where Π is the functional, $\boldsymbol{v}$ the velocity vector of material particles, $\dot{\varepsilon}_V$ the volumetric strain rate, $\boldsymbol{t}$ the specified traction acting over the surface A_t of the body, and S a constant number called the penalty factor. The penalty factor term is necessary to impose the volume constancy constraint approximately. Alternatively, the volume constancy constraint can be imposed by the Lagrange multiplier λ exactly.

It can be shown that the hydrostatic stress is given in both cases by

$$\sigma_H = S\dot{\varepsilon}_V ,$$
$$\sigma_H = \lambda . \qquad (7.44)$$

These functionals can be easily discretized by assuming shape functions for the velocities over the element domain.

After the standard discretization procedure the resulting finite element equations read

$$\left(\mathbf{K}_{\mathrm{D}}^{e}+\mathbf{K}_{\mathrm{H}}^{e}\right)\boldsymbol{v}^{e}=\boldsymbol{f}^{e}\,. \tag{7.45}$$

$\boldsymbol{f}^{e}$ is the nodal force vector of the element compatible with the nodal velocity vector $\boldsymbol{v}^{e}$. The nonlinear deviatoric stiffness matrix is given by $\mathbf{K}_{\mathrm{D}}^{e}$ and the linear hydrostatic stiffness matrix by $\mathbf{K}_{\mathrm{H}}^{e}$. The resulting nonlinear (w.r.t. nodal velocities) equations (7.45) can be solved by standard numerical methods. The common ones applied are the direct iteration and the Newton–Raphson method. Both methods are iterative and are applied in increments. The time integration is performed explicitly in most commercial software.

Implicit Static Elasto-Plastic Finite Element Formulations. These formulations usually assume an additive composition of the elastic and plastic strain rate tensors

$$\dot{\boldsymbol{\varepsilon}}_{ij}\approx\dot{\boldsymbol{\varepsilon}}_{ij}^{\mathrm{el}}+\dot{\boldsymbol{\varepsilon}}_{ij}^{\mathrm{pl}}\,. \tag{7.46}$$

This is based on so-called hypoelastic models. Also models based on hyperelasticity are used that lead to a multiplicative split of elastic and plastic deformations. For the elastic strain rates the generalized Hooke's law and for the plastic strain rates the Levy–Mises equations are used. These then lead to the modified Prandtl–Reuss equations between the objective (frame-invariant) rate of the stress tensor and the strain rates

$$\hat{\boldsymbol{\sigma}}_{ij}=\mathbf{C}_{ijmn}\dot{\boldsymbol{\varepsilon}}_{mn}\,. \tag{7.47}$$

Various types of objective rates can be used such as the Jaumann rate, the Truesdell rate, or generally any Lie-derivative of the true stress tensor. The constitutive fourth order tensor contains the elastic constants and the plastic properties such as the normal of the flow surface and the slope of the flow curve. For consistent linearization (7.47) has to be modified slightly.

The elasto-plastic field equations are derived from the principle of virtual work supplying (neglecting inertial forces)

$$\int_{V}\boldsymbol{\sigma}_{ij}\delta\left(\frac{\partial u_j}{\partial x_i}\right)\mathrm{d}V-\int_{A}t_i\delta u_i\,\mathrm{d}A=0\,. \tag{7.48}$$

Equation (7.48) must be fulfilled at the unknown current configuration. Linearization of this equation about the last known state and space discretization supply the nonlinear finite element equations. Time integration is performed primarily implicitly.

Explicit Dynamic Elasto-Plastic Finite Element Formulations. The explicit dynamic finite element formulations are based on the virtual work principle to which an inertia term is added

$$\int_{V}\boldsymbol{\sigma}_{ij}\delta\left(\frac{\partial u_j}{\partial x_i}\right)\mathrm{d}V-\int_{A}t_i\delta u_i\,\mathrm{d}A+\int_{V}\rho\ddot{\boldsymbol{u}}_i\delta u_i\,\mathrm{d}V=0\,, \tag{7.49}$$

where $\ddot{\boldsymbol{u}}_i$ is the acceleration vector and ρ the density. Discretization of (7.49) leads to

$$\mathbf{M}\ddot{\boldsymbol{u}}=\boldsymbol{F}-\boldsymbol{I}\,. \tag{7.50}$$

Here, $\mathbf{M}$ is the mass matrix, $\boldsymbol{F}$ the external force vector, and $\boldsymbol{I}$ the internal force vector at the current time. Time discretization by a central difference scheme and by adding a damping term $\mathbf{C}$ supplies the fundamental equations for the formulation

$$\left[\frac{1}{(\Delta t)^2}\mathbf{M}\right]\boldsymbol{u}^{t+\Delta t}=\boldsymbol{F}^{t}-\boldsymbol{I}^{t}+\left(\frac{\mathbf{M}}{2\Delta t}-\mathbf{C}\right)\left(\frac{\boldsymbol{u}^{t}-\boldsymbol{u}^{t-\Delta t}}{\Delta t}\right)\,. \tag{7.51}$$

Here Δt is the time increment for the computation and must satisfy the stability condition

$$\Delta t\le\frac{L}{c_{\mathrm{d}}}\,, \tag{7.52}$$

where c_{d} is the current dilatational wave speed of the material (speed of sound in that material) and L is the characteristic element dimension, which can be taken as the minimum distance between any two nodes of an element. The elastic wave speed can be found from

$$c_{\mathrm{d}}=\sqrt{\frac{2G(1-\nu)}{(1-2\nu)\rho}}\,. \tag{7.53}$$

7.2.4 Bulk Forming Processes

This section describes the basic bulk forming processes.

Upsetting

A workpiece of initial diameter d_0 and initial height h_0 is reduced between two flat dies to a specimen with final diameter d_1 and final height h_1 (Fig. 7.50). This process is also called open die forging or free forming.

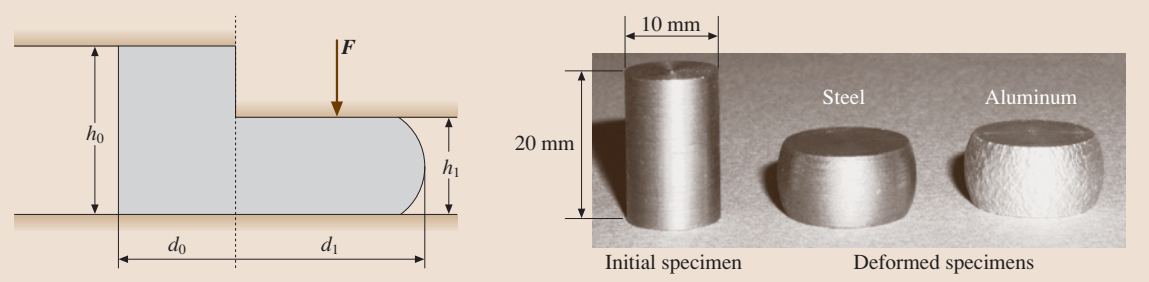

Fig. 7.50 **(a)** Principle of upsetting process. **(b)** Application examples

Due to friction between the dies and the workpiece the workpiece bulges. The upsetting process is used as a material characterization process and as a production process in various forms. The basic parameters characterizing the process are the ideal equivalent plastic strain

$$\bar{\varepsilon} = \ln\left(\frac{h_0}{h_1}\right) , \tag{7.54}$$

the upsetting ratio

$$s = \frac{h_0}{d_0} , \tag{7.55}$$

the relative height reduction

$$e = \frac{\Delta h}{h_0} = \frac{h_0 - h_1}{h_0} , \tag{7.56}$$

and finally ideal equivalent plastic strain rate

$$\dot{\bar{\varepsilon}} = \frac{\mathrm{d}\bar{\varepsilon}}{\mathrm{d}t} = \frac{v_{\mathrm{tool}}}{h} , \tag{7.57}$$

where v_{tool} is the tool velocity (precisely the velocity difference of the upper and lower dies).

Utilizing the elementary plasticity theory (slab method), the axial, radial and tangential stresses are found for Coulomb friction as

$$\sigma_z(r) = -\sigma_{\mathrm{f}} \mathrm{e}^{\frac{2\mu}{h}\left(\frac{D}{2}-r\right)} \approx \underbrace{-\sigma_{\mathrm{f}}\left[1+\frac{2\mu}{h}\left(\frac{D}{2}-r\right)\right]}_{\text{after a Taylor's series expansion}} ,$$

$$\sigma_r(r) = \sigma_\theta(r) = \sigma_z(r) + \sigma_{\mathrm{f}} \approx \underbrace{-\sigma_{\mathrm{f}}\left[\frac{2\mu}{h}\left(\frac{D}{2}-r\right)\right]}_{\text{after a Taylor's series expansion}} , \tag{7.58}$$

and for the constant shear friction model

$$\sigma_z(r) = -\sigma_{\mathrm{f}}\left[1+\frac{m}{\sqrt{3}}\frac{D}{h}\left(1-\frac{r}{D/2}\right)\right] ,$$

$$\sigma_r(r) = \sigma_\theta(r) = -\sigma_{\mathrm{f}}\frac{m}{\sqrt{3}}\frac{D}{h}\left(1-\frac{r}{D/2}\right) . \tag{7.59}$$

The stress distribution is shown in Fig. 7.51 for the linearized Coulomb friction model. The upsetting force at a generic height is given by

$$|F_z| = -\int_A \sigma_z \,\mathrm{d}A \approx \frac{\pi}{4} D^2 \sigma_{\mathrm{f}} \left(1+\frac{1}{3}\mu\frac{D}{h}\right) . \tag{7.60}$$

Figure 7.52 exhibits a typical force–displacement curve for upsetting. The steep increase of the force to-

Fig. 7.55 Preform design (after [7.39])

wards the smaller specimen heights is characteristic for upsetting.

Cold upsetting has the process limits shown in Fig. 7.53. These limits consist of the formability of the workpiece material characterized by a maximum of 80% height reduction, the buckling limit given by the maximum upsetting ratio of 2.3, and finally the tool load limit. The buckling limit can be increased by upsetting in multiple strokes. So, for a two-stroke process the upsetting ratio can be increased to 4.5, for instance. Formability limits are characterized by two types of cracks: shear cracks in the upsetted part and longitudinal cracks (basically due to initial faults in the workpiece).

For heading that is the upsetting of one end of the workpiece instead of the whole, Fig. 7.54 shows a three-step process necessitated by the buckling forming limit. Notice that the last step is no longer an open die process.

The design rules of the preforms during the head upsetting are given in Fig. 7.55.

Accuracy during cold upsetting depends on the conditions of the forming tools and machines. Wear of the tools is hereby an important issue. Table 7.21 gives some typical accuracy values for a reasonable number of parts formed.

A typical tool construction is given in Fig. 7.56. The die is usually supported by a shrink ring to increase its load carrying capacity. The basic tool materials are listed in Table 7.22 together with their hardness values.

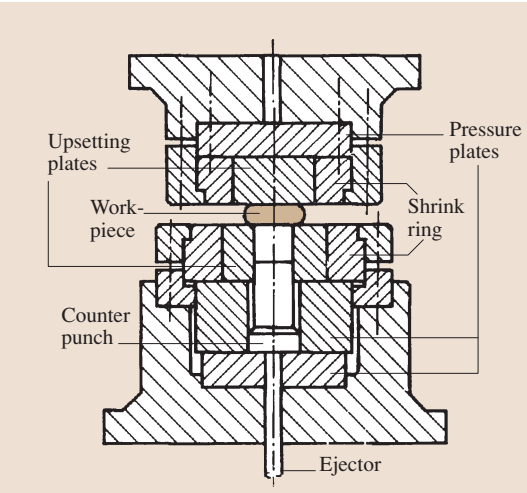

Fig. 7.56 Sketch of a typical upsetting tool (after [7.37])

Forging

Forging processes can be classified basically into two groups: Open-die forging and closed-die forging (Fig. 7.57). In open-die forging the dies possess simple geometries (usually flat) and the process is conducted hot. This process primarily serves to produce preforms for subsequent forming processes by reducing or increasing the cross-section of the workpiece. Upsetting is a fundamental process of open-die forging.

