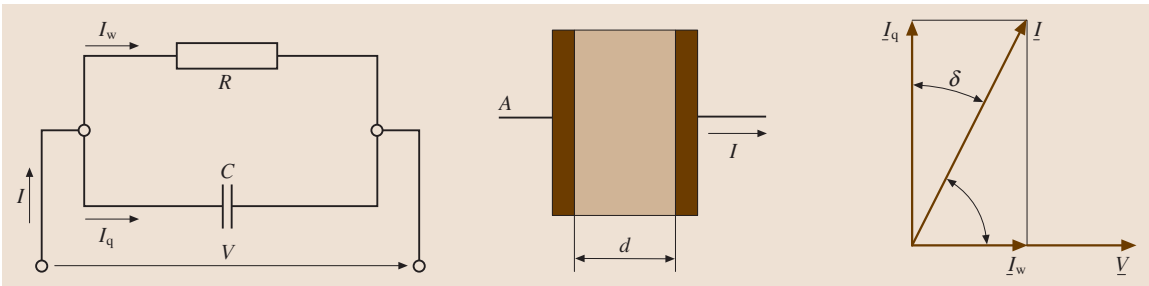

Fig. 17.116 Equivalent circuit and phasor diagram for a real capacitor for dielectric heating

material. Using higher frequencies the current density and therefore the heating can be concentrated to the surface of the materials.

Surface Bulging and Melt Circulation in the Heating Material

Currents in the inductance coil and the materials produce repulsive forces. In the melted materials they are directed towards the axis of the cylinder. This causes the static pressure to be higher at the cylinder axis than at its perimeter. As a result the upper surface of the melted material forms a bulge Fig. 17.114. Because the magnetic field contains radial components at the ends of the cylinder, torsional moments arise in the melted material which cause vorticity of the material. The bulging end and torsional moments are approximately proportional to $\sqrt{1/f}$ so they can be adapted to the requirements of the process by changing the frequency.

High-Frequency Induction Surface Heating

By using high frequencies with suitably formed induction coils, selective surface areas of the working piece can be heated to achieve surface improvement. If the input power has a high level, then the surface can be heated faster, while the heat has no time to be conducted to the inner material. Thus the depth of heating is controlled by the input power and as well by the frequency.

Electric Power Supply

The facilities of induction heating are generally single-phase loads mainly working at a frequency higher than the network frequency. Figure 17.115 shows a common method to turn the load into a symmetrical load, free of reactive power. The current in the coil is compensated by an adjustable capacitor to achieve $\cos\varphi = 1$.

If the reactance of the capacitances and inductances, which are connected to the third phase of the three-phase system, are regulated to the value of $\sqrt{3}$ of the value from the heating facility's resistance (which depends on the amount and type of the workpiece) than from the network point of view the load is symmetrical. For applications with intermediate frequencies ($< 30\,\text{kHz}$) and power of up to several megawatts thyristor converters are used. At lower power, IGBT converters that operate with frequencies of up to 500 kHz are employed. In both cases the converters have resonant circuit topologies.

17.7.4 Dielectric Heating

A high-frequency alternating electric field causes losses in non-conducting materials due to changes in the position of the molecular dipoles. In this process the phase angle of the input current is $\varphi < 90°$ with respect to the given voltages (Fig. 17.116). The angle δ is called the loss angle and is nearly independent of the frequency.

The following expression describes the specific losses and heating power

$$P'_w = E^2 \omega \varepsilon_0 \varepsilon_r \tan\delta\,,$$

$$\text{where } \tan\delta = \frac{I_w}{I_g} = \frac{P_w}{P_g}\,. \qquad (17.219)$$

The electric field intensity is limited by the breakdown field strength of the dielectric. Further increases of the power density P'_w are only possible by changing the frequency. The value of $\tan\delta$ depends on the temperature and humidity of the material and can often be used for self-regulation of the power P'_w. Because this technology is often used with multilayered material the orientation of the boundary layer can be lengthwise or transverse to the electric field. Which orientation is best depends on the required process parameters. Air in the field volume affects the process adversely.

Dielectric heating is very often applied for welding of plastic foils, particularly in the form of joints, for example, for upholstery or car interior linings.

The suitable power density is only achieved at high frequencies. The following frequencies are authorized for this process: 13.6, 27.12, 40.68, and 433.92 MHz. For the heating process in a microwave radiation field the frequency of 2450 MHz is permitted. When using other frequencies, shielding must be applied in order to achieve EMC compatibility. The mentioned frequencies are produced by electron valve generators.

18. General Tables

Stanley Baksi

Table 18.1 Basic dimensions, their symbols, and physical significance

Basic dimension	Symbol	Physical entity
Meter	m	Length
Kilogram	kg	Mass
Second	s	Time
Ampère	A	Electric current
Kelvin	K	Thermodynamic temperature, temperature difference
Mol	mol	Quantity
Candela	cd	Light intesity

Table 18.3 Prefixes for units

Power of ten	Prefix	Symbol
10^{18}	Exa	E
10^{15}	Peta	P
10^{12}	Tera	T
10^{9}	Giga	G
10^{6}	Mega	M
10^{3}	Kilo	k
10^{2}	Hekto	h
10	Deka	da
10^{-1}	Deci	d
10^{-2}	Centi	c
10^{-3}	Milli	m
10^{-6}	Micro	μ
10^{-9}	Nano	n
10^{-12}	Pico	p
10^{-15}	Femto	f
10^{-18}	Atto	a

Table 18.4 Units not defined in the Système International d'Unités (SI) system but commonly used

Characteristics of units	Example
Generally used units	Liter (l), hour (h), degree (deg, °)
Units with limited use	Electron volt (eV)

Table 18.5 Conversion values to calculate from m–kp–s in the SI system

1 kp ≈ 1 daN	1 at ≈ 1 bar	1 kp m ≈ 1 daJ
1 kp/cm ≈ 1 N/mm	1 PS ≈ 0.75 kW	
1 mm water column ≈ 0.1 mbar	1 kcal ≈ 4.2 kJ	

Table 18.6 Names and abbreviations of English units

atm	Atmosphere
bbl	Barrel
btu	British thermal unit
bu	Bushel
cwt	Hundred weight
cal	Calorie
deg F	Degree Fahrenheit
ft	Foot
gal	Gallon
hp	Horsepower
in	Inch
lb	Pound
lbf	Pound force
lntn	Long ton
mi	Mile
pdl	Poundel
shtn	Short ton
yd	Yard
UK	United Kingdom
US	United States of America

in/s ≡ inch per second; in^2 ≡ square inch; in^3 ≡ cubic inch

Table 18.9 Nomenclature for astronomical prefixes

10^{6}	Million	Mega	M
10^{9}	Billion	Giga	G
10^{12}	Trillion	Tera	T
10^{15}	Quadrillion	Peta	P
10^{18}	Quintillion	Exa	E
10^{21}	Sextillion	Zetta	Z
10^{24}	Septillion	Yotta	Y
10^{27}	Octillion	–	–

Table 18.2 Types of units and their explanation

Derived SI – units characteristics	Development of symbols for derived SI units description	Example
Units (combined) without special symbols	These symbols are developed by combining the basic units of their constituting elements, for example, units of area, volume, velocity, etc.	m^2, m^3, m/s
Units (combined) with special symbols	–	Newton (N), Pascal (Pa), Joule (J), Watt (W), Ohm (Ω)
Units (combined) with mixed symbols	These symbols are developed by combining the specific units of their constituting elements and some basic units of measurement. If necessary, a combination of symbols which describe the properties of the measurement	Newtonmeter (N m), Pascalsecond (Pa s)

Table 18.7 Roman counting system

I ≡ 1 V ≡ 5 X ≡ 10 L ≡ 50 C ≡ 100 D ≡ 500 M ≡ 1000					
1	I	10	X	100	C
2	II	20	XX	200	CC
3	III	30	XXX	300	CCC
4	IV	40	XL	400	CD
5	V	50	L	500	D
6	VI	60	LX	600	DC
7	VII	70	LXX	700	DCC
S	VIII	80	LXXX	800	DCCC
9	IX	90	XC	900	CM
Writing direction is from left to right, and the individual values are added to get the value. The lesser values always come after the bigger values. If otherwise, the lesser values have to be subtracted from the bigger values.					
V, L, D			can be written only once.		
I, X, C			can be written up to three times.		
Examples					
1496			MCDXCVI		
673			DCLXXIII		
1891			MDCCCXCI		
1981			MCMLXXXI		

Table 18.12 Commonly used units in thermodynamic calculations

Unit[a]	Symbol	Physical relation	Relation to basic units
Kelvin	K	Thermodynamic temperature, temperature potential	–
Meter square per second	m^2/s	Conductivity	–
Joule	J	Heat energy	$1\,J = 1\,kg\,m^2/s^2$
Watt	W	Heat power	$1\,W = 1\,kg\,m^2/s^3$
Joule per kilogram	J/kg	Specific inner energy	$1\,J/kg = 1\,m^2/s^2$
Joule per Kelvin	J/K	Heat capacity	$1\,J/K = 1\,m^2/(s^2K)$
Joule per kilogram and Kelvin	J/(kg K)	Specific heat capacity	$1\,J/(kg\,K) = 1\,m^2/(s^2K)$
Watt per meter square	W/m^2	Heat flux density	$1\,W/m^2 = 1\,kg/s^3$
Watt per meter square and Kelvin	$W/(m^2K)$	Heat transfer coefficient	$1\,W/(m^2K) = 1\,kg/(s^3K)$
Watt per meter and Kelvin	W/(m K)	Heat conductance	$1\,W/(m\,K) = 1\,kg\,m/(s^3K)$
Kelvin per watt	K/W	Thermal resistance	$1\,K/W = 1\,K\,s^3/(kg\,m^2)$
Degree Celsius	°C	Temperature	1 °C = 1 K

[a] Both SI and other unit systems (commonly used ones) are presented

Table 18.8 Conversion of important units from the foot–pound–second (fps) system to the SI system

	fps (foot-pound-second)	SI (m-kg-s)
Length	1 ft = yd = 12 in	1 ft = 0.3048 m; 1 mi = 1609.34 m
Area	1 ft^2 = 144 in^2	1 ft^2 = 0.092903 m^2
Volume	1 ft^3 = 1728 in^3 = 6.22882 gal (UK) 1 gal (US) = 0.83268 gal (UK)	1 ft^3 = 0.0283169 m^3 1 bu (US) = 35.23931; 1 bbl (US) = 115.6271
Velocity	1 ft/s 1 knot = 1.150785 mi/h = 1.6877 ft/s	1 ft/s = 0.3048 m/s
Acceleration	1 ft/s^2	1 ft/s^2 = 0.3048 m/s^2
Mass	1 lb = cwt/112; 1 shtn = 2000 lb 1 slug = 32.174 lb; 1 lntn = 2240 lb	1 lb = 0.453592 kg 1 slug = 14.5939 kg
Force	1 lbf 1 pdl = 0.031081 lbf	1 lbf = 4.44822 N 1 pdl = 0.138255 N
Work	1 ft lb = 0.323832 cal_{IT} 1 btu = 252 cal_{IT} = 778.21 ft lb	1 ft lb = 1.35582 J 1 btu = 1.05506 kJ
Pressure	1 lb/ft^2 = 6.9444 × 10^{-3} lb/in^2 1 lb/in^2 = 0.068046 atm 1 atm = 29.92 in Hg = 33.90 ft water	1 lb/ft^2 = 47.88 N/m^2 1 lb/in^2 = 6894.76 N/m^2 1 atm = 1.01325 bar
Density	1 lb/ft^3 = 5.78704 × 10^{-4} lb/in^3 1 lb/gal = 6.22882 lb/ft^3	1 lb/ft^3 = 16.0185 kg/m^3 1 lb/gal = 99.7633 kg/m^3
Temperature	32°F = 0 °C, 212°F = 100 °C	1°F = 0.5556 °C
Power	1 ft lb/s = 1.8182 × 10^3 hp = 1.28505 × 10^{-3} btu/s	1 ft lb/s = 1.35582 W
Specific heat capacity	1 btu/(lb°F)	1 btu/(lb°F) = 4.1868 kJ/(kg K)
Thermal conductivity	1 btu/(ft h°F)	1 btu/(ft h°F) = 1.7306 W/(m K)
Heat transfer coefficient	1 btu/(ft^2 h°F)	1 btu/(ft^2 h°F) = 5.6778 W/(m^2 K)
Viscosity, kinematic	1 ft^2/s	1 ft^2/s = 0.092903 m^2/s
Viscosity, dynamic	1 lb/(ft s)	1 lb/(ft s) = 1.48816 kg/(m s)

Table 18.11 Units commonly used for calculation in mechanics

Unit[a]	Symbol	Physical meaning	Relation to basic units
Kilogram	kg	Mass	–
Kilogram per second	kg/s	Mass flow	–
Kilogram meter square	kg m^2	Mass moment	–
Kilogram per cubic meter	kg/m^3	Density	–
Cubic meter per kilogram	m^3/kg	Specific volume	–
Square meter per second	m^2/s	Kinematic viscosity	–
Newton	N	Force	1 N = 1 kg m/s^2
Pascal	Pa	Pressure	1 Pa = 1 kg/(m s^2)
Joule	J	Work, energy	1 J = 1 kg m^2/s^2
Watt	W	Power	1 W = 1 kg m^2/s^3
Newtonmeter	N m	Moment	1 J Nm = 1 kg m^2/s^2
Newton per square meter	N/m^2	Pressure	1 N/m^2 = 1 kg/(m s^2)
Pascalsecond	Pa s	Dynamic viscosity	1 Pa s = 1 kg/(m s)
Joule per cubic meter	J/m^3	Energy density	1 J/m^3 = 1 kg/(m s^2)
Ton	t	Mass	1 t = 1000 kg
Gram	g	Mass	1 g = 1/1000 kg

[a] Both SI and other unit systems (commonly used ones) are presented

Table 18.10 Space and time units

Unit[a]	Symbol	Physical relation and technical value	Description through the basic units
Meter	m	Length	–
Second	s	Time	–
Square meter	m^2	Surface	–
Cubic meter	m^3	Volume	–
Meter per second	m/s	Velocity	–
Meter per second square	m/s^2	Acceleration	–
Meter cube per second	m^3/s	Volume flow	–
Radian	rad	Angle	$1\,\text{rad} = 1\,\text{m/m}$
Steradian	sr	Three-dimensional angle	$1\,\text{sr} = 1\,\text{m}^2/\text{m}^2$
Hertz	Hz	Frequency	$1\,\text{Hz} = 1\,/\text{s}$
Radian per second	rad/s	Angular velocity	–
Radian per second squared	rad/s^2	Angular acceleration	–
Liter	l	Volume	$1\,\text{l} = 10^{-3}\,\text{m}^3$
Degree	°	Angle	$1° = \pi/180\,\text{rad}$
Minute	′	Angle	$1' = \pi/(180\times60)\,\text{rad}$
Second	″	Angle	$1'' = \pi/(180\times60\times60)\,\text{rad}$
Minute	min	Time	$1\,\text{min} = 60\,\text{s}$
Hour	h	Time	$1\,\text{h} = 60\,\text{min} = 3600\,\text{s}$
1 per second	1/s	Frequency	$1/\text{min} = (1/60)\,1/\text{s}$
			$1/\text{h} = (1/60)\,1/\text{min} = (1/60)^2\,1/\text{s}$

[a] Both SI and other unit systems (commonly used ones) are presented

Table 18.13 Commonly used units in electric current calculations

Unit[a]	Symbol	Physical relation	Relation to basic units
Ampère	A	Electric current	–
Ampère per square meter	A/m^2	Electric current density	–
Ampère per meter	A/m	Electric current distribution	–
Coulomb	C	Electric charge	$1\,\text{C} = 1\,\text{A s}$
Watt	W	Electric power	$1\,\text{W} = 1\,\text{kg m}^2/\text{s}^3$
Volt	V	Electric potential	$1\,\text{V} = 1\,\text{kg m}^2/(\text{A s}^3)$
Farad	F	Electric capacity	$1\,\text{F} = 1\,\text{A}^2\text{s}^4/(\text{kg m}^2)$
Ohm	Ω	Electric resistance	$1\,\Omega = 1\,\text{kg m}^2/(\text{A}^2\text{s}^3)$
Siemens	S	Electric conductance	$1\,\text{S} = 1\,\text{A}^2\text{s}^3/(\text{kg m}^2)$
Coulomb per square meter	C/m^2	Electric flux density	$1\,\text{C/m}^2 = 1\,\text{A s/m}^2$
Volt per meter	V/m	Electric field intensity	$1\,\text{V/m} = 1\,\text{kg m}^3/(\text{A s}^3)$
Farad per meter	F/m	Dielectric constant, electric field constant	$1\,\text{F/m} = 1\,\text{A}^2\text{s}^4/(\text{kg m}^3)$
Ohmmeter	Ω m	Specific electric resistance	$1\,\Omega\,\text{m} = 1\,\text{kg m}^3/(\text{A}^2\text{s}^3)$
Siemens per meter	S/m	Specific electric conductivity	$1\,\text{S/m} = 1\,\text{A}^2\text{s}^3/(\text{kg m}^3)$

[a] Both SI and other unit systems (commonly used ones) are presented

Table 18.14 Commonly used units in magnetic calculations

Unit[a]	Symbol	Physical relation	Relation to basic units
Ampère	A	Magnetic potential	–
Ampère per meter	A/m	Magnetic intensity	–
Weber	Wb	Magnetic flux	$1\,\mathrm{Wb} = 1\,\mathrm{kg\,m^2/(A\,s^2)}$
Tesla	T	Magnetic induction	$1\,\mathrm{T} = 1\,\mathrm{kg/(A\,s^2)}$
Henry	H	Inductivity, magnetic conductance	$1\,\mathrm{H} = 1\,\mathrm{kg\,m^2/(A^2s^2)}$
Henry per meter	H/m	Permeability, magnetic field constant	$1\,\mathrm{H/m} = 1\,\mathrm{kg\,m/(A^2s^2)}$
1/Henry	1/H	Magnetic resistance	$1\,/\mathrm{H} = 1\,\mathrm{A^2s^2/(kg\,m^2)}$

[a] Both SI and other unit systems (commonly used ones) are presented

Table 18.15 Commonly used units in luminosity calculations

Unit[a]	Symbol	Physical relation	Relation to basic units
Candela	cd	Luminosity	–
Candela per square meter	$\mathrm{cd/m^2}$	Light density	–
Lumen	lm	Luminous flux	$1\,\mathrm{lm} = 1\,\mathrm{cd\,sr}$
Lux	lx	Illumination	$1\,\mathrm{lx} = 1\,\mathrm{cd\,sr/m^2}$
Lumen second	lm s	Luminous energy	$1\,\mathrm{lm\,s} = 1\,\mathrm{cd\,sr\,s}$
Lux second	lx s	Exposure	$1\,\mathrm{lx\,s} = 1\,\mathrm{cd\,sr\,s/m^2}$

[a] Both SI and other unit systems (commonly used ones) are presented

Table 18.16 Physical constants

Gravitational constant	G	$6.672 \times 10^{-11}\,\mathrm{N\,m^2/kg^2}$
Acceleration due to gravity	g_n	$9.8067\,\mathrm{m/s^2}$
Gas constant	R	$8314.41\,\mathrm{J/(kmol\,K)}$
Molar volume	V_m	$22.414\,\mathrm{m^3/kmol}$ at 1.01325 bar, 0 °C
Avogadro constant	N_A	$6.0221 \times 10^{26}\,\mathrm{kmol^{-1}}$
Loschmidt constant	N_L	$2.6868 \times 10^{25}\,\mathrm{m^{-3}}$
Boltzmann constant	k_B	$1.3807 \times 10^{-23}\,\mathrm{J/K}$
Electric field constant	ε_0	$8.8542 \times 10^{-12}\,\mathrm{F/m}$
Magnetic field constant	μ_0	$1.2566 \times 10^{-6}\,\mathrm{H/m}$
Electric charge	e	$1.6022 \times 10^{-19}\,\mathrm{C}$
Faraday constant	F	$9.6485 \times 10^{7}\,\mathrm{C/kmol}$
Speed of light in vacuum	c	$2.9979 \times 10^{8}\,\mathrm{m/s}$
Planck constant	h	$6.626 \times 10^{-34}\,\mathrm{Js}$
Wave drag in vacuum	Γ	$376.731\,\Omega$
Stefan–Boltzmann radiation constant	σ	$5.6703 \times 10^{-8}\,\mathrm{W/(m^2\,K^4)}$
Planck radiation constants	c_1	$3.741 \times 10^{-16}\,\mathrm{W\,m^2}$
	c_2	$1.438 \times 10^{-2}\,\mathrm{m\,K}$
Wien constant	K	$2.8978 \times 10^{-3}\,\mathrm{m\,K}$
Rydberg constant	R	$1.09737 \times 10^{7}\,\mathrm{m^{-1}}$
Static weight of electrons	m_e	$9.109 \times 10^{-31}\,\mathrm{kg}$
Radius of an electron	r_e	$2.8178 \times 10^{-15}\,\mathrm{m}$
Atomic mass unit	amu	$1.6606 \times 10^{-27}\,\mathrm{kg}$