The basic closed-die forging process is impression forging in which a flash is produced that has to be separated from the workpiece after forging, [7.40]. The processes of fullering and gathering are used as pre-

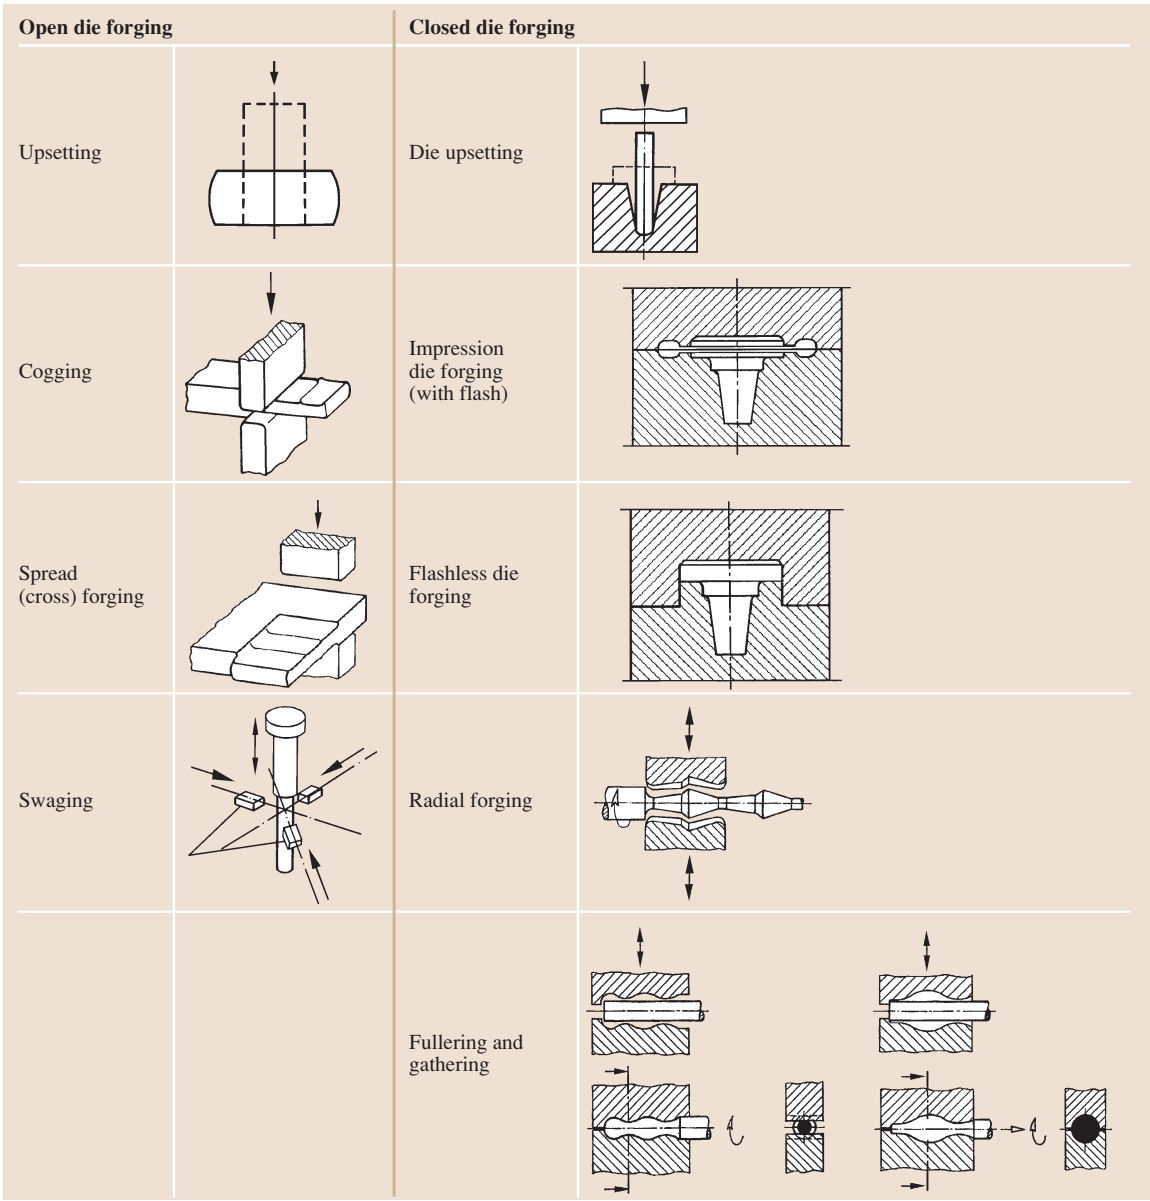

Fig. 7.57 Classification of forging processes

form processes before impression die forging. A typical impression forged product is shown in Fig. 7.58.

A typical closed die for forging (Fig. 7.59) consists of the upper and lower die parts. These parts form the forging cavity and the flash cavity separated by the parting line. A gutter is placed at the end of the flash land to collect the excess material. The forging cavity consists of webs and ribs. The flash is an important element in forging and controls the filling of the die. Furthermore, it serves as a means to compensate excessive material. On the other hand, it is the source of waste material in forging and should be kept as small as possible.

The force–displacement characteristics of closed-die forging exhibit three regions (Fig. 7.60): Until point P_1 the workpiece in the cavity is upset and then widens.

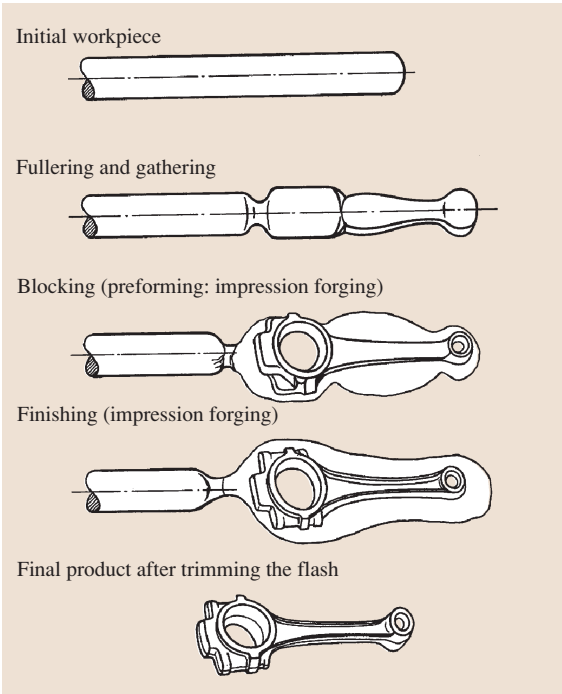

Fig. 7.58 Typical forging sequence (after [7.41])

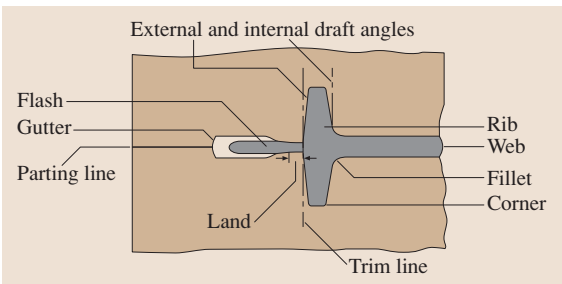

Fig. 7.59 Typical closed forging die (after [7.41])

At point P_1 the flash starts to form and hence the resistance to material flow increases, leading to the rising of the material during which the form of the die cavity is filled. At P_2 the die cavity fills and additional load is applied to close the dies finally. The necessary forming work is the shaded area under the load-displacement curve. This work has to be supplied as the forming energy by the forming machine.

The effect of the flash dimensions is twofold (Fig. 7.61): Increasing the flash–land ratio length/thickness (b/s), the braking effect of the flash increases and hence increasing the stress $\sigma_{z\,max}$ in the contact zone die-workpiece so that the forging force $\boldsymbol{F}$ increases. At

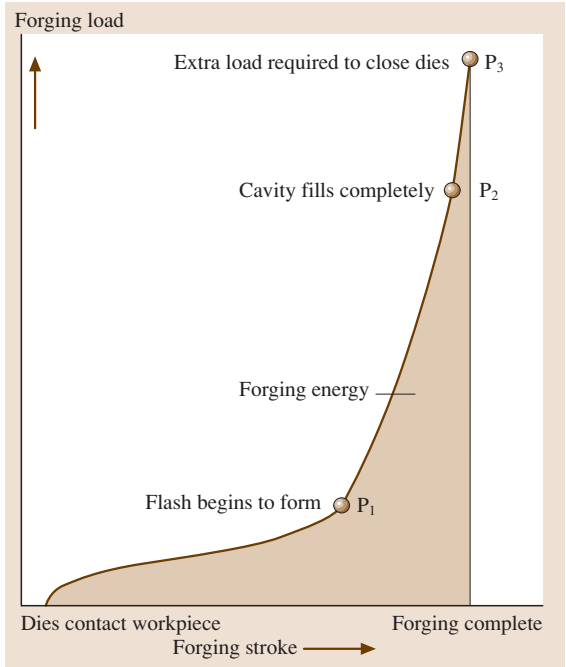

Fig. 7.60 Force–displacement characteristics of impression forging (after [7.42])

the same time however the excess mass Δm flowing into the die or the gutter decreases lowering the required forming energy W. In the given example, for a flash–land ratio of 4.5 there is nearly no change in the excess material so that the minimum forging energy is given for a die–land ratio of 4 to 5.

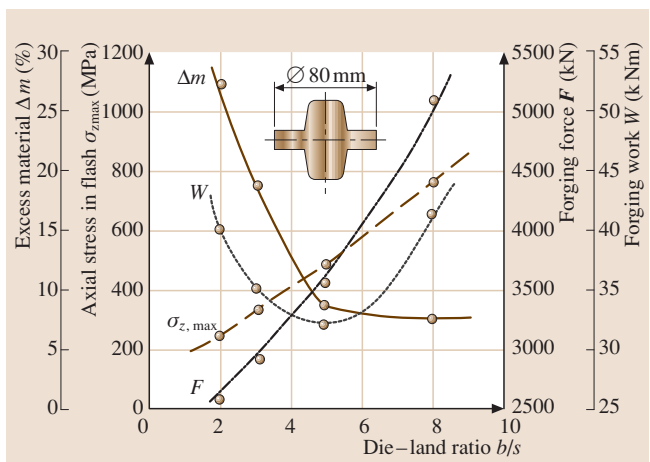

Fig. 7.61 Effect of flash dimensions on forging force and excessive material (after [7.37])

The stress distribution for axial-symmetric forgings resembles by elementary plasticity theory the stress distribution in upsetting (Fig. 7.62). The maximum stress occurs at the center of the part and is higher for wider flash–land ratios.

The maximum forging force can be estimated, for instance, by the upsetting equations as

$$\boldsymbol{F}^{\max} = -\sigma_{\mathrm{f}} \left(1 + 2\mu \frac{b}{s}\right) A_{\mathrm{p}} \,, \tag{7.61}$$

where σ_{f} is the flow stress (Table 7.23, see also [7.43]), μ the Coulomb friction coefficient (for steel at 1000 to 1100 °C $\mu = 0.12$ for lubricated and $\mu = 0.35$ for unlubricated cases), b/s (Table 7.24) the flash–land ratio, and A_{p} the total projected area including the flash. The flow stress can be approximated for the temperature and strain rate at the beginning of the process although the maximum force occurs towards the end. Hence, the strain rate is found as

$$\dot{\varepsilon} = \frac{v}{h_0} \,, \tag{7.62}$$

where h_0 is the initial height of the billet and v is the striking speed of the tool (Sect. 7.2.6). Notice that in Table 7.24 the b/s ratio is given for the three basic types of material flow in forging: upsetting, spreading (with large relative motions along the die surface), and rising (filling of the die cavities).

$\sigma_{\mathrm{f}}(T, \dot{\varepsilon}) = K(T)\dot{\varepsilon}^{m(T)}$

Typical failures in forged products are as follows:

1. Surface defects: These are surface scratches and cracks that are basically due to defects on the sheared surfaces of the billets or flash formation during preforming as well as imprints of cracks on the die surfaces.
2. Incomplete filling: Due to insufficient initial workpiece mass, inappropriate preforms, inaccurate workpiece positioning, wrong flash–land ratios, or too high gas pressures of the lubricant the die cavities may not fill completely.
3. Microstructural failures: The basic failure type is an insufficient grain flow.

Some of these failures can be removed by the subsequent machining operations of the forged products, so that these workpieces are not scrapped.

Basic die failures in forging are shown in Fig. 7.63. Dies are exposed to high temperatures, pressures, and sliding of workpiece materials along their sur-

Table 7.24 Recommended flash–land ratios (after [7.38])

Projected area of workpiece excluding the flash area (mm^2)	Flash–land ratio b/s

faces. The local pressures are as high as 1000 MPa or even higher and they vary with time. The wear is caused by sliding of workpiece materials with up to 50 m/s relative speed. Temperatures increase from 100–200 °C to 700–800 °C in extremely short durations with temperatures gradients of 1000 to 3000 °C/s. These effects lead to failure of dies through wear, thermal fatigue, mechanical fatigue, and plastic deformation.