Table 18.17a,b Basic definitions (a) and constants (b) of nuclear physics

(a) Definitions

Nomenclature	Definition	Unit	Formula	Remarks
Atomic mass	The relative mass of nucleus of C_{12} is taken as unit weight	amu $= 1.6603\times10^{-27}$ kg	amu $= m_{C_{12}}/M_{C_{12}}$ $= 1/N_A$	–
Atomic number	–	–	$N = \frac{m}{N} N_A$	$N = \frac{10^{-3}\,\text{kg}}{226\,\text{kg/kmol}} 6.0221\times10^{26}\,1/\text{kmol}$ $= 2.665\times10^{21}$
Half-life period	Time required for decay of half of the original atomic mass	s, min, d, y	$T_{1/2} = \ln 2/\lambda$	${}^{238}_{92}\text{U}: T_{1/2} = 4.5\times10^{9}$ a, γ and α radiation ${}^{3}_{1}\text{H}: T_{1/2} = 2.3$ a, β radiation
Atomic energy	The energy required to move an electron through a voltage of 1 V	Electron volt $1\,\text{eV} = 1.6022\times10^{-19}$ J	$W = eU$	Nuclear fission of uranium
Mass of electron	Based on Einstein's theory of energy and mass	$1\,\text{MeV} \approx 1.728\times10^{-33}$ g	$m = \frac{E}{c_0^2}$; $m = \frac{m_0}{\sqrt{1-(c/c_0)^2}}$	$m \cong \frac{E}{c_0^2} = \frac{1.6022\times10^{-19}\,\text{J}}{(2.998\times10^{8}\,\text{m/s})^2}$ $= 1.782\times10^{-33}$ g
Absorbed energy	Amount of absorbed radiation energy per unit mass of a material	Gray $1\,\text{Gy} = 1\,\text{J/kg}$	$D = W/m$	–
Equivalent absorption	Measurement of biological radiation effect that is emitted from a γ ray of 10^{-2} Sv and is absorbed in the human body	Sievert $1\,\text{Sv} = 1\,\text{J}$	$H = DQ_F$	X-ray, β, ${}^{0}_{-1}\text{e}$, ${}^{0}_{+1}\text{e}$ radiation Quality factor Q_F Thermal neutrons 3 Alpha radiation 10
Activity	Measurement of intensity of a radioactive ray. Count of decay per unit of time	Bequerel $1\,\text{Bq} = 1/\text{s}$	–	–
Atomic cross section	Measurement of yield in a nuclear reaction. Virtual cross section of radiating atom	m^2	σ	Fission σ_f Absorption σ_a Scattering σ_s

Explanation of the table entries

${}^{A}_{Z}N : N =$ nuclear weight , $Z =$ neutron count , $A =$ atomic mass , $N = A - Z$

Fission of uranium:

$${}^{235}_{92}\text{U} + {}^{1}_{0}\text{n} \rightarrow {}^{89}_{36}\text{Kr} + {}^{144}_{56}\text{Ba} + 3\,{}^{1}_{0}\text{n} + 200\,\text{MeV}\,.$$

Energy emitted by fission of 1 g of uranium:

$$Q = \frac{m}{M} N_A W = \frac{1\,\text{g}\,6.0221\times10^{23}\,(1/\text{mol})\,200\,\text{MeV}\,1.6022\times10^{-13}\,\text{Ws/MeV}}{235\,\text{g/mol}\,3600\,\text{s/h}} = 22\,810\,\text{kW h}\,.$$

Isotopes are different types of nucleus of the same chemical elements. There nuclei have the same proton count but different atomic weights. For example:

${}^{12}_{6}\text{C}$, ${}^{13}_{6}\text{C}$, ${}^{14}_{6}\text{C}$ and ${}^{234}_{92}\text{U}$, ${}^{235}_{92}\text{U}$, ${}^{238}_{92}\text{U}$.

Types of radiation:

α : ${}^{4}_{2}\alpha$ nucleus of helium atom

β : Electrons or positrons

γ : Short-wavelength, energy-rich penetrative electromagnetic waves, which changes either the nuclear charge or the atomic mass of the radiating nucleus

Neutrons ${}^{1}_{0}\text{n}$, positrons ${}^{0}_{+1}\text{e}$, electrons ${}^{0}_{-1}\text{e}$

Table 18.17 (continued)

(b) Constants	
Velocity of light	$c_0 = 2.998 \times 10^8$ m/s
Static weight of electron	$m_{e0} = 9.110 \times 10^{-31}$ kg
Avogadro constant	$N_A = 6.0221 \times 10^{26}$ kmol^{-1}
Static weight of proton	$m_{p0} = 1.6606 \times 10^{-27}$ kg
Electric charge of an electron	$e = 1.6022 \times 10^{-19}$ C
Static weight of neutron	$m_{n0} = 1.675 \times 10^{-27}$ kg

Table 18.18 Basic units for light calculations

Measure	Definition	Unit	Mathematical relation	Remarks
Luminous flux	Amount of rays emanating from a light source in all directions	Lumen (lm)	$\phi = \mathrm{d}Q/\mathrm{d}t$	Light energy emitted per unit time
Light intensity	Intensity of light rays inside the elementary space angle[a]. 1 cd is the radiation emitted by a black body perpendicular to its surface $[1/(6\times10^6)\,\mathrm{m}^2]$ at 2042.5 K and 1.0133 bar	Candela (cd) cd = m/sr SI basic units	$I = \mathrm{d}\phi/\mathrm{d}\omega$	Stearin candle ≈ 1 cd Bulb (40 W) ≈ 35 cd
Luminance	Ratio of light emitted at the source to the light received at a particular surface	Lux (lx) $\mathrm{lx} = \mathrm{lm/m}^2$	$E = \phi/A = I\omega/A = I/r^2$	Summer sunlight 10^5 lx Living room 10–150 lx Full-moon night 0.2 lx No-moon night 3×10^{-4} lx
Light density	Light intensity per unit of illuminated surface	$\mathrm{cd/m}^2$	–	Full moon 2500 $\mathrm{cd/m}^2$ Candle 7500 $\mathrm{cd/m}^2$ Bulb 2×10^7 $\mathrm{cd/m}^2$ Sun 2.2×10^9 $\mathrm{cd/m}^2$
Light yield	Luminous flux per unit of electric power	lm/W	$\eta = \phi/P$	Tube light 44 lm/W Bulb (1000 W) 19 lm/W Bulb (40 W) 11 lm/W
Light range	Product of luminous flux and the duration of radiation	lm s	$Q = \int \phi\,\mathrm{d}t$	

[a] The unit steradian (sr) is valid for the space angles. Steradian is the ratio of the surface of a section of a sphere to the square of its radius. If α is the opening angle of a section of a sphere with an area of $A = 2\pi rh$, its height is given by $h = r[1-\cos(\alpha/2)] = 2r\sin^2(\alpha/4)$. The space angle is defined as $\omega = A/r^2 = 4\pi\sin^2(\alpha/4)$.
Special cases: $\omega = 1$ sr for $\alpha = 4\arcsin(0.5/\sqrt{\pi}) = 65.54°$. For a sphere $\alpha = 360°$ and $\omega = 4\pi$ sr. For $\alpha = 120°$ is $\omega = \pi$ sr

Table 18.20 Approximated acoustic measures

Noise source	$\eta = P_{\mathrm{acu}}/P_{\mathrm{mech}}$[a]	Noise source	$\eta = P_{\mathrm{acu}}/P_{\mathrm{mech}}$
Siren		Diesel engine	
with funnel	$3–7\times10^{-1}$	Cylinder at 800 rpm	4.00×10^{-7}
without funnel	1.00×10^{-2}	Cylinder at 3000 rpm	5.00×10^{-6}
Rotating disk with ultrasonic velocity	2.50×10^{-1}	Exhaust with turbocharger	1.00×10^{-4}
Schmidt tube	2.00×10^{-2}	Electromagnetic loudspeaker	5.00×10^{-2}
Ventilator optimal point		Electric motor	
$\Delta p < 2.5$ mbar[a]	1.00×10^{-6}	Special low noise	2.00×10^{-8}
$\Delta p > 2.5$ mbar	$4\times10^{-8}\Delta p$	Normal	1.00×10^{-6}
Escape noise		Machines	
Ma < 0.3[a]	$8(1\times10^{-6}–1\times10^{-5})\,(\mathrm{Ma})^3$	Special class	3.00×10^{-8}
0.4 < Ma < 1.0	$1.0\times10^{-4}\,(\mathrm{Ma})^5$	Quiet machines	2.00×10^{-7}
Ma > 2.0	2.00×10^{-3}	Normal	2.00×10^{-7}
		Bad	3.00×10^{-6}
Motor bike 250 cm^3 capacity		Airplane propeller	
without damper	1.00×10^{-3}	2700 kW in test stand	5.00×10^{-3}
Organ	$1\times10^{-3}–1\times10^{-2}$	Human voice	5.00×10^{-4}
Small gas turbine		Ship propeller	
Suction	1.00×10^{-4}	Without cavitation	$1\times10^{-9}–1\times10^{-8}$
Exhaust	1.00×10^{-5}	With cavitation	1.00×10^{-7}
Housing	1.00×10^{-6}		

[a] Δp = compression, P_{acu} = acoustic power, Ma = mach number, P_{mech} = mechanical power

Table 18.19 Important terms in acoustic technology

Term	Definition	Mathematical formula	Unit	Remarks
Velocity of sound	Solids			
	Longitudinal waves in big bodies	$c_L = \sqrt{\frac{2G(1-\upsilon)}{\varsigma(1-2\upsilon)}}$	m/s	1000–5000 m/s
	Transversal waves in big bodies	$c_T = \sqrt{\frac{G}{\varsigma}}$		500–3500 m/s
	Bending waves in bars	$c_D = \sqrt{\frac{E}{\varsigma}}$		Rubber 50 m/s
	Liquids	$c = \sqrt{\frac{\chi}{\varsigma}}$		Water 1485 m/s
	Gases	$c = \sqrt{xRT}$		Air: 331 m/s at 1 bar, 0 °C Hydrogen: 1280 m/s at 1 bar, 0 °C
Transverse vibrational speed of sound	Speed of vibrational part	$u = a_0\omega = 2\pi a_0 f$	m/s	5×10^{-8}–1 m/s
Sound pressure	Static and dynamic pressure in elastic media	p	N/m^2	10^{-2}–10^2 N/m^2 Normal audio waves $= 2\times10^{-5}$ N/m^2 Piano $= 0.2$ N/m^2 Siren $= 35$ N/m^2
Sound power	Sound energy that passes per unit time through a particular surface area	P	W	1×10^{-12}–1×10^5 W Audio waves $= 1\times10^{-12}$ W Voice $\approx 1\times10^{-3}$ W Siren $\approx 1\times10^3$ W
Sound intensity	Sound power per unit area	$I = P/A = p^2/cp$	W/m^2	1×10^{-11}–1×10^3 W/m^2 Audio waves $= 1\times10^{-12}$ W/m^2
Sound level	Logarithmic scale for sound pressure	$L = 10\lg(P/P_0)$		0–140 dB
		$= 10\lg(I/I_0)$	Bel	$P_0 = 1\times10^{-12}$ W $I_0 = 1\times10^{-12}$ W/m^2
		$= 20\lg(p/p_0)$	B, dB	$P_0 = 2\times10^{-5}$ N/m^2
Sound volume	Measurement of subjective perception of the sound intensity for the ear	$\Lambda = 10\lg(I/I_0)$	phon	0–130 phon Audio wave 0 phon Entertainment 50 phon Pain level 130 phon
Sound absorption factor	Measurement of loss of sound energy in heat due to friction	$\alpha = (P_a - P_f)/P_f$	1	For 500 Hz
	Index a and r indicate absorption and reflection, respectively	$= (p_a^2 - p_r^2)/p_r^2$		Concrete 0.01 Glass 0.03 Foam 0.36
Sound damping	Logarithmic measurement for sound damping by a wall, Index 1 indicates energy before reflection and 2 indicates energy after reflection	$R = 10\lg(I_1/I_2)$	dB	1 mm-thick steel plate 29 dB
Acoustic coefficient	Ratio of sound to mechanical power	$\eta = P_{acu}/P_{mech}$	1	See Table 18.20

a_0 Amplitude, A surface area, P power, x isentropic exponent, f frequency, E modulus of elasticity, R gas constant, υ Poisson ratio, G modulus of rigidity, T absolute temperature, ς density, χ compressibility

Acknowledgements

B.6 Design of Machine Elements

by Oleg P. Lelikov

The author would like to thank Dr. Juri Postnikov for his great collaboration and efforts in the preparation of this chapter.

B.7 Manufacturing Engineering

by Thomas Böllinghaus, Gerry Byrne, Boris Ilich Cherpakov (deceased), Edward Chlebus, Carl E. Cross, Berend Denkena, Ulrich Dilthey, Takeshi Hatsuzawa, Klaus Herfurth, Horst Herold (deceased), Andrew Kaldos, Thomas Kannengiesser, Michail Karpenko, Bernhard Karpuschewski, Manuel Marya, Surendar K. Marya, Klaus-Jürgen Matthes, Klaus Middeldorf, Joao Fernando G. Oliveira, Jörg Pieschel, Didier M. Priem, Frank Riedel, Markus Schleser, A. Erman Tekkaya, Marcel Todtermuschke, Anatole Vereschaka, Detlef von Hofe, Nikolaus Wagner, Johannes Wodara, Klaus Woeste

The author would like to express his thanks to all his colleagues from leading welding institutions and departments for their deep interest and active cooperation in revising the section “Joining Technology”, and to representatives of the Deutscher Verband für Schweißen und verwandte Verfahren e.V. (German Association for Welding and Related Processes) in Düsseldorf for writing the essential analytical introduction.

In particular, I owe thanks to my colleague Dr.-Ing. J. Pieschel from the Institute of Joining and Beam Technology at the Otto von Guericke University in Magdeburg for his careful editorial preparation of the manuscript.

About the Authors

Gritt Ahrens

Daimler AG X944
Systems Integration and Comfort Electric
Sindelfingen, Germany
gritt.ahrens@daimler.com

Chapter B.13, Sect. 13.2

Gritt Ahrens received the PhD degree from the Department of Engineering Design and Methodology at the Technical University of Berlin. She developed a method for capture and management of product requirements and substantiated its practical applicability. Since 2001 she has been developing and optimizing various processes in the context of car development at Mercedes-Benz Cars Development (Daimler AG).

Seddik Bacha

Université Joseph Fourier
Grénoble Electrical Engineering
Laboratory
Grenoble, France
seddik.bacha@g2elab.inpg.fr

Chapter C.17, Sect. 17.4

Professor Seddik Bacha received the Engineering and Magister degree from École Nationale Polytechnique of Algiers in 1982 and 1990, and the PhD and HDR degrees in 1993 and 1998 from Polytechnic Institute of Grenoble, France, respectively. He is presently the manager of the Power System Group in the Grénoble Electrical Engineering Laboratory and Professor at the Université Joseph Fourier, Grenoble. His interests are power electronics systems, power quality, and renewable energy.

Stanley Baksi

TRW Automotive, Lucas Varity GmbH
Koblenz, Germany
stanley.baksi@trw.com

Chapter C.18

Stanley Baksi received the BA degree in Engineering in 2000 from Visvesvaraya National Institute of Technology and the MSc in Mechanical Engineering from California State University, Long Beach. He completed his doctoral research on rapid bone reconstruction using reverse engineering at Otto-von-Guericke University, Magdeburg, in 2007. Since January 2008 he has been a Project Engineer with TRW Automotive providing computer-aided engineering support for the development of automotive brakes.

Thomas Böllinghaus

Federal Institute for Materials Research and Testing (BAM)
Berlin, Germany
thomas.boellinghaus@bam.de

Chapter B.7, Sect. 7.4.8

Professor Thomas Böllinghaus received the Dr.-Ing. degree in 1995 from the Helmut-Schmidt-University, Hamburg, and qualified there as a Professor for Materials Science and Welding Technology in 1999. He then became head of Division V.5 Safety of Joined Components at the Federal Institute for Materials Research and Testing (BAM), Berlin. Since 2003 he has been Vice President of BAM and became Honorary Professor for Failure Analysis and Failure Prevention in the Faculty for Mechanical Engineering at the Otto-von-Guericke University, Magdeburg in 2008. His research interests focus on hydrogen-assisted cracking of structural metallic materials, numerical simulation of hydrogen transport and cracking, hot cracking phenomena in welds, and failure analysis and lifecycle evaluations of joined components.

Alois Breiing

Eidgenössische Technische Hochschule
Zürich (ETH)
Institut für mechanische Systeme (IMES)
Zentrum für Produkt-Entwicklung (ZPE)
Zurich, Switzerland
breiing@imes.mavt.ethz.ch

Chapter B.9, Sect. 9.6

Alois Breiing is a retired Professor (Titularprofessor) at ETH Zürich. He was a Lecturer (Privatdozent) at the Institute of Mechanical Systems. He has 23 years of experience as an aerospace engineer in the Development and Design Department of the aerospace company Dornier. Beginning in 1985 he worked at the Institute of Design and Construction Methods of ETH Zurich (now the Institute of Mechanical Systems), starting as a Senior Researcher and Section Leader. He received a doctor's degree in 1991. He gave lectures in machine design. The main topics of his research work were evaluation and decision processes.

Eugeniusz Budny

Institute of Mechanized Construction and Rock Mining
Warsaw, Poland
e.budny@imbigs.org.pl

Chapter B.14, Sect. 14.1

Dr. Eugeniusz Budny is a Professor of Mechanical Engineering and Emeritus Director of the Institute of Mechanized Construction and Rock Mining (IMBiGS) in Warsaw, Poland. He began his career as an automotive industry product designer and then moved to the construction equipment manufacturing industry, specializing in the design of single-bucket excavators, hydraulic drives, and hydraulic engineering machine controls. Since 1977 he has been engaged in the mechanization of construction work. Professor Budny served as President of the International Association for Automation and Robotics in Construction (IAARC) and has been Chair of ISO/TC 195 and the Polish Committee for Standardization in the field of building construction machinery since 2005.

Gerry Byrne

University College Dublin
School of Electrical, Electronic and Mechanical Engineering
Belfield, Dublin 4, Ireland
gerald.byrne@ucd.ie

Chapter B.7, Sects. 7.3.1, 7.3.2

Gerry Byrne F.R.Eng. is the Professor of Mechanical Engineering and Director of the Advanced Manufacturing Science Research Centre at University College Dublin (UCD), Ireland. He has over 30 years of experience with high-precision manufacturing processes, surface engineering, and aspects of surface microstructuring. He is an expert in the field of cutting processes and has published extensively. He is a Fellow of the International Academy for Production Engineering (CIRP) and a Member of the Council of that Academy. He is an International Fellow of the Royal Academy of Engineering, UK, and of the Society of Manufacturing Engineers, USA.

Edward Chlebus

Wrocław University of Technology
Centre for Advanced Manufacturing Technologies
Wrocław, Poland
edward.chlebus@pwr.wroc.pl

Chapter B.7, Sect. 7.5

Professor Edward Chlebus is Director of the Institute of Production Engineering and Automation at Wrocław University of Technology, Poland, and the Head of the Centre for Advanced Manufacturing Technologies (CAMT). His main research areas are design methodology and CA*x* and PDM/PLM systems, rapid prototyping, reverse engineering, modeling, optimization, and simulation of production processes. He is a Contractor for six International Projects in FP6, Leonardo da Vinci, and ERA Net. He is also a Graduate of the University of Connecticut Business School.

Mirosław Chłosta

IMBiGS – Institute for Mechanized Construction and Rock Mining (IMBiGS)
Warsaw, Poland
m.chlosta@imbigs.org.pl

Chapter B.14, Sect. 14.1

Miroslaw Chlosta received the M.S. degree from Warsaw Technical University in 1980. In that year he began work at IMBiGS as a Research Associate. He received the PhD degree from IMBiGS in 2003 and was an Assistant there from 2003 onwards. His research interests are mainly in CAD and robotics in the building industry.

Norge I. Coello Machado

Universidad Central "Marta Abreu" de Las Villas
Faculty of Mechanical Engineering
Santa Clara, Cuba
norgec@uclv.edu.cu

Chapter B.8, Sect. 8.1

Norge Coello Machado received the Dipl.-Ing. degree from the Universidad of Santa Clara in 1982 and the Dr.-Ing. degree from the University of Magdeburg, Germany, in 1989. From 2003 he was Temporary Professor at the University of Magdeburg, Germany. His research interests are mainly in the use of statistical methods in quality management, quality engineering, and measurement technology.

Francesco Costanzo

Alenia Aeronautica
Procurement/Sourcing Management
Department
Pomigliano (NA), Italy
fcostanzo@inwind.it

Chapter B.15, Sect. 15.8

Graduated in Aeronautical Engineering in 1977 in Naples, Italy, Francesco Costanzo has a long experience in design and industrialization processes at Alenia Aeronautica (formerly Aeritalia) until 1983. He was then in charge of process and information management with responsibility for CAE/CAD/CAM until 2000. Later he was responsible for the information systems of the A380 program in Alenia and has been head of Procurement Direction/Sourcing Management as Supplier Value Creation Manager, with focus on processes and information for Alenia's supply chain. Currently Costanzo is a Senior Consultant in processes for procurement and the digitization of supply chains.

Carl E. Cross

Federal Institute for Materials Research
and Testing (BAM)
Joining Technology
Berlin, Germany
carl-edward.cross@bam.de

Chapter B.7, Sect. 7.4.8

Carl Cross received the B.Sc., MSc, and PhD degrees in Metallurgical Engineering from the Colorado School of Mines. He has worked in welding research for over 30 years in both industry and academia, specializing in solidification defects and weldability testing of nonferrous alloys. Currently he is a Senior Scientist at BAM (the German Federal Institute for Materials Research and Testing), investigating the critical conditions needed to initiate and grow hot cracks.

Frank Dammel

Technical University
Department of Mechanical Engineering/
Institute of Technical Thermodynamics
Darmstadt, Germany
dammel@ttd.tu-darmstadt.de

Chapter B.4, Sect. 4.3

Frank Dammel is a postdoctoral scientific assistant (Akad. Oberrat) at the Institute of Technical Thermodynamics at the Technische Universitaet Darmstadt. His main field of research is phase-change phenomena with an emphasis on numerical simulations.

Jaime De La Ree

Virginia Tech
Electrical and Computer Engineering
Department
Blacksburg, VA, USA
jreelope@vt.edu

Chapter C.17, Sect. 17.3

Jaime De La Ree received the PhD degree from the University of Pittsburgh, Pittsburgh, PA, USA in 1984. He worked at the ECE Department at Virginia Tech and became Assistant Department Head in 2004. His teaching and research interest is in the areas of electric machinery and power systems protection. He is the recipient of several Outstanding Teaching Awards from both the University of Pittsburgh and Virginia Tech.

Torsten Dellmann

RWTH Aachen University
Department of Rail Vehicles and
Materials-Handling Technology
Aachen, Germany
torsten.dellmann@ifs.rwth-aachen.de

Chapter B.13, Sect. 13.1

Dr. Torsten Dellmann is a Professor of Rail Vehicles and Materials-Handling Technology at RWTH Aachen University, Germany. He obtained the Dr. degree in materials-handling technology from RWTH Aachen in 1986. Prior to joining the RWTH Aachen University as a professor he worked as Managing Director for Knorr-Bremse MRP Systems for Rail Vehicles. His current research is focused on innovative braking systems as well as innovative undercarriages and guiding technology for rail vehicles.