Extrusion

Extrusion processes are classified according the technological differences into extrusion, impact extrusion and reducing (open-die extrusion) processes. The basic differences between extrusion and impact extrusion are that extrusion aims to produce profiles (semifinished products) whereas impact extrusion aims to produce single parts which are finished products. Furthermore, extrusion is performed usually hot (especially for steel materials almost always), whereas impact extrusion is usually performed cold (therefore also named as cold forging). Reducing is extrusion with area reductions less than 25 to 30%. In this case, there is no deformation of the material in the container. Further classifications are done according to the workpiece geometry and the relative motion between tools and workpiece during forming.

Figure 7.64 gives an overview of the principles of various extrusion processes.

In Fig. 7.65 the stress states as estimated by the elementary theory of plasticity for forward rod extrusion are given. Plastic deformation only occurs in the die-shoulder region and all stress components are compressive. The workpiece within the container remains basically elastic as well as the extruded rod after the exit of the die.

The fundamental parameters of the process are defined as area reduction

$$e = \frac{A_0 - A}{A_0} , \tag{7.63}$$

where A_0 and A_1 are the initial and final cross-sectional areas of the workpiece, and the ideal equivalent plastic strain φ

$$\varphi = \ln \frac{A_0}{A} = 2 \ln \frac{d_0}{d_1} . \tag{7.64}$$

The latter is the plastic equivalent strain at the axis of the extrudate. This strain is the minimum strain across the cross-section of the steady state region of the extruded shaft (Fig. 7.66).

A typical force–displacement curve for the extrusion process is given in Fig. 7.67. After the process starts at point A, there is a steep increase in force due to the elastic deformation of the billet followed by its plastification and filling of the dies. In many processes a discontinuity in the curve between A and B can be observed, which is due to the upsetting of the billet in the container (billets are slightly smaller in diameter – about 0.1 to 0.2 mm – than the container). The die is filled until point C. There is a local maximum due to the contact between unlubricated sheared surfaces of the specimens and the die. After point D the deformation zone in the die-shoulder remains

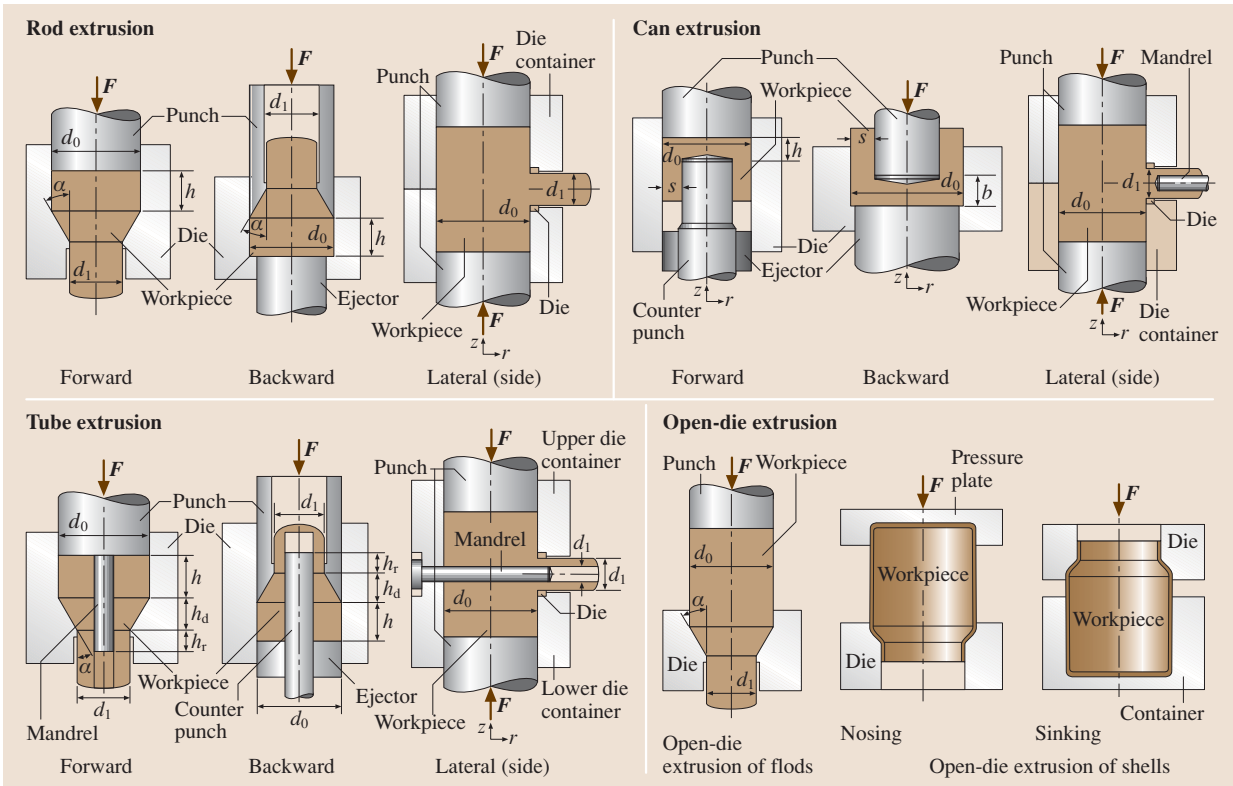

Fig. 7.64 Principles of typical extrusion processes

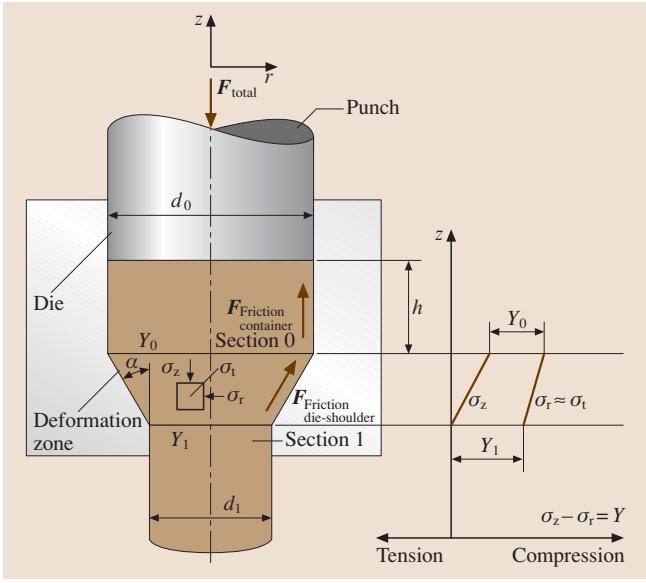

Fig. 7.65 Schematic sketch of forward (impact) extrusion of rods and stress states during extrusion (after [7.37])

steady so that there is only a decrease in the force due to the decrease in the friction forces in the die chamber.

The forming forces in extrusion of rods and tubes can be determined by the model suggested by Siebel. The total extrusion force consists in this case of the following parts

$$F_{\text{total}} = F_{\text{ideal}} + F_{\text{shear}} + F_{\text{friction container}} + F_{\text{friction die-shoulder}} + F_{\text{friction mandrel}} + F_{\text{friction mandrel-land}} \,. \quad (7.65)$$

The force components are described in Table 7.25. Here, σ_{fm} is the mean flow stress in the deformation zone given by

$$\sigma_{\text{fm}} = \frac{1}{\varphi_1 - \varphi_0} \int_{\varphi_0}^{\varphi_1} \sigma_{\text{f}}(\varphi)\,\mathrm{d}\varphi \,. \quad (7.66)$$

μ is the friction coefficient (between 0.04 to 0.08 for forward rod extrusion, 0.1 to 0.125 for tube extrusion), h is the billet length in the container, h_{r} is the length

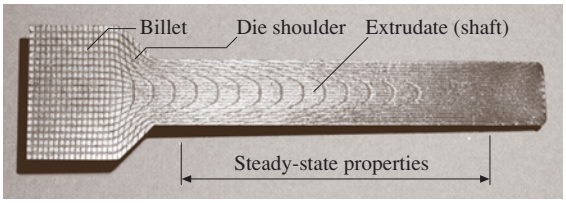

Fig. 7.66 Cross-section of a typical forward rod extrusion product with a deformation grid

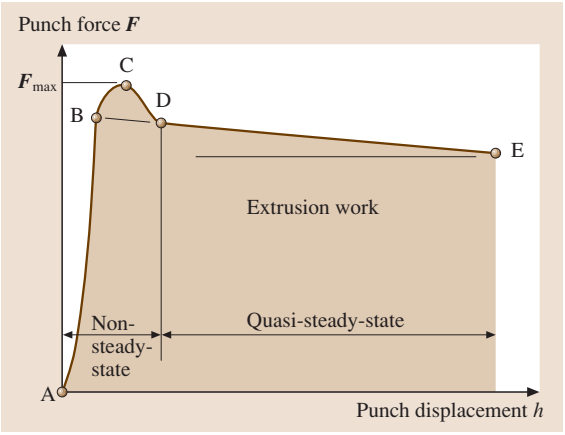

Fig. 7.67 A typical force displacement curve for forward rod extrusion

of the die exit land, and p_r is the pressure acting between the workpiece and the die (10–12 N/mm^2). For backward extrusion and the open-die container the friction is zero. For extrusion of profiles the cone angle $2\alpha = 180°$ usually. In this case, a dead-zone of workpiece material builds in the die so that the effective cone angle is $2\alpha = 90°$. This effective angle must be used in all force terms and the coefficient of Coulomb friction must be taken as 0.5 in the die-shoulder.

The effect of the die cone angle on various force components is exhibited in Fig. 7.68. The ideal force and the container friction is independent of the cone angle. The shear force increases with the cone

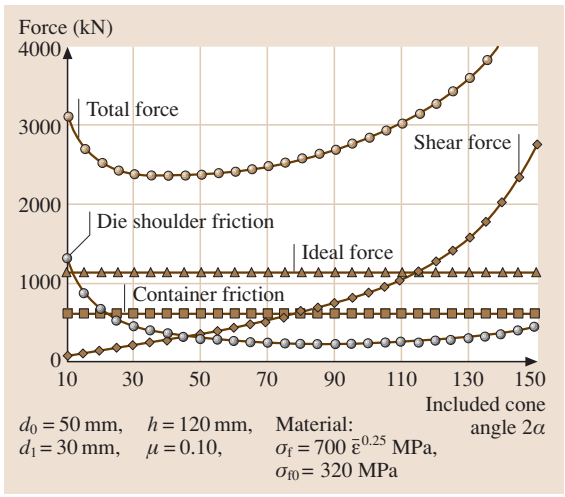

Fig. 7.68 Effect of various parameters on the extrusion force

angle, whereas the die-shoulder friction is minimum at $2\alpha = 90°$. Hence, the total force assumes a minimum value for the given process parameters around $2\alpha = 40°$.

The force for backward can extrusion can be computed by the equation of Dipper (Fig. 7.64)

$$F_{\text{punch}} = A_i \sigma_{f1} \left(1 + \frac{1}{3}\mu \frac{d_i}{b}\right) + \sigma_{f2} \left(1 + \frac{\mu + 0.5}{2} \frac{b}{s}\right) , \qquad (7.67)$$

where A_i is the punch cross-sectional area, μ the coefficient of friction (0.04 to 0.08), and the flow stresses

$$\sigma_{f1} = \sigma_f \left(\varphi = \ln\left[\frac{h_0}{b}\right]\right) ,$$
$$\sigma_{f2} = \sigma_f \left(\varphi = \ln\left[\frac{h_0}{b}\right]\left[1 + \frac{d_i}{8s}\right]\right) , \qquad (7.68)$$

where h_0 is the initial height of the billet.

A simpler but effective equation for the punch load during backward can extrusion is given by Hoogen-

Table 7.25 Force computations for rod and tube extrusion (after [7.37])

boom for ideal plastic materials

$$\frac{p}{\sigma_f} = \frac{2+\sqrt{3}}{\sqrt{3}} + \frac{1}{3}\sqrt{\frac{6s+d_i}{s}} \quad \text{early stage,}$$

$$\frac{p}{\sigma_f} = \frac{2+\sqrt{3}}{\sqrt{3}} + \frac{1}{2\sqrt{3}}\sqrt{\frac{s}{b}+\frac{b}{s}} \quad \text{late stage,} \qquad (7.69)$$

where p is the punch pressure and σ_f is the constant flow stress. The early stage is the quasi steady state process, whereas the late stage corresponds to the transient deformation for a can bottom of

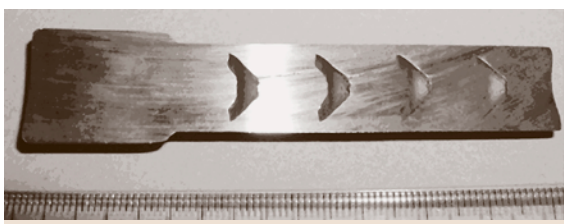
$$\frac{b}{s} < 5.5\frac{A_i}{A_e}\,, \qquad (7.70)$$

where A_e is the cross-sectional area of the billet. Other useful equations are given in [7.34].