Berend Denkena

Leibniz University Hannover
IFW – Institute of Production Engineering and Machine Tools
Garbsen, Germany
denkena@ifw.uni-hannover.de

Chapter B.7, Sects. 7.3.1, 7.3.2, 7.3.3

Professor Denkena earned the PhD degree at Leibniz University Hanover, Germany, in 1992. He then became Manager Standards Engineering at Thyssen Production Systems in Auburn Hills, USA (1993–1995). Back in Germany he served as Manager Mechanical Development at Thyssen Hüller Hille in Ludwigsburg for 1 year before he went to Bielefeld as Manager Engineering and Development for Gildemeister Turning Machines. Since 2001 he has been a Professor at the Leibniz University Hannover and the Head of the Institute of Production Engineering and Machine Tools.

Ludger Deters

Otto-von-Guericke University
Institute of Machine Design
Magdeburg, Germany
ludger.deters@ovgu.de

Chapter B.5

Ludger Deters is Professor of Machine Elements and Tribology at the Otto-von-Guericke University of Magdeburg. He received the PhD degree from the Mechanical Engineering Department of the University of Clausthal in 1983. From 1983 to 1994 he worked in executive positions in different development and design departments of the machine-building industry. His current main research activities include tribology, slider and rolling bearings, wheel/rail contacts, and friction and wear of combustion engine parts.

Ulrich Dilthey

RWTH Aachen University
ISF Welding and Joining Institute
Aachen, Germany
di@isf.rwth-aachen.de

Chapter B.7, Sects. 7.4.3, 7.4.4, 7.4.7

Professor Dr.-Ing. Ulrich Dilthey holds degrees in Mechanical Engineering/Production Engineering and a doctorate from RWTH Aachen University, where he was research assistant in the ISF, the Welding and Joining Institute of the RWTH Aachen. He has many years of working experience in leading positions of worldwide operating companies in the fields of mechanization, automation, and robotics. From 1989 to 2007 he was Professor of Welding Manufacturing Processes and Director of the ISF. In July 2008 he was elected the President of the International Institute of Welding (IIW).

Frank Engelmann

University of Applied Sciences Jena
Department of Industrial Engineering
Jena, Germany
frank.engelmann@fh-jena.de

Chapter B.9, Sects. 9.1–9.4

Frank Engelmann studied mechanical engineering at the Engineering Department at the University of Magdeburg. After he finished his studies he worked as Managing Director for a production business while also working at the University of Magdeburg, where he received the PhD degree. His research activities focus on secondary explosion protection and on biomedical technology. In October 2007 Frank Engelmann joined the University of Applied Sciences in Jena, Germany, as a full professor.

Ramin S. Esfandiari

California State University
Department of Mechanical & Aerospace Engineering
Long Beach, CA, USA
esfandi@csulb.edu

Chapter A.1

Dr. Esfandiari is Professor of Mechanical and Aerospace Engineering at the California State University, Long Beach. He received the PhD degree from the University of California at Santa Barbara in Applied Mathematics with emphasis on optimal control theory. He has published numerous research papers in refereed journals in the areas of distributed control and numerical methods. He is the author/coauthor of three textbooks and author of a MATLAB manual.

Jens Freudenberger

Leibniz-Institute for Solid State and Materials Research Dresden
Department for Metal Physics
Dresden, Germany
j.freudenberger@ifw-dresden.de

Chapter B.3, Sect. 3.1

Dr. Jens Freudenberger is Head of the Department for Metal Physics and Supervisor of the Pulsed High-Magnetic-Field Laboratory at the IFW, Dresden. His current research is dedicated to plastic deformation and metal forming. He is an expert in materials science and solid-state physics with particular interest in materials such as superconductors, high-strength nanostructured conductors, and magnetic materials.

Stefan Gies

RWTH Aachen University
Institute for Automotive Engineering
Aachen, Germany
gies@ika.rwth-aachen.de

Chapter B.13, Sect. 13.1

Professor Dr.-Ing. Stefan Gies received the doctor degree in 1993 from Aachen University at the Institute for Automotive Engineering (IKA), where he was employed as a Scientific Research Engineer between 1989 and 1993 and Chief Engineer from 1993 until 1994. From 1994 to 2000, he was with Ford AG and changed in 2000 to Audi AG, where he was Manager of vehicle dynamics and driving comfort with steering systems, suspension, wheels/tires, chassis controls. Since 2007, he has been a Professor at RWTH Aachen University and the head of IKA.

Joachim Göllner

Otto-von-Guericke University
Institute of Materials and Joining Technology Department of Mechanical Engineering
Magdeburg, Germany
joachim.goellner@mb.uni-magdeburg.de

Chapter B.3, Sect. 3.6

Dr. Joachim Göllner is a Lecturer for materials and corrosion. He habilitated from Otto-von-Guericke University Magdeburg, Germany, and is the Head of a research group. His research interests are in electrochemical noise and the development of corrosion test methods. He has authored more than 150 publications and is a member of various professional societies.

Timothy Gutowski

Massachusetts Institute of Technology
Department of Mechanical Engineering
Cambridge, MA, USA
gutowski@mit.edu

Chapter B.9, Sect. 9.5

Timothy Gutowski is a Professor of Mechanical Engineering at the Massachusetts Institute of Technology. He received the PhD degree in Mechanical Engineering from MIT, the M.S. degree in Theoretical and Applied Mechanics from the University of Illinois, and the B.Sc. degree in Mathematics from the University of Wisconsin. His current research interests focus on the relationship between manufacturing and the environment. He was Director of MIT's Laboratory for Manufacturing and Productivity for 10 years and Associate Department Head of Mechanical Engineering from 2001 to 2005.

Takeshi Hatsuzawa

Tokyo Institute of Technology
Precision and Intelligence Laboratory
Yokohama, Japan
hat@pi.titech.ac.jp

Chapter B.7, Sect. 7.6

Takeshi Hatsuzawa received the Dr. Eng. degree from Tokyo Institute of Technology in 1993. After 12 years at the National Research Laboratory of Metrology, he became Associate Professor in the Tokyo Institute of Technology in 1995, and full professor in 2002. His current research is focused on MEMS and NEMS applications in biochemistry using biotechnology.

Markus Hecht

Berlin University of Technology
Institute of Land and Sea Transport Systems Department of Rail Vehicles
Berlin, Germany
markus.hecht@tu-Berlin.de

Chapter B.13, Sect. 13.3

Marskus Hecht obtained his industrial experience at the Swiss Locomotive and Machine Works Winterthur, working on radially steered bogies and low-noise equipment. Since 1997 he has been Professor for Rail Vehicles at Berlin University of Technology (TU). His research fields are wheel–rail interaction, vehicle design, vehicle acoustics, and safety. He works in several EU projects and is a member of various advisory boards. Since 2005 he has been Director of the Institute of Land and Sea Transportation at TU Berlin. He is responsible for the vehicle-related part of the postgraduate master study on Public Transport Management at Ruhr Campus, Essen, and is Advisory Professor at Tongji University Shanghai.

Hamid Hefazi

California State University
Mechanical and Aerospace Engineering
Department of Mechanical and
Aerospace Engineering
Long Beach, CA, USA
hefazi@csulb.edu

Chapter B.13, Sect. 13.4

Hamid Hefazi received the PhD degree in Aerospace Engineering from the University of Southern California in 1985. He is currently Professor and Chair of mechanical and aerospace engineering and Director of the Boeing Technology Center at California State University, Long Beach. His research activities include computational fluid dynamics (CFD), aerodynamic design optimization, aeroacoustics, hydrodynamics, neural networks, and advanced optimization methods.

Martin Heilmaier

Technical University
Department of Physical Metallurgy
Darmstadt, Germany
m.heilmaier@phm.tu-darmstadt.de

Chapter B.3, Sects. 3.1, 3.4

Professor Martin Heilmaier graduated in Materials Science from the University of Erlangen-Nuremberg. From 2002 he was Professor for Materials Testing at the Otto-von-Guericke University, Magdeburg. Since October 2008 he holds the chair for Physical Metallurgy at the TU Darmstadt. His research is dedicated to the synthesis and properties of structural materials such as refractory metal silicide alloys and intermetallic alloys for high-temperature applications.

Rolf Henke

RWTH Aachen University
Institute of Aeronautics and Astronautics
Aachen, Germany
henke@ilr.rwth-aachen.de

Chapter B.13, Sect. 13.1

Since 2006, Professor Rolf Henke has been Head of the Institute of Aeronautics and Astronautics at RWTH Aachen University. He has 20 years of experience working for Airbus R&T, in charge of large technology projects at the aircraft level including flight testing. At Aachen University, his current research projects include seamless air transport, conceptual aircraft design, development of high-lift systems, investigation of wake vortices, and aircraft component and trajectory noise. He is a member of the executive board of the German aerospace society (DLR).

Klaus Herfurth

Industrial Advisor
Langenfeld, Germany
klaus.herfurth@t-online.de

Chapter B.7, Sect. 7.1

Professor Dr.-Ing. habil. Klaus Herfurth is an expert from the foundry industry. He earned the Dr.-Ing. degree from Technische Universitat Bergakademie Freiberg, Germany in 1963, and his Habilitation in 1979. He is author of 132 technical papers and book and handbook chapters. He was a Teacher at Technische Universitat Chemnitz from 1968 to 2002 in foundry technology and materials science. From 1987 to 2001 he was Manager of the Iron and Steel Casting Technical Group and the Standardization Technical Group of the German Foundrymen's Association in Düsseldorf. He also worked in R&D at this time in the field of analysis of energy demand in foundries and realization of material and energy savings through castings.

Chris Oliver Heyde

Otto-von-Guericke University
Electric Power Networks and Renewable
Energy Sources
Magdeburg, Germany
chris.heyde@ovgu.de

Chapter C.17, Sect. 17.2

Chris O. Heyde studied electrical engineering at the Otto-von-Guericke University Magdeburg, Germany. He graduated in 2005 with the Dipl. -Ing. degree. He then joined the Chair of Electric Power Networks and Renewable Energy Sources at the Otto-von-Guericke University Magdeburg, Germany as a Research Engineer in 2005. His primary field of interest is network stability.

Andrew Kaldos

AKM Engineering Consultants
Bebington, Wirral, UK
andrew.kaldos@ntlworld.com

Chapter B.7, Introduction

Andrew Kaldos received the Dipl.-Ing. degree in Mechanical and Production Engineering and Electrical, Instrumentation, and Control Engineering (1966, 1971) and the Dr.- Ing. degree in 1974 from the Technical University of Budapest, Hungary. He then held various positions at the Technical University of Budapest, from 1986 to 1989 at Leeds Polytechnic, from 1989 to 2000 at John Moores University, Liverpool, and since 2007 he has been Managing Director of AKM Engineering Consultants. He is involved in industrial technology transfer in the area of manufacturing engineering by research cooperation with eight departments of six universities in Europe, and development of cooperation with industrial companies.