For workpieces with nonaxial-symmetrical cross-sections such as bolts and nuts, the above equations can be applied replacing the diameters by equivalent diameters corresponding to the cross-section of the products.

Typical limits for the various extrusion processes are given in Fig. 7.69. The basic reason for limiting the process is the capacity of the forming presses and the tools. Another limiting factor is the formability of the material.

Typical failures in cold forged parts are internal and surface ductile cracks as well as galling. Examples of internal cracks are so-called Chevron cracks in extrusion



Material: 100Cr6 (not annealed) $2\alpha = 100°$ $\varphi = 0.25$

Fig. 7.70 Chevron cracks in cold extruded rods

Fig. 7.71 Typical process sequences of backward can extrusion

(Fig. 7.70). Galling is a type of adhesive wear. Adhesive wear occurs when the tools slide against the workpiece under high pressure after the breakdown of the lubricant. The heat generated due to friction causes microwelds to form between the sliding surfaces. Both the tools surface and the workpiece surface may be damaged.

Fig. 7.71 shows a typical sequence of processes for cold backward can extrusion. First, a slug is sheared off from a rod. Then these pieces are phosphated to carry the lubricant under high pressures. The lubricant in this case is soap. An upsetting process is performed in order to remove the irregular shear surface and supply a centering aid for the main extrusion process. Besides soap various other lubrications are possible (Table 7.26). Depending on the degree of deformation soap or MoS_2 or both with various pressure and fatty additives must be used.

A standard cold forging tool-setup is displayed in Fig. 7.72. It consists of reusable parts such as the base plates, pressure plates, intermediate plate, and the guides, as well as the product dependent interchangeable parts such as the punch, the die insert, and the shrink ring. The dies are exposed to radial, tangential,

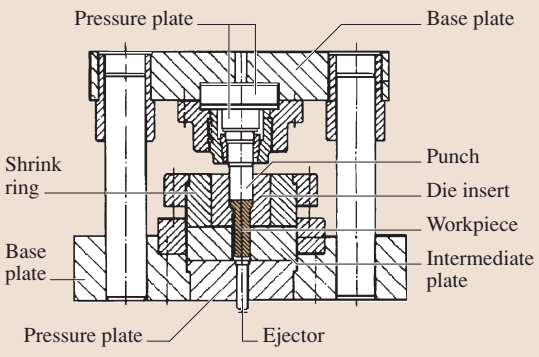


Fig. 7.72 Typical tool set-up for cold forward rod extrusion (after [7.44])

and equivalent stresses as shown in Fig. 7.73. With no precautions the maximum internal pressure can be

$$p_i \leq \frac{\text{yield strength of die material}}{2} . \qquad (7.71)$$

By imposing on the die a ring that has a smaller internal diameter than the outer diameter of the inner die, the sustainable internal pressure can be increased to

$$p_i \leq \text{yield strength of die material.} \qquad (7.72)$$

Drawing

Drawing can be broadly classified as drawing of solids parts such as rods, wires, or slabs, and drawing of hollow parts such as tubes or cans [7.45]. Figure 7.74a,b show typical wire drawing processes with the associated stress state in the deformation zone. Principally,

Table 7.26 Typical lubrication procedures (after [7.44])

Process	Deformation	Lubrication
Upsetting	Light	None
		Mi + EP + FA
	Severe	Ph + SP
Ironing and open-die extrusion	Light	Ph + Mi + EP + FA
	Severe	Ph + SP
Extrusion	Light	Ph + Mi + EP + FA
	Severe	Ph + SP
		Ph + MoS_2
		Ph + MoS_2 + SP

Mi = Mineral oil
SP = Soap
EP = Extreme pressure additive
Ph = Phosphate coating
FA = Fatty additives

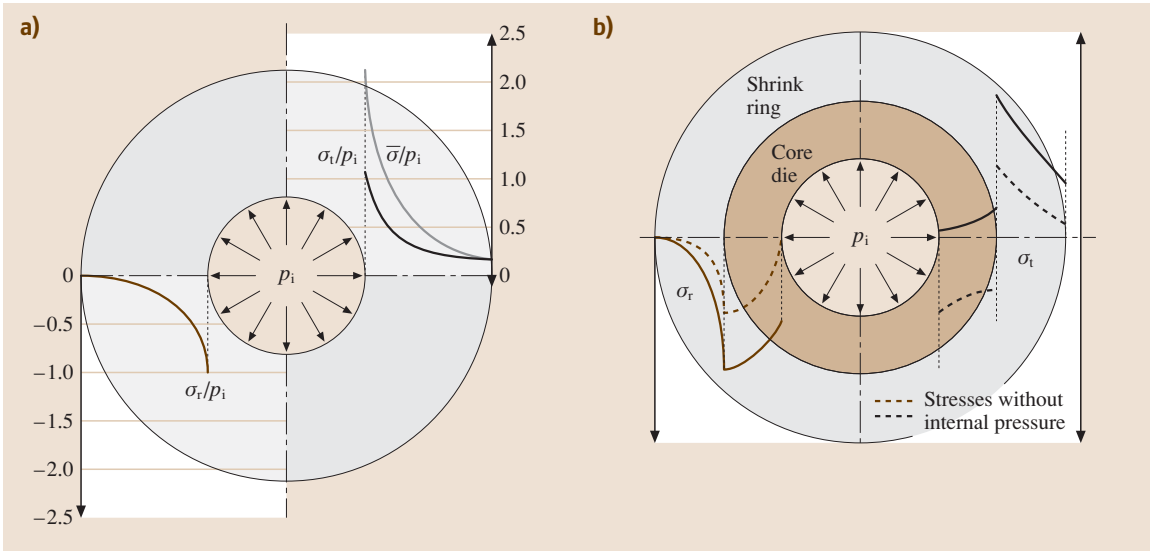

Fig. 7.73a,b Stresses in a die as a function of the internal forming pressure: **(a)** without a shrink ring, **(b)** with a shrink ring

the mechanics of deformation in drawing and extrusion are similar. The only difference is that in drawing the external force is applied on the exit side of die as a tension force as compared to extrusion where this force is on the entry side of the die and is compressive. Hence, the axial stresses in drawing processes are basically tensile compared to the compressive ones in extrusion. But both the radial and the circumferential stresses are compressive like in extrusion. In the case of the drawing of tubes, basically two broad categories are recognized: drawing with a mandrel or drawing without a mandrel. If a mandrel is used, this can be fixed, freely moving, or may have a guided move. One distinct group of tube drawing processes is the ironing process. This is often considered as a sheet metal forming process since basically the workpiece is a can obtained in deep-drawing. However, from the mechanics of deformation, this process is a typical bulk forming process in which the wall thickness of the can is reduced by drawing it through a die (Fig. 7.74b).

The drawing force can be determined by Siebel's equation

$$F_{\text{total}} = F_{\text{ideal}} + F_{\text{shear}} + F_{\text{friction die-shoulder}} + F_{\text{friction mandrel}} \,, \tag{7.73}$$

where the force components are given in Table 7.27. In the case of ironing, the punch force is given only by the first three components. However, if the force to be transmitted by the base of the can has to be determined, the force due to friction at the mandrel must be taken as negative.

The working window of the process of tube drawing is given in Fig. 7.75. There are basically three types of failure modes:

1. Rupture of the tube: The basic limitation of the process is that the tensile force must be applied through the formed tube portion. To prevent plastification leading to rupture

$$\sigma_z \leq \sigma_{f1} \,, \tag{7.74}$$

Table 7.27 Force computations for wire and tube drawing (after [7.37])

Process	F_{ideal}	F_{shear}	F_{Friction} (die-shoulder)	F_{Friction} (mandrel-die)
Wire and bar drawing	$A_1\sigma_{fm}\varphi$	$\frac{2}{3}\tan\alpha\sigma_{fm}A_1$	$2\sigma_{fm}\varphi\mu A_1/\sin 2\alpha$	0
Ironing and tube drawing over fixed mandrel	$A_1\sigma_{fm}\varphi$	$\frac{1}{2}\tan\alpha\sigma_{fm}A_1$	$2\sigma_{fm}\varphi\mu_s A_1/\sin 2\alpha$	$\pm\sigma_{fm}\varphi\mu_M A_1/\tan\alpha$

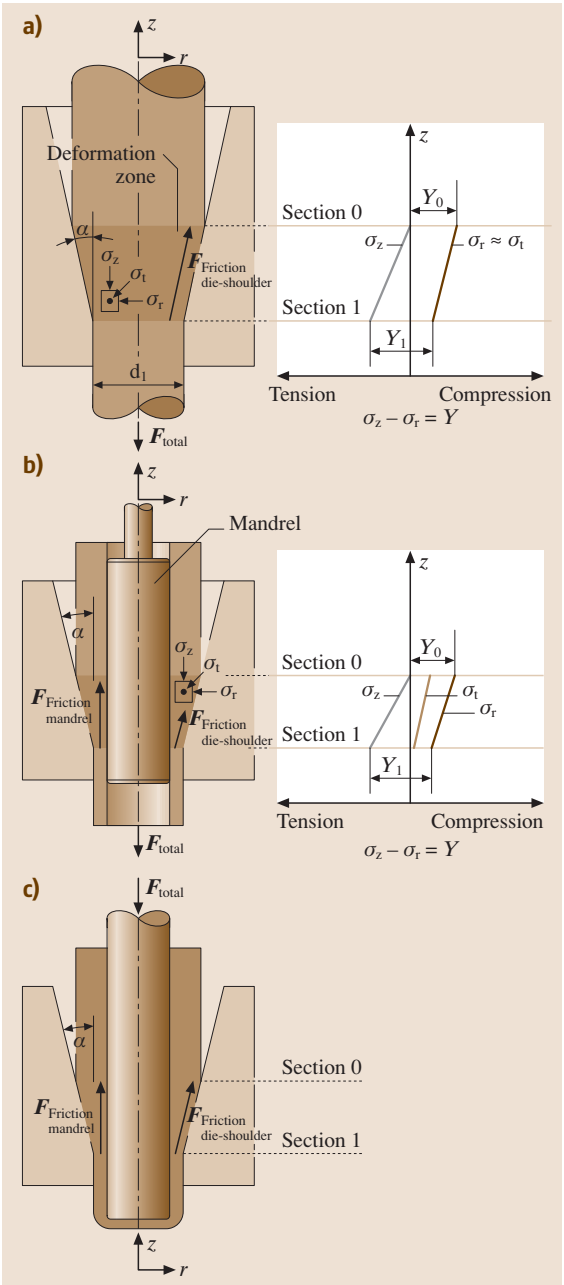

Fig. 7.74a–c Principles of typical drawing processes: (a) wire drawing, (b) tube drawing, (c) ironing

where σ_z is the uniform axial stress at the exit side and σ_{f1} is the mean flow stress at the same side. To ensure stability of the process usually the axial stress is taken less than 75% of the mean flow stress.

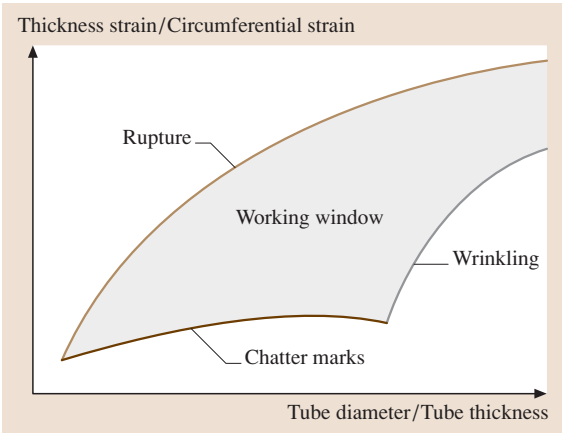

Fig. 7.75 Working window for tube drawing (after [7.37])

2. Chatter marks: Due to stick-slip effects the surface of the product shows marks that lower its quality. This defect can be avoided by increasing the stiffness of the system workpiece–tools.
3. Wrinkling: This failure type results from the compressive circumferential stresses in the tubes.

The maximum amount of area reductions for various wire materials during multiple die drawing is given in Table 7.28:

Wire drawing is basically a cold forming process. Residual stresses in the product are important both for service loading, as well as for subsequent processing of the material. Basically, harmful, large tensile residual stresses are left at the surface of the tube or rod after forming. Therefore, various precautions are suggested to reduce these high tensile residual stresses. One methodology is to use a double die design in which the second die has a very low area reduction. Figure 7.76 shows the effect of the after-reduction. Through a second low strain drawing die the high tensile stresses are reduced from about 550 to 250 MPa.

If the second area reduction is too small the plastification in the second die will be so low that the residual stress state will not change considerably; if, however, the area reduction is too large, this may cause a high plastic strain that may generate its own residual stress state that may be also not beneficial. Hence there is an optimum amount of area reduction and also a minimum distance between the two drawing dies.

Rolling

The forming process of passing a workpiece between rotating rolls is called rolling [7.30, 33]. According

Table 7.28 Allowable area reductions for wire drawing (after [7.38])

Material	Ultimate strength (MPa)	Initial wire diameter (mm)	Strain φ in each die	Total Strain	Number of draws
Steel	400	4–12	0.18–0.22	2.80–4.00	8–21
	1200	4–12	0.18–0.22	3.80–4.00	
	1200	0.5–2.5	0.12–0.15	1.20–1.50	
Cu-alloys	Cu (soft)	8–10	0.40–0.50	3.50–4.00	5–13
	250	1–3.5	0.18–0.20	2.00–2.00	
Al-alloys	Al (soft)	12–16	0.20–0.25	2.50–3.00	5–13
	80	1–3.5	0.15–0.20	1.50–2.00	

to the kinematics of the rolls and the workpiece motion rolling can be classified into three process families (Fig. 7.77). By the die geometry flat rolling (Fig. 7.78a) and profile rolling (Fig. 7.78b) processes are categorized. The process of reducing the thickness of a slab to produce a thinner and longer but only slightly wider product is referred to as flat rolling, whereas the forming by shaped rolls is known as profile rolling. Besides producing continuous products such as slabs, rolling is also used to form discrete parts such as bolts (Fig. 7.79) and rings.

Flat rolling is the basic forming process to produce plates and sheets. In the initial stages is conducted hot.

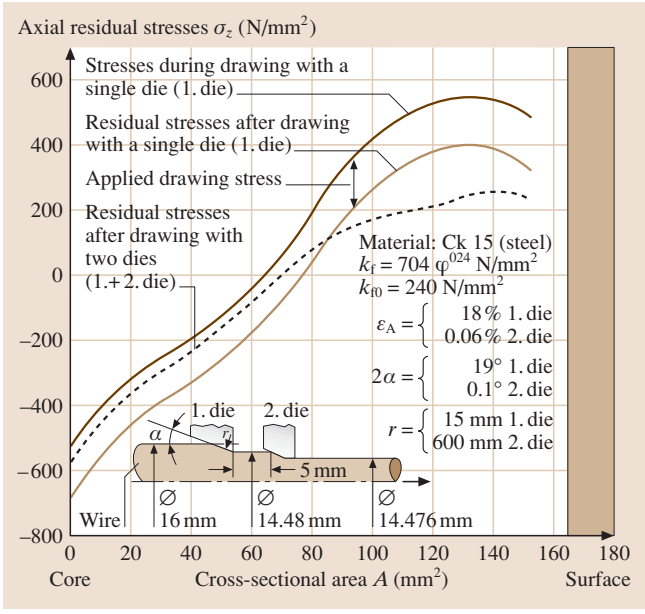

Fig. 7.76 Effect of second drawing die on the residual stresses (after [7.46])

For precision sheets the final passes are done cold. In both cases, the rolling process generates a typical texture in the products that is the source of anisotropic behavior of sheet products.

The variables of the rolling process are given in Fig. 7.80. It can be assumed that the width b of the workpiece is large enough such that during rolling no widening occurs. At a position of s_n a neutral plane exists. Before that neutral plane the workpiece material is slower than the rolls and after that it is faster. In order to ensure initial grasping of the workpiece by the rolls the contact angle α must fulfil

$$\alpha \le \mu \,, \tag{7.75}$$

where μ is the coefficient of Coulomb friction. The mean equivalent strain over the deformation zone is given by

$$\varphi = \ln\left(\frac{h_0}{h_1}\right) \,, \tag{7.76}$$

whereas the mean equivalent strain rate is

$$\dot{\varphi} = \varphi\omega\sqrt{\frac{R}{h_0 - h_1}} \,, \tag{7.77}$$

where ω is the rotational speed of the rolls in rad/s and R is the roll radius.

The vertical component of the pressure on the rolls can be approximated by [7.33]

$$\sigma(x) = \sigma_{fm}\left(1 + \frac{x^2/R + 2\mu x}{h_1 + x^2/R}\right) \quad \text{for} \quad 0 \le x \le s_n \,,$$

$$\sigma(x) = \sigma_{fm}\left(1 + \frac{2\mu R(s-x) - (s^2 - x^2)}{h_1 R + x^2}\right) \quad \text{for} \quad s_n \le x \le s \,. \tag{7.78}$$

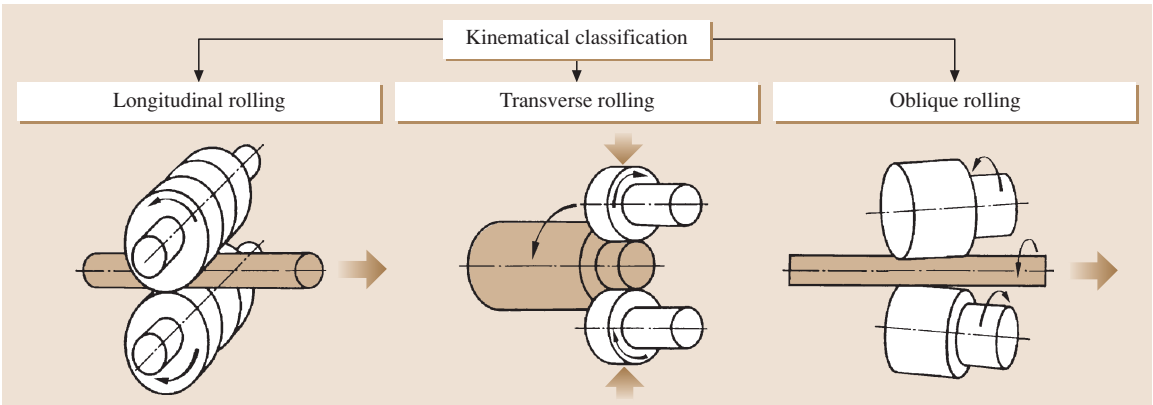

Fig. 7.77 Kinematical classification of rolling processes

The location of the neutral plane is given by

$$s_n = \frac{s}{2}\left(1 - \frac{s}{2\mu R}\right) , \qquad (7.79)$$

with

$$s = \sqrt{R(h_0 - h_1)} .$$

The mean flow stress is given in hot rolling for the mean equivalent strain rate and in cold rolling for the mean equivalent strain. The pressure on the rolls assumes a maximum value at the neutral plane (*friction hill*).

The rolling force F is found by

$$F = b \int_0^s \sigma(x)\,\mathrm{d}x . \qquad (7.80)$$

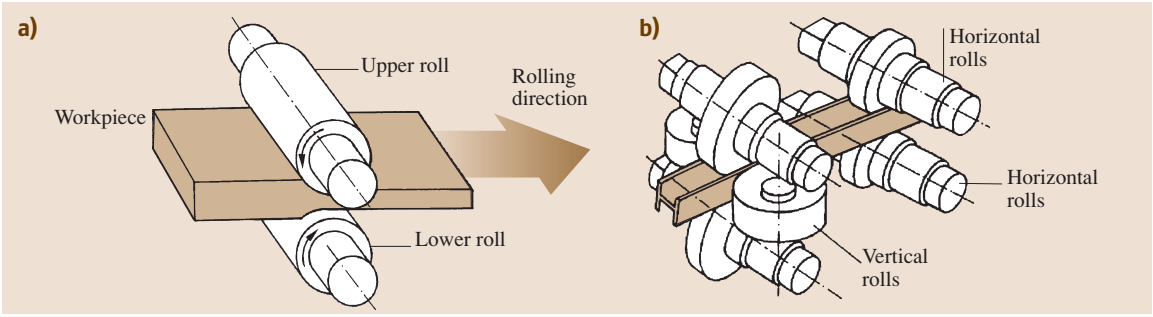

Fig. 7.78a,b Classification of rolling processes by die geometries: (a) Flat rolling, (b) profile rolling

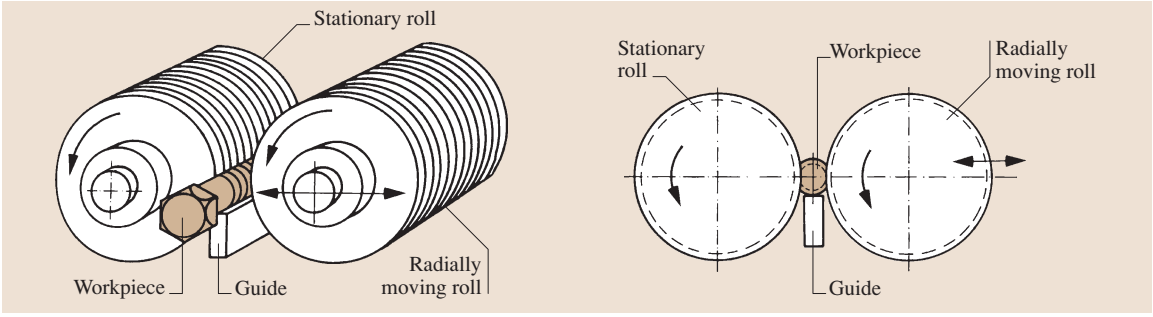

Fig. 7.79 Thread rolling of bolts

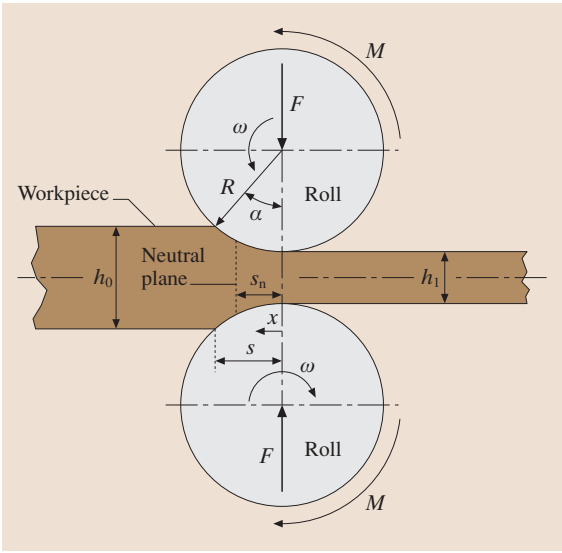

Fig. 7.80 Parameters of flat rolling

The rolling moment M of a single roll is given by

$$M = Fr\,, \tag{7.81}$$

where r is the moment arm given by [7.47]

$$r = 0.385s \quad \text{for} \quad \frac{R}{h_1} > 25\,,$$

$$r = \left[0.78 + 0.017\left(\frac{R}{h_1} - 0.163\sqrt{\frac{R}{h_1}}\right)\right] s \quad \text{for} \quad s \le 25\,. \tag{7.82}$$

The power necessary for the rolling process is

$$P = 2M\omega\,. \tag{7.83}$$

The rolls are exposed to a rather uniformly distributed forming load along their axis and hence behave like a simply supported beam and bend with maximum deflection at the center of the roll. To counter this deflection, which may lead to a rolled sheet with varying thickness, rolls are usually cambered, i. e. profiled rather than cylindrical. If the camber is insufficient, the thinner edges elongate plastically more than the center. Hence, in the rolled product compressive residual stresses are built at the edges and tensile residual stresses are built in the center parts (Fig. 7.81). This may lead also to centerline cracking, warping, or edge wrinkling. On the other hand, if the camber is too much, then the edge regions are elongated less plastically, leading to tensile residual

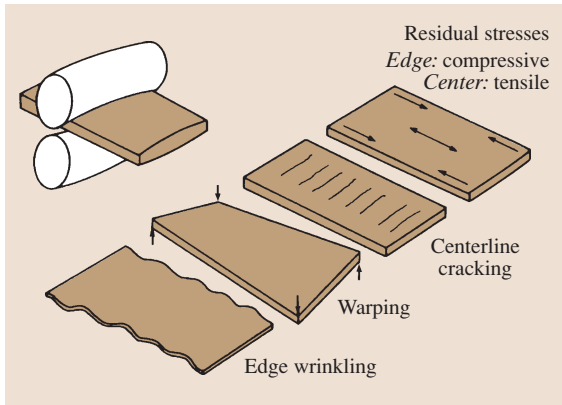

Fig. 7.81 Effects of insufficient camber of rolls (after [7.30])

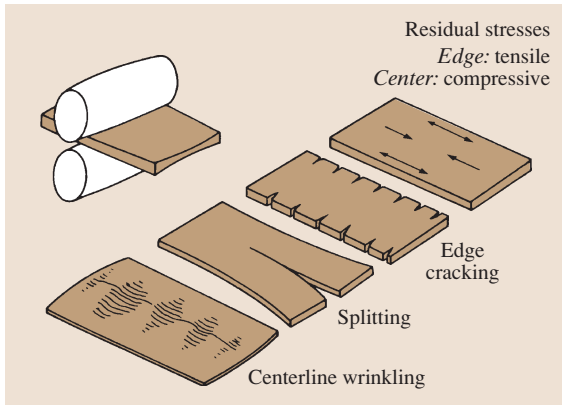

Fig. 7.82 Effects of excessive camber of rolls (after [7.30])

stresses at the edge region with edge cracking, centerline wrinkling, and splitting (Fig. 7.82). Roll bending can also be reduced by one or several back-up rolls.