Yuichi Kanda

Toyo University
Department of Mechanical Engineering
Advanced Manufacturing Engineering Laboratory
Kawagoe-City, Japan
cimkanda@toyonet.toyo.ac.jp

Chapter B.15, Sect. 15.6

Yuichi Kanda, is a Professor in the Faculty of Engineering at Toyo University, Japan where he received the M.S. and PhD degrees in Mechanical Engineering. His area of research is advanced manufacturing systems using networks and ultraprecision machining. He is a Fellow of the Japan Society of Mechanical Engineering and is the Chairperson of the FA Control Network committee of JEMA and the Society of Project Management.

Thomas Kannengiesser

Federal Institute for Materials Research and Testing (BAM)
Joining Technology
Berlin, Germany
thomas.kannengiesser@bam.de

Chapter B.7, Sect. 7.4.8

Thomas Kannengiesser studied Materials Engineering at Magdeburg University, Faculty of Mechanical Engineering. He was a scientific employee within the scope of a doctoral candidate program of BAM Federal Institute for Materials Research and Testing, Berlin, Germany. Since 2005, he has been Head of the Working Group Testing of Welded Components. His main fields of activity are component weld tests and full-scale tests under defined restraint intensities, cold cracking investigations on small and large specimens, and mobile residual stress measurement on components.

Michail Karpenko

New Zealand Welding Centre
Heavy Engineering Research Association (HERA)
Manukau City, New Zealand
michail.karpenko@hera.org.nz

Chapter B.7, Sect. 7.4.2

Dr. Karpenko obtained the Mechanical Engineer degree from the Kiev Polytechnic Institute in 1995. He extended this qualification with the Welding Engineer's degree (IWE). He completed the PhD degree at the Otto-von-Guericke University, Magdeburg, Germany, in 2001. From 1996 to 2006 he was a Research Fellow at the University of Magdeburg involved in a number of research projects in laser welding, drilling, and hybrid and plasma welding. In 2006 Dr. Karpenko took over the position of the NZ Welding Centre Manager in Manukau, New Zealand.

Bernhard Karpuschewski

Otto-von-Guericke University
Department of Manufacturing Engineering
Magdeburg, Germany
karpu@mb.uni-magdeburg.de

Chapter B.7, Sects. 7.3.1, 7.3.2, 7.3.3

After receiving the PhD degree and holding the Chief Engineer position at the University of Hannover, Germany, Bernhard Karpuschewski worked for 1.5 years as Associate Professor at Keio University, Japan, and then for 4.5 years as a Full Professor for Production Technology at TU Delft, The Netherlands. Since 2005 he has been Full Professor and Managing Director of IFQ in Magdeburg. He is a Fellow of the International Academy for Production Engineering (CIRP), and the current Chairman of Abrasive Processes.

Toshiaki Kimura

Japan Society for the Promotion of Machine Industry (JSPMI)
Production Engineering Department
Technical Research Institute
Tokyo, Japan
kimura@tri.jspmi.or.jp

Chapter B.15, Sect. 15.6

Toshiaki Kimura is an Engineering Leader of the Production Engineering Department at the Technical Institute of the Japan Society for the Promotion of Machine Industry (JSPMI). His interests and research areas are methodologies and application systems of manufacturing support systems using information technologies. He is a member of the JSME and the JSPE.

Dwarkadas Kothari

VIT University
School of Electrical Sciences
Vellore, TN, India
dkothari@ces.iitd.ac.in

Chapter C.16

Prof. D.P. Kothari is Former Director (in charge) of IIT, Delhi. He is currently Vice Chancellor of VIT University, Vellore. He is FNAE, FNASc, SMIEEE, MIEE, FIE (India), National Khosla Award Winner for Life Time Achievements in engineering. He has co-authored 20 books and more than 540 research publications, and has guided 28 PhD and 59 masters theses. His area of research interest is power and energy system engineering, operation, control, reliability, and optimization.

Hermann Kühnle

Otto-von-Guericke University
Institute of Ergonomics Factory
Operations and Automation
Magdeburg, Germany
hermann.kuehnle@ovgu.de

Chapter B.15, Sects. 15.1, 15.2, 15.4, 15.5, 15.9

Hermann Kühnle is Full Professor for Factory Operation and Manufacturing Systems and Executive Director at the Otto-von-Guericke University of Magdeburg. Hermann Kühnle has worked on approaches and concepts for high-performance organizations on the base of fractal geometry and complexity theory, and implemented these structures in many world market-leading companies. He has been involved in numerous research projects with international partners of global dimensions. Hermann Kühnle is a member of several international scientific committees.

Oleg P. Lelikov

Bauman Moscow State Technical University
Moscow, Russia

Chapter B.6

Professor Lelikov received the degree as Mechanical Engineer from Bauman Moscow State Technical University (BMSTU) in 1965, and in 1969 the academic status of Candidate of Technical Sciences. Since 1971 he has been working in the Department of Design Principles of Machines. Since 1992 he has been Professor at BMSTU, carrying out research on power-train loading, roadholds of multiaxial and multi-drive cars, safety of the multiple-unit reducer mechanisms, efficiency of gearings, ballscrew assemblies, and computer-aided design of machine components. He is an editor of one of the volumes of the Russian mechanical engineering encyclopedia in 40 volumes.

Andreas Lindemann

Otto-von-Guericke University
Institute for Power Electronics
Magdeburg, Germany
andreas.lindemann@ovgu.de

Chapter C.17, Sect. 17.4

Andreas Lindemann holds the Dr.-Ing. degree in Electrical Engineering. For 10 years he was responsible for the development of power semiconductor components in industry. Being appointed Professor of Power Electronics at Helmut-Schmidt-Universität, Hamburg, in 2004, he now holds the Chair for Power Electronics at Otto-von-Guericke University Magdeburg, Germany.

Bruno Lisanti

AST
Lonate Pozzolo (VA), Italy
bruno.lisanti@ast-italia.com

Chapter B.15, Sect. 15.8

Partner and Principal Consultant at AST in Italy, Bruno Lisanti has more than 25 years of experience in technical and management consulting in a wide range of markets (aerospace and defense, energy, automotive, and engineering) and company sizes, including large, small, and medium-sized organizations. Graduating in Nuclear Engineering from the University of Pisa, he is directly involved in consulting services, and in the last 10 years has participated in and coordinated several European research projects on concurrent engineering, virtual organizations, and advanced collaborative approaches, methods, and tools.

Manuel Marya

Schlumberger Reservoir Completions
Material Engineering
Rosharon, TX, USA
mmarya@slb.com

Chapter B.7, Sect. 7.4.9

Dr. Marya is Group Leader with Schlumberger Technology Corp., TX. After completing his education in France, Canada, and the USA, where he received the M.S. and PhD degrees (Colorado School of Mines), he spent 3 years at General Motors R&D (MI) and NanoCoolers (TX). Dr. Marya has over 50 publications in materials design and processing to his name and is the recipient of the 2000 AWS Graduate Fellowship Award, 2002 IIW Henry Granjon Prize, and the 2006 AWS William Spraragen Award.

Surendar K. Marya

GeM–UMR CNRS 6183, Ecole Centrale Nantes
Institut de Recherche en Génie Civil et Mécanique
Nantes, France
surendar.marya@ec-nantes.fr

Chapter B.7, Sect. 7.4.9

Surendar Marya is Professor in Materials Science and Engineering, Physical Metallurgy, and Manufacturing Processes at Centrale Nantes, France. He holds the PhD degree from Punjab University College, India, and the Dr. Es. Sc. degree from the University of Paris Orsay, France. Professor Marya is a technical advisor to several industries and is heavily involved in scientific missions worldwide. He has been a Visiting Professor in the USA, Japan, and Korea, and frequently lectures in Southwest Asia.

Ajay Mathur

Simon India Limited
Plant Engineering
New Delhi, India
avm2k@vsnl.net

Chapter B.11

Ajay Mathur is a Mechanical Engineer graduated from The Maharaja Sayaji Rao University, Baroda, India. He has over 20 years of experience in design and fabrication of pressure vessels, heat exchangers, skid-mounted plants, and fired heater modules for refinery, petrochemical, nuclear, and chemical projects in India and elsewhere.

Klaus-Jürgen Matthes

Chemnitz University of Technology
Institute for Manufacturing/Welding Technology
Chemnitz, Germany
schweisstech@mb.tu-chemnitz.de

Chapter B.7, Sect. 7.4.5

Klaus-Jürgen Matthes is a Professor of Welding Engineering and Director of the Institute for Manufacturing/Welding Technology at Chemnitz University of Technology. His research interests include welding processes, engineering and design weldments, laser welding of microstructures, and automation and sensor-based monitoring of welding processes. He held the position of Vice President for Research from 1997 to 2003 and has been President of Chemnitz University of Technology since October 2003.

Henning Jürgen Meyer

Technische Universität Berlin
Berlin Institute of Technology
Konstruktion von Maschinensystemen
Berlin, Germany
henning.meyer@tu-berlin.de

Chapter B.14, Sect. 14.2

Dr. Meyer is a Professor of Machinery System Design at the Berlin Institute of Technology. He studied Mechanical Engineering at the Technische Universität Braunschweig, obtaining the PhD degree in 1998. From 1998 to 2002 he worked in the Wirtgen Group and was responsible for electronic systems in road pavers. His research work is concentrated on self-configuring mobile networks and on driving dynamics and braking systems of commercial vehicles, tractors, and mobile working machines.

Klaus Middeldorf

DVS – German Welding Society
Düsseldorf, Germany
klaus.middeldorf@dvs-hg.de

Chapter B.7, Sect. 7.4.1

Klaus Middeldorf graduated as a Mechanical Engineer (1982) and received the Doctorate in Materials Science (1986) from the University of Essen. He worked as Project Manager for Paper Production for Procter &Gamble, then took the position of R&D Managing Director at the Federation of Industrial Research Associations, Cologne (1988–1999). He currently serves as R&D Managing Director, and since 2006 as General Manager, for the German Welding Society (DVS).

Gerhard Mook

Otto-von-Guericke University
Department of Mechanical Engineering
Institute of Materials and Joining Technology and Materials Testing
Magdeburg, Germany
mook@mb.uni-magdeburg.de

Chapter B.3, Sect. 3.5

Professor Mook's main area of research is nondestructive testing and evaluation as well as structural health monitoring. His work is focused on high-resolution imaging systems suitable for in-field application in aerospace and ground transportation systems. He is the chairman of the Board of University Teachers of the German Society for Nondestructive Testing (DGZfP).

Jay M. Ochterbeck

Clemson University
Department of Mechanical Engineering
Clemson, SC, USA
jochter@clemson.edu

Chapter B.4, Sect. 4.2

Jay M. Ochterbeck has been a Professor of Mechanical Engineering at Clemson University since 1994. His main fields of research are multiphase flows and heat transfer, capillary-driven loops, heat pipe science and technology, and thermal contact conductance. He is an Associate Fellow of the AIAA and is a member of several professional societies and international committees in thermal sciences.

Joao Fernando G. Oliveira

University of São Paulo
Department of Production Engineering
São Carlos, SP, Brazil
jfgo@sc.usp.br, presidencia@ipt.br

Chapter B.7, Sect. 7.3.3

Dr. Oliveira is Professor of Production Engineering at the University of São Paulo, Brazil. His area of research is abrasive machining process and its automation. He has published more than 200 papers and four patents. Currently he is the President of the Institute for Technological Research of the State of São Paulo and a member of the International Academy for Production Engineering.

Antje G. Orths

Energinet.dk
Electricity System Development
Fredericia, Denmark
ano@energinet.dk

Chapter C.17, Sect. 17.6

Antje Orths graduated in Electrical Engineering at the TU Berlin and received the PhD degree from the Otto-von-Guericke University Magdeburg, Germany. Afterwards she lead the Critical Infrastructures Group at the Fraunhofer-Institute IFF in Magdeburg. Since 2005 she has been with the Planning Department of Energinet.dk, the Danish TSO for electricity and natural gas. Her research interests are planning issues such as the implementation of wind energy into electric power networks and systems. She is a member of the IEEE, VDE-ETG, and CRIS.

Vince Piacenti

Robert Bosch LLC
System Engineering, Diesel Fuel Systems
Farmington Hills, MI, USA
vince.piacenti@us.bosch.com

Chapter B.10, Sect. 10.4

Vince Piacenti received the B.S. degree in Mechanical Engineering from Bradley University in 1976. He spent 7 years at Bosch's Headquarters working on diesel fuel injection. Currently he is Senior Manager at Bosch in Michigan responsible for hydraulic systems integration. He has experience in all forms of diesel and gasoline fuel injection, and research experience with thermoplastics and alternate fuels.

Jörg Pieschel

Otto-von-Guericke University
Institute of Materials and Joining Technology
Magdeburg, Germany
pieschel@mb.uni-magdeburg.de

Chapter B.7, Sect. 7.4.2

Jörg Pieschel earned the Dipl.-Ing. and and Dr.-Ing. degrees from Otto-von-Guericke University Magdeburg in 1991 and 1999, respectively. In 2001 he was promoted to Head of Laboratories of the Materials and Joining Technology Institute and Welding Supervisor of the University of Magdeburg. Dr. Pieschel is an International Welding Engineer (IWE) and has specialized on joinability of materials, innovation of laser joining processes, quality assurance, and clarification of welding damages.

Stefan Pischinger

RWTH Aachen University
Institute for Combustion Engines
Aachen, Germany
pischinger@vka.rwth-aachen.de

Chapter B.13, Sect. 13.1

Professor Pischinger studied Mechanical Engineering at RWTH Aachen University. Form 1985 to 1989 he worked as a Research Assistant at the Sloan Automotive Laboratory at MIT until he received the PhD degree for his work on spark ignition. Form 1989 to 1997 he held various positions at Daimler, working on diesel and gasoline engine development, and became project leader for the new Common Rail V8-Diesel engine. Since 1997 he has been Professor at RWTH Aachen University and Director of the Institute for Combustion Engines. Since April 2003 he has also been President and CEO of FEV, an Engineering Services Company in the field of combustion engines and powertrain.

Didier M. Priem

École Centrale Nantes
Department of Materials
Nantes, France
didier.priem@ec-nantes.fr

Chapter B.7, Sect. 7.4.9

Didier M. Priem is an Engineer and Laboratory Manager for welding joining and forming technologies. For the last 20 years, he has been actively engaged in electromagnetic and electrohydraulic forming and welding technologies. He holds a patent on the electromagnetic forming of titanium dental parts.

Frank Riedel

Fraunhofer-Institute for Machine Tools and Forming Technology (IWU)
Department of Joining Technology
Chemnitz, Germany
frank.riedel@iwu.fraunhofer.de

Chapter B.7, Sect. 7.4.5

Frank Riedel graduated as a Mechanical Engineer, receiving the PhD degree and PhD habilitatus in Joining Technology from Chemnitz University of Technology. From 2003 to 2006 he was the Deputy Head of Professorship of Welding Technology and Chief Engineer of the Institute of Manufacturing/Welding Technology at Chemnitz University of Technology. Since 2006 he has been establishing the Department of Thermal Processing at the Fraunhofer-Institute for Machine Tools and Forming Technology in Chemnitz, Germany.

Holger Saage

University of Applied Sciences of Landshut
Faculty of Mechanical Engineering
Landshut, Germany
holger.saage@fh-landshut.de

Chapter B.3, Sect. 3.7

Holger Saage received the PhD degree from the Otto-von-Guericke University Magdeburg. His experience covers various fields of materials science, including alloy development, powder technology, modeling of mechanical properties, and methods of materials analysis. Prior to joining the university he worked as a Materials Analyst in the semiconductor industry (AMD Saxony, Dresden). His current research work focuses on high-temperature materials, especially those with intermetallic phases such as TiAl and Mo silicides.

Shuichi Sakamoto

Niigata University
Department of Mechanical and Production Engineering
Niigata, Japan
sakamoto@eng.niigata-u.ac.jp

Chapter B.8, Sect. 8.2

Shuichi Sakamoto worked as Research Associate of the JSPS in 1989 and 1990. After that he received the PhD degree from Niigata University in 1991. He joined Niigata University in 1991 as a Research Associate, and became Associate Professor in 1998. His research interests are the development of new measuring or detection methods using acoustics, the characteristics of airborne sound-absorbing materials, and noise control.

Roger Schaufele

California State University
Long Beach, CA, USA
rdschaufele@aol.com

Chapter B.13, Sect. 13.4

Roger Schaufele graduated from Rensselaer Polytechnic Institute in 1949 with a degree in Aeronautical Engineering and obtained a M.S. degree in Aeronautics from CalTech in 1952. During the following years he held a number of key roles including Lead Aerodynamics Engineer for the DC-8 project, Aerodynamicist on the DC-9 and DC-10, and General Manager of Commercial Advanced Products. Since retiring from Douglas in 1989, he has been a part-time faculty member at California State University, Long Beach. He teaches courses in aircraft preliminary design and performance.

Markus Schleser

RWTH Aachen University
Welding and Joining Institute
Aachen, Germany
schleser@isf.rwth-aachen.de

Chapter B.7, Sect. 7.4.7

Dipl.-Ing. Markus Schleser studied at RWTH Aachen University and majored in Production Engineering in 2001. From 2001 to 2007 he has been employed as a Research Assistant in the Department of Adhesive Bonding and since August 2007 has been Chief Engineer at the Welding and Joining Institute (ISF) of RWTH Aachen University.

Meinhard T. Schobeiri

Texas A&M University
Department of Mechanical Engineering
College Station, TX, USA
tschobeiri@tamu.edu

Chapter B.12

Dr. Schobeiri, a Professor of Mechanical Engineering, received his entire engineering education at the Technical University Darmstadt, Germany. He was Group Leader for Gas Turbine Aero-Thermodynamic Design at Brown Boveri Co., Baden, Switzerland. His area of expertise includes unsteady aerodynamics, turbine and compressor aerodynamics design, and nonlinear gas turbine engine dynamic simulations. He is the author of one book and more than 100 technical papers and reports. He is a member of VDI and a Fellow of the ASME.

Miroslaw J. Skibniewski

University of Maryland
Department of Civil and Environmental Engineering
College Park, MD, USA
mirek@umd.edu

Chapter B.14, Sects. 14.1, 14.3–14.8

Prof. Skibniewski is the holder of the A. James Clark Endowed Chair in Construction Engineering and Project Management at the University of Maryland, USA. A recipient of Civil Engineering degrees from Warsaw University of Technology and from Carnegie Mellon University and author of over 150 publications, he serves as Editor-in-Chief of *Automation in Construction*, an international research journal.

Jagjit Singh Srai

University of Cambridge
Centre for International Manufacturing
Institute for Manufacturing
Cambridge, UK
jss46@cam.ac.uk

Chapter B.15, Sect. 15.3

Jag Srai is currently Head of the Centre for International Manufacturing, Institute for Manufacturing, University of Cambridge, an academic and practice-focused group of some 25 personnel. Before joining Cambridge University, Jag's previous Director-level roles have been in industry, working for leading multinationals in manufacturing and supply chain management, with over 17 years industrial experience. Jag has a degree in Chemical Process Engineering and is a Chartered Engineer and a Fellow of the Institute for Chemical Engineers.

Vivek Srivastava

Corporate Technology Strategy Services
Aditya Birla Management Corporation
Navi Mumbai, India
vivek.srivastava@adityabirla.com

Chapter B.3, Sect. 3.3

Vivek's research interest include room- and elevated-temperature mechanical properties of materials and their relationship with microstructure. He completed the PhD degree at the University of Sheffield, UK, on high-temperature creep of metals and alloys and was awarded the Bournton Medal for his thesis. He has published over ten research papers in international journals and has a deep interest in commercialization of technology.

Peter Stephan

Technical University Darmstadt
Institute of Technical Thermodynamics
Department of Mechanical Engineering
Darmstadt, Germany
pstephan@ttd.tu-darmstadt.de

Chapter B.4

Peter Stephan is a Professor at the Technische Universitaet Darmstadt and Head of the Institute of Technical Thermodynamics since 1997. His main fields of research are boiling heat transfer, microscale heat and mass transfer, interfacial phenomena, heat pipe technology, and drying and freezing processes. He is president of the VDI Heat and Mass Transfer Committee and is a member of several international thermal science associations.

Zbigniew A. Styczynski

Otto-von-Guericke University
Electric Power Networks and Renewable Energy Sources
Magdeburg, Germany
sty@ovgu.de or sty@ieee.org

Chapter C.17, Sects. 17.2, 17.7

Zbigniew Styczynski received the PhD degree from the Technical University of Wrocław, Poland. He worked at the University of Stuttgart, Germany, and in 1999 became Professor and Chair of Electric Power Networks and Renewable Energy Sources at the Otto-von-Guericke University, Magdeburg. From 2002 until 2006 he was the dean of the EE Faculty and since 2006 has been the President of the Centre of Renewable Energy Saxonia-Anhalt, Germany.

P.M.V. Subbarao

Indian Institute of Technology
Mechanical Engineering Department
New Delhi, India
pmvs@mech.iitd.ac.in

Chapter C.16

Dr. P.M.V. Subbarao is an Associate Professor of Mechanical Engineering Department at IIT, Delhi. He obtained the PhD degree in Mechanical Engineering from IIT Kanpur in 1996. He has developed ultramicro hydropower plants installed in remote rural areas for rural electrification. He has also developed a technology for production of bio-CNG from biogas for use in automobiles. His current research activities include power generation, renewable energy systems, and micro and pico power-generation systems.

Oliver Tegel

Dr.-Ing. h.c. F. Porsche AG
R&D, IS-Management
Weissach, Germany
oliver.tegel@porsche.de

Chapter B.13, Sect. 13.2

Dr. Oliver Tegel is working at IS-Management in R&D at Porsche AG. Previously, he has managed business process reengineering projects related to various aspects of the car development process. His educational background is in engineering design and design methodology, in which he earned the Doctor degree from the Technical University Berlin, Germany.

A. Erman Tekkaya

ATILIM University
Department of Manufacturing Engineering
Ankara, Turkey
etekkaya@atilim.edu.tr

Chapter B.7, Sect. 7.2

Professor Tekkaya completed his doctoral thesis at the University of Stuttgart in 1985. Until 2005 he was Professor at the METU, Ankara. From 2005 he was the Chairman of the Department of Manufacturing at ATILIM University in Ankara, Turkey. From 2007 he was Director of the Institute of Forming Technology and Lightweight Construction. His current research is on numerical simulation of sheet/bulk metal forming processes and material characterization. He is a member of CIRP and President of the International Cold Forging Group (ICFG).