Roll flatting is another limiting phenomenon of flat rolling. Due to the elastic deformations of rolls there is a minimum thickness of the end product [7.30]

$$(h_1)_{\min} = \frac{C\mu R}{E/(1-\nu^2)}(\sigma_{\mathrm{fm}} - \sigma_{\mathrm{t}})\,, \tag{7.84}$$

where C is a factor between 7 and 8, E is Young's modulus of the roll material, ν Poisson's ratio, σ_{fm} the mean flow stress for the deformation zone, and σ_{t} the front or back tension applied to the rolled sheet. Hence, the minimum thickness to be rolled can be decreased by decreasing friction, decreasing the roll diameter, increasing the stiffness of the rolls, decreasing the flow stress, and increasing the back and/or front tension.

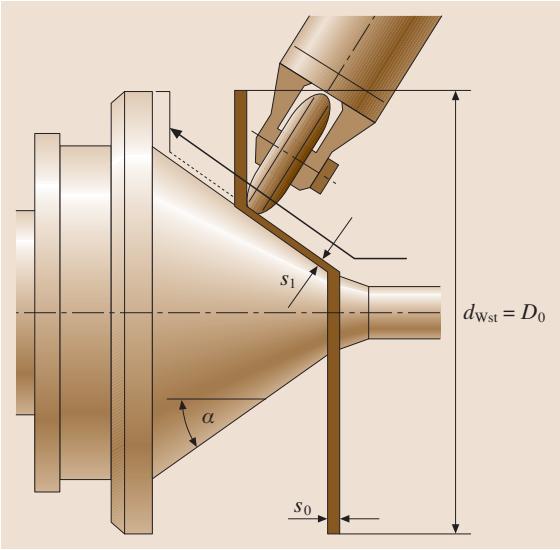

Fig. 7.83 Principle of shear forming process

Another process of rolling is the flow (shear) forming (turning) process (Fig. 7.83). In this process, a flat sheet is formed over a mandrel by means of a shear forming roll that is reducing its thickness but keeping its diameter constant. This process should not be mixed with sheet forming process spinning in which the sheet thickness is more or less constant but the diameter of the initial workpiece is reduced (Fig. 7.35). The final thickness of the workpiece is given by

$$s_1 = s_0 \sin\alpha \,. \tag{7.85}$$

If the final thickness is selected correctly the plastic deformation is confined only at the roll region, so that the rest of the workpiece remains stress-free. The key parameter of the process is the mandrel angle α. This angle must be less than 80° for localized plastic shear deformation and can be at least 12 to 18°. By a second pass this minimum angle can be reduced to even 8°.

The process of producing cylindrical parts is usually called flow forming whereas the forming of tapered parts is called shear forming.

7.2.5 Sheet Forming Processes

Membrane Theory

The approximate analysis of sheet forming processes can be performed by membrane theory [7.48]. Consider an axisymmetrical shell as shown in Fig. 7.84. The principal radii of curvature are in the hoop plane and in the meridian plane.

For thin plastically deforming shells, the bending moments are negligible and because of axial symmetry the hoop (σ_θ) and tangential (σ_ϕ) stresses are principal stresses (Fig. 7.85). The stress normal to the surface can be neglected, so that the resulting stress state is the one of plane stress. Friction forces are neglected. Only uniform pressure loads normal to the surface (although small enough with respect to the flow stress) and uniform edge tensions tangential to the surface are allowed.

It is furthermore assumed that work hardening is compensated by thinning of the sheet, so that the product of flow stress times current thickness is constant

$$\sigma_f t = T_f = \text{const.} \,, \tag{7.86}$$

where T_f is the so-called force resultant.

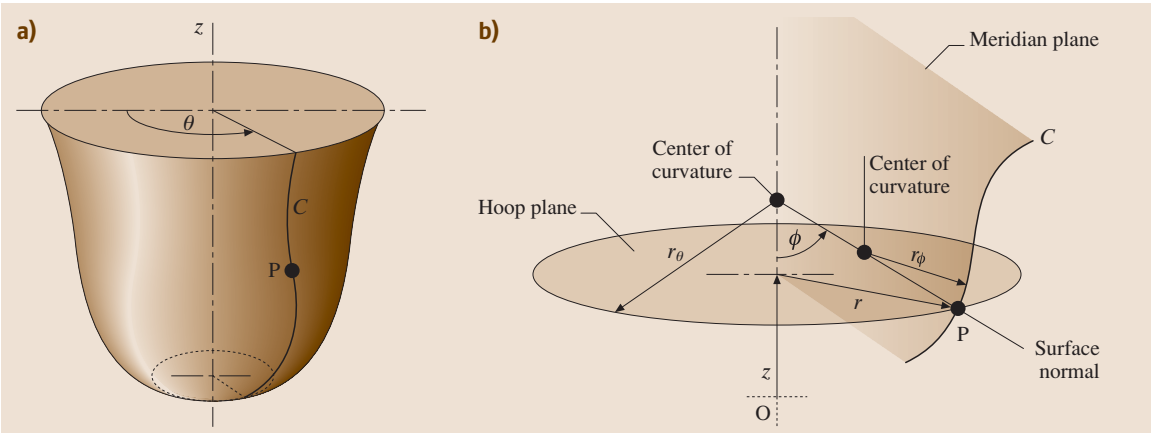

Fig. 7.84 (a) Axisymmetrical shell. (b) Radii of curvature r_θ and r_ϕ

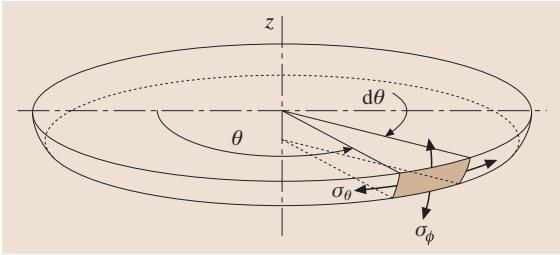

Fig. 7.85 Stress components in a shell

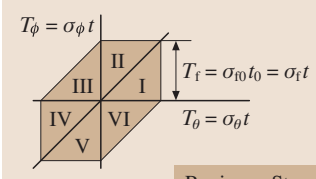

Region	Stress state	Flow condition
I	$T_\theta > T_\phi > 0$	$T_\theta = T_f$
II	$T_\phi > T_\theta > 0$	$T_\phi = T_f$
III	$T_\phi > 0 > T_\theta$	$T_\phi - T_\theta = T_f$
IV	$0 > T_\phi > T_\theta$	$T_\theta = -T_f$
V	$0 > T_\theta > T_\phi$	$T_\phi = -T_f$
VI	$T_\theta > 0 > T_\phi$	$T_\theta - T_\phi = T_f$

Fig. 7.86 Tresca flow criterion in terms of the force resultants

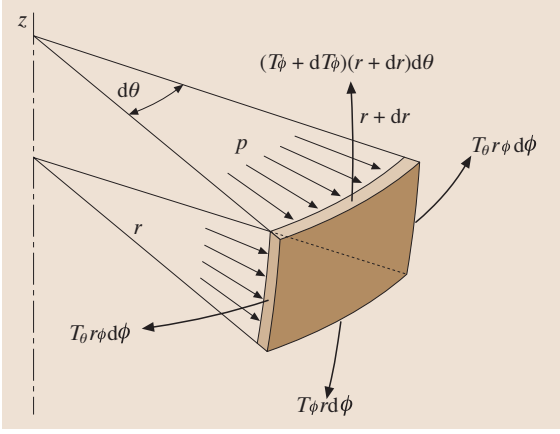

Fig. 7.87 Free body diagram of a typical shell element

Finally, the Tresca flow criterion is assumed to be valid as given in Fig. 7.86.

The static equilibrium of forces acting on a typical infinitesimal shell element (Fig. 7.87) supplies in the normal direction to the shell

$$p = \frac{T_\theta}{r_\theta} + \frac{T_\phi}{r_\phi} \tag{7.87}$$

and in the circumferential direction

$$\frac{dT_\phi}{dr} - \frac{T_\theta - T_\phi}{r} = 0\,. \tag{7.88}$$

Equations (7.87) and (7.88) together with the Tresca flow criterion (Fig. 7.86) constitute the framework of the membrane model to analyze sheet forming processes.

Plastic Anisotropy

Characterization of Anisotropy. Grains tend to assume preferred orientations during plastic deformation, since this deformation is achieved by slip or twinning. Preferred orientation of the grains will induce a direction dependent behavior of metals called anisotropy. The most obvious effect of anisotropy is observed in forming of sheets that are produced by rolling. Anisotropy of sheets results in earing at the rim of a deep drawn product (Fig. 7.109c).

Anisotropy in sheets is characterized by the Lankford parameter or anisotropy coefficient r. It is measured in the simple tension test (Fig. 7.88)

$$r = \frac{\varepsilon_b}{\varepsilon_t} = \frac{\ln \frac{b_1}{b_0}}{\ln \frac{t_1}{t_0}}\,, \tag{7.89}$$

where ε_b and ε_t are the true strains in width and thickness directions. For most metals the value of r changes

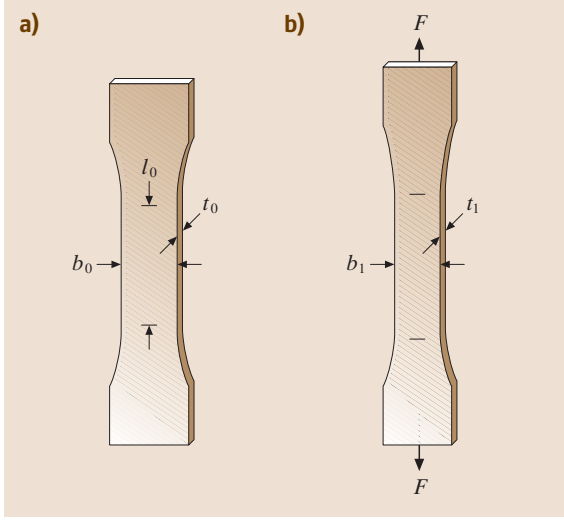

Fig. 7.88a,b Simple tension test of sheet metal: **(a)** undeformed, **(b)** deformed states

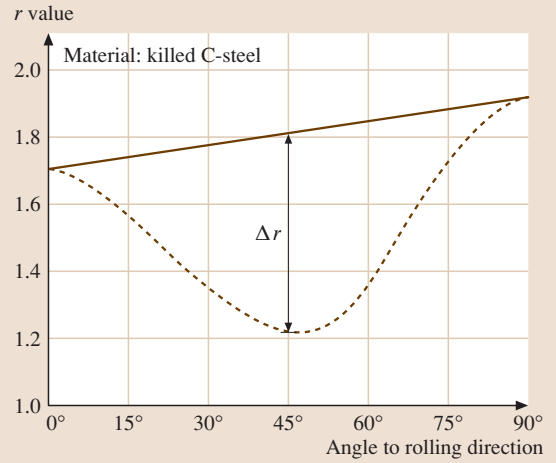

Fig. 7.89 Geometrical interpretation of the planar anisotropy coefficient

with the longitudinal strain, and by convention a longitudinal elongation of 20% is used for comparison purposes.

More importantly, the r-value changes with the orientation of the specimen with respect to the rolling direction. This variation is determined by three r-values obtained from specimens in the rolling direction, transverse to the rolling direction, and 45° to it. The average r-value, also called normal anisotropy r_n, is defined as

$$r_n = \frac{r_{0°} + 2r_{45°} + r_{90°}}{4} . \qquad (7.90)$$

Variation of the r-value over the plane of the sheet is described by Δr, the planar anisotropy coefficient

$$\Delta r = \frac{r_{0°} + r_{90°} - 2r_{45°}}{2} . \qquad (7.91)$$

Table 7.29 Anisotropy values for various materials

Material	r_n value	Δr
Deep drawing steels (DC01–DC07; cold rolled)	1.30 to 2.00	up to 0.70
Stainless steel	0.70 to 1.10	−0.25 to 0.20
TRIP steels	0.9	about −0.03
Aluminum alloys	0.60 to 0.80	−0.60 to −0.15
Copper	0.60 to 0.80	–
Brass	0.80 to 1.00	–
Zinc alloys	0.20 to 0.6	–
Titanium alloys	2.00 to 8.00	up to 4.00

The geometric interpretation of the planar anisotropy coefficient is given in Fig. 7.89.

Typical anisotropy values for various materials are tabulated in Table 7.29.

The Anisotropic Flow Condition. The oldest anisotropic flow condition was proposed by *Hill* [7.26]. Neglecting planar anisotropy and assuming plane stress states (which is usually justified for sheet forming processes), the criterion reads in the principal stress configuration as

$$\sigma_1^2 - \frac{2r}{r+1}\sigma_1\sigma_2 + \sigma_2^2 = \sigma_f^2 , \qquad (7.92)$$

where σ_1 and σ_2 are the in-plane principal stresses and σ_f is the flow stress. The effect of the normal anisotropy value r on the flow locus is shown in Fig. 7.90. For $r = 1$ the standard von Mises ellipse is obtained. For r-values larger than 1, the ellipse elongates along the major axis whereas it shrinks along the minor axis. Hence, in the case of biaxial tension or biaxial compression larger relative stresses are necessary to initiate plastic flow. In the second and forth quadrants plastic flow will oc-

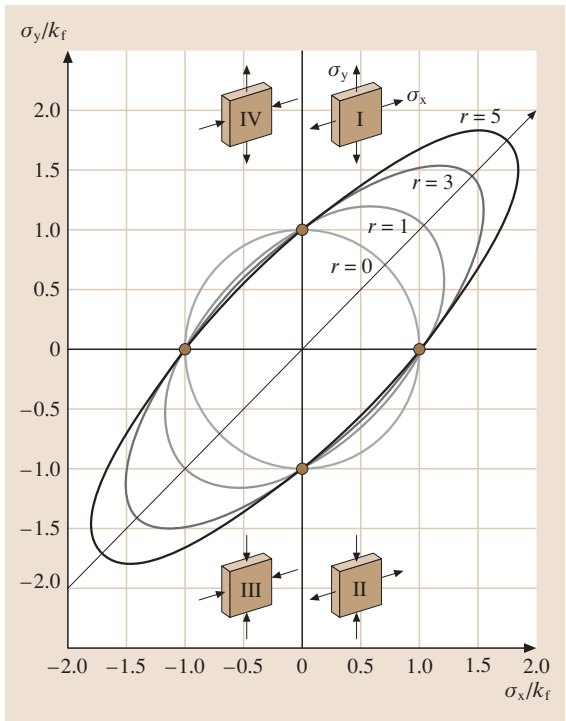

Fig. 7.90 Effect of the r value on the flow locus

Table 7.30 Various nonquadratic anisotropic flow criteria (flow planar isotropy) (after [7.36])

Flow criterion	Equation	Suggested parameter values
Hill 1979	$\lvert\sigma_1+\sigma_2\rvert^m+(2r+1)\lvert\sigma_1-\sigma_2\rvert^m=2(r+1)\sigma_f^m$	$1.3\le m\le 2.2$ (for $m=2$ criterion reduces to Hill 1948)
Hosford	$\sigma_1^a+r(\sigma_1-\sigma_2)^a+\sigma_2^a=(r+1)\sigma_f^a$	$a=6$ for ffc metals $a=8$ for bbc metals
Barlat 1989	$a\lvert k_1+k_2\rvert^M+a\lvert k_1-k_2\rvert^M+(2-a)\lvert 2k_2\rvert^M=2\sigma_f^M$ $k_1=\frac{\sigma_x+h\sigma_y}{2}$, $k_2=\left[\left(\frac{\sigma_x-h\sigma_y}{2}\right)^2+p^2\tau_{xy}^2\right]^{1/2}$	a, h, p and M are material parameters
Banabic–Barlat 2000	$(m\sigma_1+n\sigma_2)^{2k}+(p\sigma_1+q\sigma_2)^{2k}+(r\sigma_1+s\sigma_2)^{2k}=2\sigma_f^{2k}$ $m=\frac{\left(-\frac{\sigma_f}{\sigma_b}+4\right)}{3}$, $n=\frac{\left(\frac{\sigma_f}{\sigma_b}-4\right)}{3}$, $p=2\frac{\left(\frac{\sigma_f}{\sigma_b}-1\right)}{3}$, $q=\frac{\left(\frac{\sigma_f}{\sigma_b}+2\right)}{3}$, $r=\frac{\left(-\frac{\sigma_f}{\sigma_b}-2\right)}{3}$, $s=2\frac{\left(\frac{\sigma_f}{\sigma_b}+1\right)}{3}$	σ_f is the uniaxial flow stress and σ_b is the biaxial flow stress

cur for slightly lower relative stresses than the isotropic case.

Hill's criterion has proven itself successful for steel, however for aluminum particularly this criterion fails. Also, it is able only to predict two or four ears in deep-drawing, although a different number of ears is also observed for certain materials. Several criteria, also called nonquadratic flow criteria have been introduced for these reasons. Table 7.30 depicts a few of them. Most of them have been developed basically to model forming of aluminum sheets.

Formability

Basic Failure Modes. Sheet parts can fail under various modes (Fig. 7.91) There are three basic failure types:

1. Wrinkling caused by compressive stresses.
2. Rupture/tearing caused by exceeding the capability of the material, usually preceded by necking.
3. Surface defects.

Most of the tests to evaluate the formability of sheet metals in sheet forming operations and particularly in deep drawing and stretch forming are focusing on the fracture failure mode. Fracture usually follows a necking, i. e. a localized thinning of the metal. Therefore, necking is usually accepted as a failure mode as well.

Necking. Sheets neck under simple tension in two stages: diffuse necking and localized necking

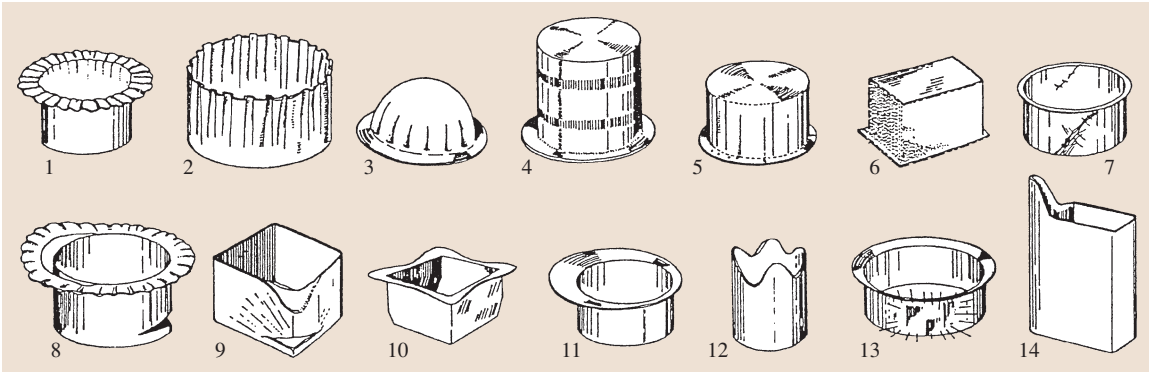

Fig. 7.91 Various failure modes in deep-drawing: 1 – flange wrinkling; 2 – wall wrinkling; 3 – part wrinkling; 4 – ring prints; 5 – traces; 6 – orange skin; 7 – Lüder's strips; 8 – bottom fracture; 9 – corner fracture; 10–12 – folding; 13,14 – corner folding (after [7.36])

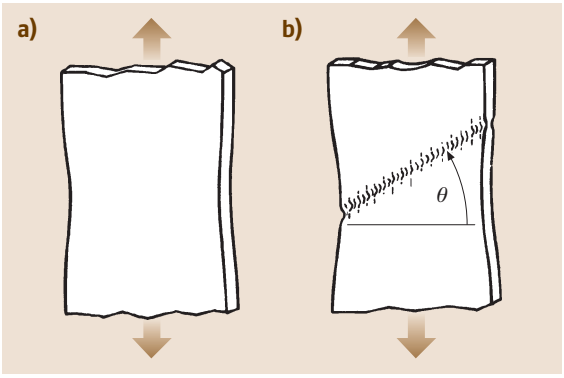

Fig. 7.92a,b Necking of sheet specimens under uniaxial tension: **(a)** Diffuse necking, **(b)** localized necking (after [7.30])

(Fig. 7.92); bulk specimens only exhibit diffuse necking. If the material's flow curve is represented by the Ludwik flow curve $\sigma_f = C \times \bar{\varepsilon}^n$, then it can be shown that

$$\text{for diffuse necking} \quad \varepsilon_1^{\text{necking}} = n \,,$$
$$\text{for localized necking} \quad \varepsilon_1^{\text{necking}} = 2n \,. \qquad (7.93)$$

If the stress state is not uniaxial, as is the usual case in most sheet forming processes, then the localized necking strain for an isotropic material is given as [7.30, 48]

$$\varepsilon_1^{\text{necking}} = \frac{n}{1 + \varepsilon_2/\varepsilon_1} \,. \qquad (7.94)$$

The localized necking angle with the tension axis is estimated as

$$\tan\theta = \frac{1}{\sqrt{-\varepsilon_2/\varepsilon_1}} \,, \qquad (7.95)$$

yielding an angle of 54° for simple tension of an isotropic specimen. For positive ratios of the two principal in-plane strains no localized neck is possible and only diffuse necking occurs.

Simulative Formability Tests. The Olsen or Erichsen test (Fig. 7.93) is the oldest test to evaluate formability of sheet metals. Both tests only differ slightly in the size of the tools. The principle is to stretch a sheet of metal by a hemispherical punch until fracture is observed. The punch depth in millimeters corresponds to the Erichson index (IE).

Another common test is the limiting dome height test by *Hecker* [7.49] (Fig. 7.94). Hecker's test is an improved Erichson test with larger tools and drawbeads increasing the measuring accuracy.

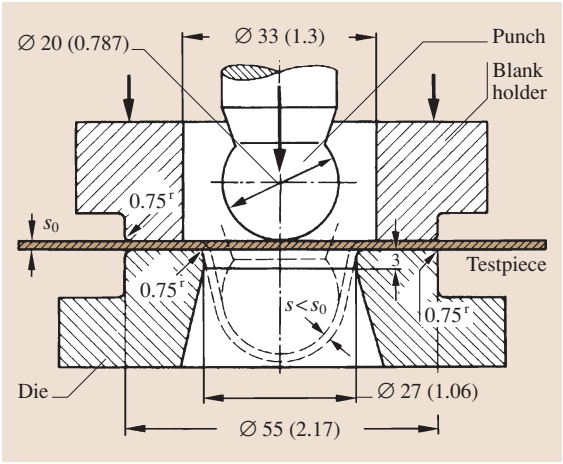

Fig. 7.93 Erichsen test (Dimensions in parentheses are in inches)

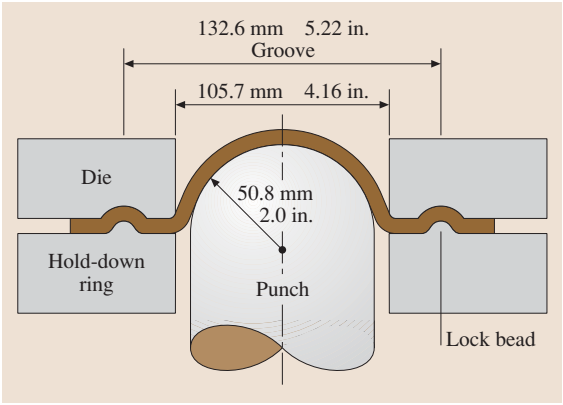

Fig. 7.94 Limiting dome height test by Hecker

Other tests such as Swift's cup test, the stretch–bend test, the wedge drawing test, the biaxial stretch test, the plane torsion test, hole expansion test etc. have been introduced in practice.

Forming Limit Diagrams. The forming limit diagram (FLD) consists of a curve in the principal in-plane strain space at which either necking starts or fracture is observed. It is basically a material property. Necking is localized in the tension–compression part and is expected to be diffuse in the tension–tension part (Fig. 7.95). The loading line on the left (dashed line) corresponds to a pure shear deformation, the central vertical line to plane strain tension, and the left dashed line to equibiaxial tension. Uniaxial simple tension is a loading line between the left dashed and the middle vertical lines.