Klaus-Dieter Thoben

University of Bremen
Bremen Institute for Production and Logistics GmbH Department of ICT Applications in Production
Bremen, Germany
tho@biba.uni-bremen.de

Chapter B.15, Sect. 15.10

After finishing his studies in Mechanical Engineering, Klaus-Dieter Thoben worked as a Research Assistant at the Department of Production Engineering at the University of Bremen, where he received the Doctor of Engineering degree in 1989. He received the state doctorate (Habilitation) in the domain of Production Systems in 2002. In the same year he was appointed Professor for IT Applications in Production Engineering at the University of Bremen. Since 2003 he has been Director of Bremen Institute for Production and Logistics GmbH (BIBA) in the Department of ICT Applications in Production.

Marcel Todtermuschke

Fraunhofer-Institute for Machine Tools and Forming Technology
Department of Assembling Techniques
Chemnitz, Germany
marcel.todtermuschke@saxonia.net

Chapter B.7, Sect. 7.4.5

After studying mechanical engineering with major subject welding and manufacturing technologies, Marcel Todtermuschke started working at the University of Technology Chemnitz in the Department of Welding Technology. He worked in various fields such as welding design and finally gained his Doctorate in the field of mechanical joining. Since 2006 he has been concentrating on assembling technologies at the Fraunhofer-Institute for Machine Tools and Forming Technology.

Helmut Tschoeke

Otto-von-Guericke University
Institute of Mobile Systems
Magdeburg, Germany
tschoeke@ovgu.de

Chapter B.10

Helmut Tschoeke is a Professor of Reciprocating Machines at the University of Magdeburg. From 1981 to 1995 he worked with Bosch Diesel Division, where he was responsible for development and production of distributor and inline pumps. During his career he has held positions as Chief Engineer and Executive Plant Manager. He is an active member of VDI and member of SAE and the head of the automotive research program at the University of Magdeburg.

Jon H. Van Gerpen

University of Idaho
Department of Biological and Agricultural Engineering
Moscow, ID, USA
jonvg@uidaho.edu

Chapter B.10

Jon Van Gerpen has been Professor and Department Head of Biological and Agricultural Engineering at the University of Idaho since July 2004. Before that, he was a Professor of Mechanical Engineering at Iowa State University for 20 years. He received the PhD degree from the University of Wisconsin-Madison in 1984. His current research interests include the production and utilization of biofuels and the development of a nationwide biodiesel education program.

Anatole Vereschaka

Moscow State University of Technology "STANKIN"
Department of Mechanical Engineering Technology and Institute of Design and Technological Informatics Laboratory of Surface Nanosystems
Russian Academy of Science
Moscow, Russia
dr_averes@rambler.ru

Chapter B.7, Sects. 7.3.1, 7.3.2

Anatoly Vereschaka, who received the PhD and Science Doctor degrees from Moscow State University in 1965 and 1986, respectively, is a Professor of Engineering Technology, Material Cutting Technology, and Surface Engineering Technology in the Department of Mechanical Engineering Technology of Moscow State University of Technology (STANKIN), Russia. His research interests are in the physics of metal cutting processes, design theory and methodology of wear resistance, and functional coating for cutting tools. He is Director of the Research Laboratory of Surface Nanosystems of the Russian Academy of Sciences.

Detlef von Hofe

Krefeld, Germany
detlef.von.hofe@web.de

Chapter B.7, Sect. 7.4.1

Detlef von Hofe was responsible for stationary gas turbine fabrication at Siemens Power Generation until 1991 and has been the Chairman of CEN/TC 121 Welding since 2003.
He was the Chief Executive Director and a Member of the Executive Council of the DVS, the German Welding Society until January 2006. He was appointed a Honorary Professor at the Otto-von-Guericke University in Magdeburg, teaching quality assurance in welding technology.

Nikolaus Wagner

RWTH Aachen University
ISF Welding and Joining Institute
Aachen, Germany
wa@isf.rwth-aachen.de

Chapter B.7, Sect. 7.4.4

Dipl.-Ing. Nikolaus Wagner studied Mechanical Engineering from 1997 to 2004 at the RWTH Aachen University with an emphasis on production engineering. Since January 2005 he has been working as a Scientific Assistant in the Laser Beam Department of the ISF – Welding and Joining Institute at the RWTH Aachen University. After carrying out research on laser hybrid welding of light metals, he is currently working on laser-beam welding with pressure-sensitive adhesives. He is also doing research in the Cluster of Excellence Integrative Production Technology for High-Wage Countries.

Jacek G. Wankowicz

Institute of Power Engineering
Warsaw, Poland

Chapter C.17, Sect. 17.1

Jacek Wankowicz received the PhD and Dr. Sc. degrees from the Technical University of Wrocław, Poland. He worked at the Technical University of Wrocław, Poland and Bayero University Kano, Nigeria, and since 1997 has been the Managing Director of the Institute of Power Engineering, Warsaw, Poland. He is a Member of many Supervisory Boards, Member of the IEC, CIGRE and is currently the President of the Polish National Committee of the CIGRE.

Ulrich Wendt

Otto-von-Guericke University
Department of Materials and Joining Technology
Magdeburg, Germany
wendt@ovgu.de

Chapter B.3, Sects. 3.2, 3.7

Ulrich Wendt studied chemistry and received the Dr. rer. nat. degree for the investigation of a catalytic reaction and a second degree (Habil.) for work on polymer melt crystallization. He heads the Microscopy and Stereology Laboratory and lectures on microscopy, spectroscopy, image analysis, and chemical analysis. His research activities are related to microstructure characterization, topometry, and failure analysis.

Steffen Wengler

Otto-von-Guericke University
Faculty of Mechanical Engineering
Institute of Manufacturing Technology and Quality Management
Magdeburg, Germany
swengler@ovgu.de

Chapter B.8, Sect. 8.2

Steffen Wengler graduated and obtained the Doctor degree in Mechanical Engineering, both from Otto-von-Guericke University of Magdeburg, Germany. His fields of specialization include manufacturing measurement technology and gear metrology, mainly cylindrical involute gears, and gear pairs. Since 1990 he has been Head of the Laboratory for Measurement Technology in the Institute of Manufacturing Technology and Quality Management at this university.

Bernd Wilhelm

Volkswagen AG
Sitech Sitztechnik GmbH
Wolfsburg, Germany
bernd.wilhelm2@volkswagen.de

Chapter B.15, Sect. 15.7

Bernd Wilhelm has had a career in the automotive industry, first as Specialist for manufacturing strategies, later as Manager of a Volkswagen assembly line, as Chief Industrial Engineer for the Volkswagen Group, and as Executive Manager of plants in Zaragoza and Brussels. As CEO for Sitech, a subsidiary of VW, he guarantees global seat production for the Volkswagen group and teaches operations planning as a Professor. He chairs leading automobile associations and is a Board Member of the German MTM Society.

Patrick M. Williams

Assystem UK
Bristol, UK
pwilliams@assystemuk.com

Chapter B.15, Sect. 15.8

Patrick has been involved in the UK aerospace industry for over 25 years. He qualified with the MSc degree in Technology Management from Universities in Bristol. His career has covered managing programmes in the UK, Europe, and the USA. Recently, Patrick has been involved in European research work in collaborative engineering in aerospace, focusing on management techniques in the supply chain.

Lutz Wisweh

Otto-von-Guericke University
Faculty of Mechanical Engineering
Institute of Manufacturing Technology and Quality Management
Magdeburg, Germany
lutz.wisweh@ovgu.de

Chapter B.8, Sect. 8.1

Lutz Wisweh received the Dipl.-Ing. and Dr.-Ing. degrees from the University of Magdeburg. In 1999 he was a Visiting Professor at the Niigata University, Japan. In 1999 he had an unlimited Visiting Professorship at the Universidad Central de Las Villas, Cuba. Currently, he is an Extracurricular Professor at the University of Magdeburg. His research interests are mainly in the use of statistical methods in quality management and measurement uncertainty in manufacturing measurement technology.

Johannes Wodara

Schweißtechnik-Consult
Magdeburg, Germany
johanneswodara@hotmail.com

Chapter B.7, Sect. 7.4.6

Professor Wodara was working for many years in speciality areas of welding. He was Head of the Institute of Assembling and Welding Engineering at the Otto-von-Guericke University Magdeburg. He also taught fundamentals of manufacturing in vehicle and aircraft engineering at Hamburg University of Applied Sciences. He has more than 170 publications to his name and is (co)author of several books in the field of welding, soldering, and brazing.

Klaus Woeste

RWTH Aachen University
ISF Welding and Joining Institute
Aachen, Germany
wo@isf.rwth-aachen.de

Chapter B.7, Sect. 7.4.3

Dr.-Ing. Klaus Woeste studied Mechanical Engineering from 1994 to 2001 at RWTH Aachen University with emphasis on Production Engineering. From 2001 to 2004 he worked as a scientific assistant at the ISF – Welding and Joining Insitute at the RWTH Aachen University in the Electron Beam Department. From 2004 to August 2007 he was Chief Engineer of the ISF and was responsible for the coordination of scientific projects. He earned his doctorate in 2005. Since August 2007 he has been working in the Innovation Centre R&D of Gottwald Port Technology GmbH, Düsseldorf, Germany

Hen-Geul Yeh

California State University
Department of Electrical Engineering
Long Beach, CA, USA
heyeh@csulb.edu

Chapter A.2

Dr. Hen-Geul Yeh's research areas are dynamics and adaptive controls, digital signal processing, and digital communication systems. He has been selected twice as the NASA summer faculty fellow, in 1992 and 2003. He was the recipient of four NASA tech brief awards and one NASA new technology award. He was the recipient of the Aerospace Corporation inventor's award. He has been selected as the Boeing A. D. Welliver faculty summer fellow in 2006. He owns several engineering patents.

Hsien-Yang Yeh

California State University Long Beach
Department of Mechanical and
Aerospace Engineering
Long Beach, CA, USA
hyyeh@csulb.edu

Chapter A.2

Hsien-Yang Yeh received the PhD degree from the University of Southern California. His research interests include the mechanics of composite materials, fracture mechanics, structural and machine components failure analysis, and nanotechnology applications. Dr. Hsien-Yang Yeh's research interests include the mechanics of composite materials, fracture mechanics, structural and machine components failure analysis, and nanotechnology applications.

Shouwen Yu

Tsinghua University
School of Aerospace
Beijing, P.R. China
yusw@mail.tsinghua.edu.cn

Chapter A.2

Professor Shouwen Yu is a Professor in the Department of Engineering Mechanics at Tsinghua University, Beijing, China. Professor Yu has been working in the field of fracture mechanics and nano/micro/mesomechanics over the last few decades. From 1985 to 1987 he was with the Institute of Mechanics, Technische Hochschule Darmstadt, Germany as a Visiting Research Fellow under an Alexander von Humboldt Fellowship. Professor Yu was Vice President of Tsinghua University from 1992 to 1999 and Dean of Graduate School of Tsinghua University from 1994 to 1999.