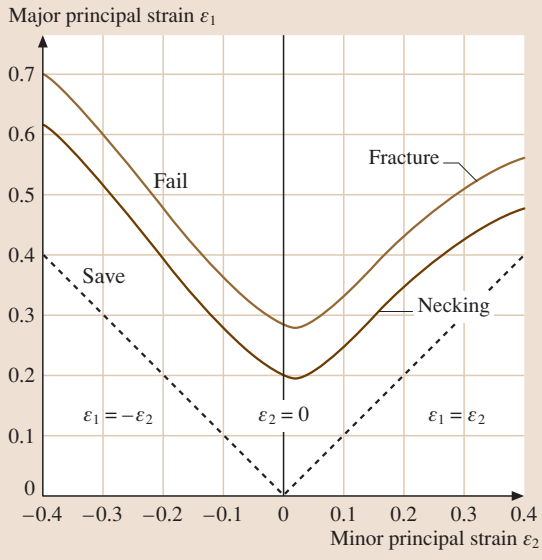

Fig. 7.95 Forming limit diagram for plane stress

FLD provided an efficient and practical method to assess the formability of a sheet product. It is applied in two different manners. *Experimentally*, a circular grid pattern is imposed on the sheet either mechanically, photochemically, or electrochemically. During forming the circles are deformed into ellipses. The principal strains are assumed to be along the major and minor axes of the ellipses. These minor and major radii of the ellipse are measured either manually or automatically by a digital camera. By comparing the measured local strains with the FLD, the range of safety for deep-drawing, the critical zones where necking and/or fracture are most likely to occur, the strain level and the favorable working conditions (blank-holder pressure, lubrication, placement of draw beads, etc.) can be determined, and hence the deep-drawing process can be improved. In this context a *severity index* ranging from 0 to 10 is introduced, indicating the distance of the measured strain state from the FLD-curve. *Numerically*, the analysis of the sheet forming process can be done, for instance, by finite element models a priori to the actual pressing and the computed strains can be compared with the respective FLD and the forming process can be assessed. This latter application is basic industrial practice today.

FLDs can be measured by various methods such as the uniaxial tensile test using specimens having various dimensions with and without notches (Fig. 7.96a), the hydraulic bulge test using elliptical dies (Fig. 7.96b), the

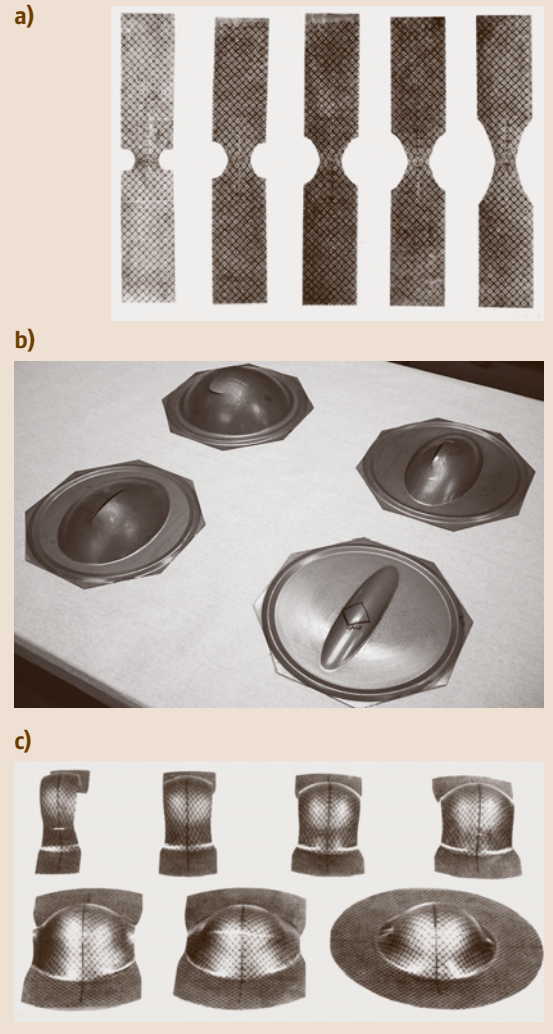

Fig. 7.96a–c Various methods of determining FLD: **(a)** uniaxial tensile test (courtesy V. Hasek), **(b)** hydraulic bulging test (courtesy N. Bay, DTU), **(c)** punch stretching test (courtesy V. Hasek)

punch stretching test using strips with various widths (Fig. 7.96c), the Nakamiza test (which is similar to the punch stretching test with the difference that the sheet is drawn instead of being stretched), the Hasek test (where circular specimens are used with various recesses), and the Marciniak test with hollow punches, etc.. Common to all tests is that numerous specimens or die geometries have to be used to simulate various principal strain ratios corresponding to various points on the FLD-curve.

The experimentally measured FLDs are not completely material properties. They depend on various other factors. It is known that the FLD-curve rises with increasing sheet thickness. Furthermore, it has been experimentally noticed that there is strain path dependence of the failure. Hence, if a tensile load path (meaning a strain path with positive slope on Fig. 7.95) is followed by a compressive load path (negative slope), the failure strain is lower than the one predicted by the FLD. On the other hand, if a compressive load path is followed by a tensile one, the failure strain is larger than the FLD strain. Also the grid size used in the experiments effects the measurements.

Bending

Bending Processes. Basic bending processes can be classified into two broad groups [7.50]: bending by linear tool motion (Fig. 7.97) and bending by rotary tool motion (Fig. 7.98).

In free bending [7.51] there is no contact between the workpiece and the die surface, whereas in die bending the sheet is bent between male and female dies. Free round bending is a continuous free bending process conducted in steps along the bending legs. In curling the workpiece is continuously bent by pushing it into a curved die. Bending by buckling is obtained by causing the workpiece to buckle normal to the applied force. The deformation region is limited either by local heating of the workpiece or clamping of the portion of the workpiece not to be deformed. In draw bending the sheet is shaped by being pulled through a die opening.

Roll bending is achieved by moving the workpiece through the gap created by three adjustable rolls. In roll forming the sheet is formed into a section between rolls with the form of the section. Folding is bending with a folding wing that folds the workpiece around the bending edge, whereas wiper bending or wiping is bending creating a full plastic section between a roller and a tool. The section is forced to conform to the roller as the tool is dragged around the roller. In roll straightening the roll axes can be normal or inclined to the bending plane. The workpiece is roll bent by corrugated rolls in the corrugating process.

The Mechanics of Bending. If a strip of width w and thickness t is bent by pure moments M at both ends, the strip assumes a curvature with radius r at its neutral axis (Fig. 7.99). The directions 1–3 are assumed as shown in the figure.

The bending strain for any axial fiber is given by

$$\varepsilon_1 = \ln\left(1 + \frac{y}{r}\right) , \tag{7.96}$$

where y is the distance of the fiber from the neutral axis having a radius of curvature r. This strain is positive at the upper fibers and negative at the lower fibers.

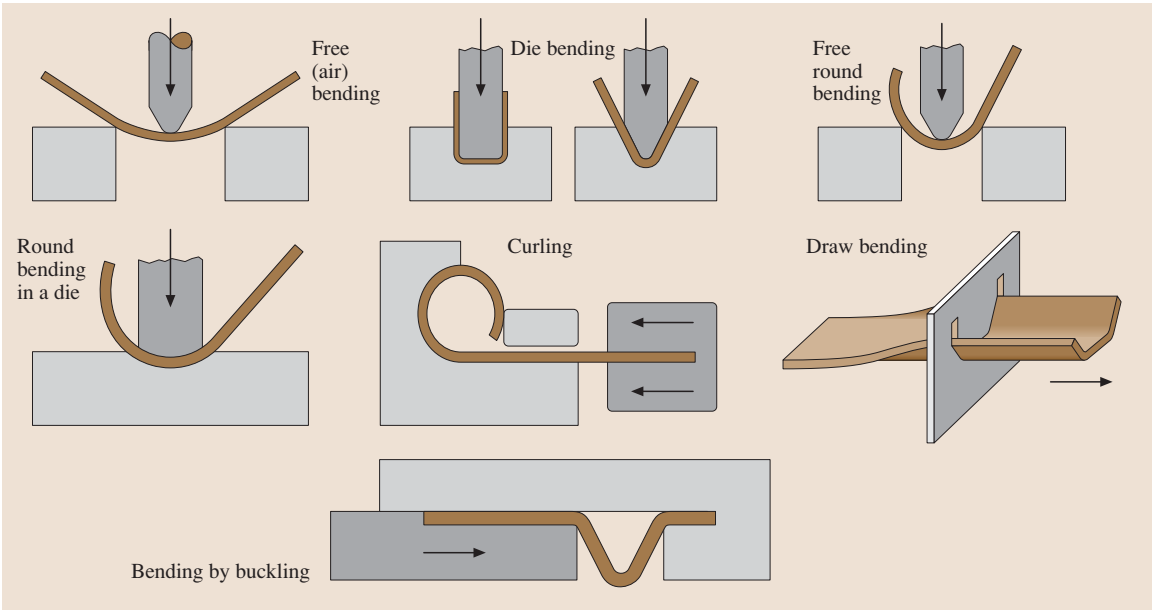

Fig. 7.97 Bending with linear tool motion

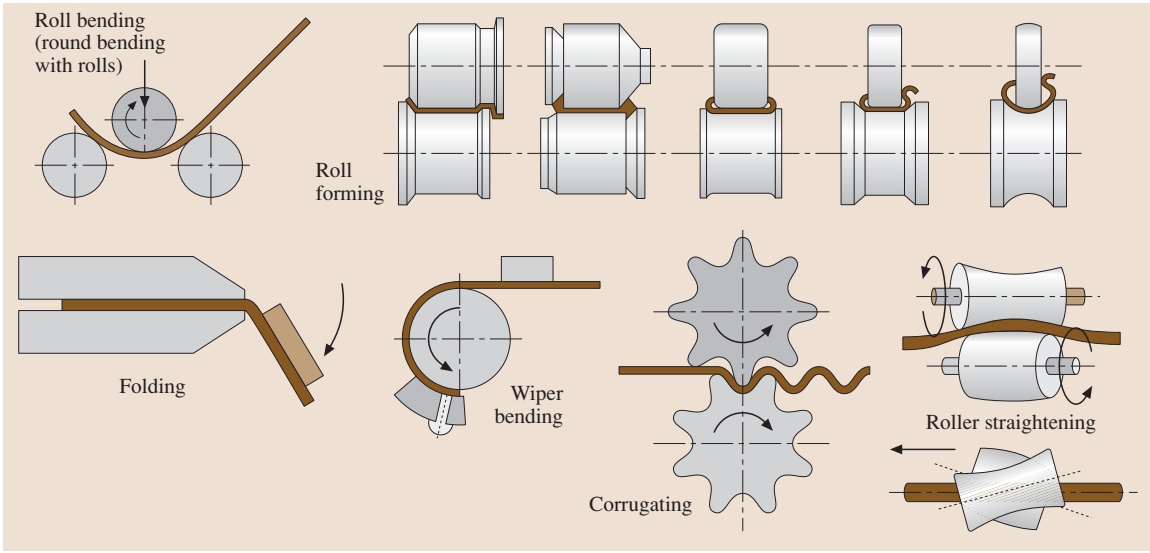

Fig. 7.98 Bending with rotary tool motion

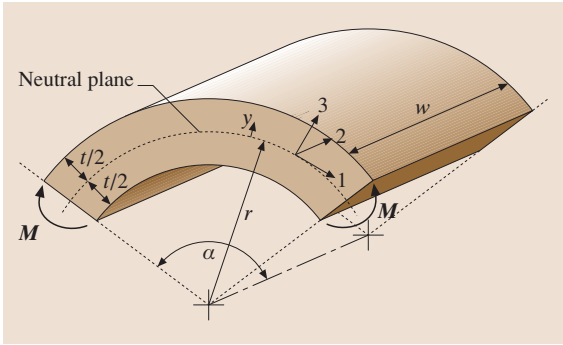

Fig. 7.99 Bending of a strip by pure moments

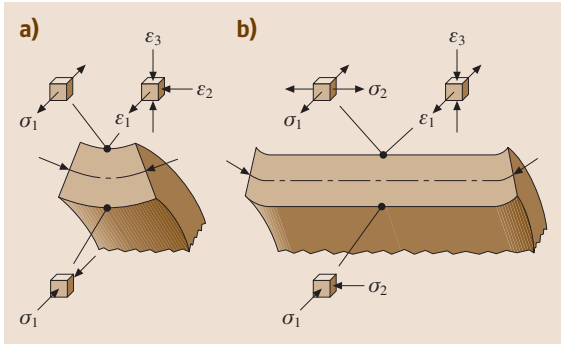

Fig. 7.100a,b Stress and strain states for bending of **(a)** narrow and **(b)** wide strips (after [7.52])

There are two extreme bending cases [7.52]: If the width of bent strip w is small as compared to its thickness t (Fig. 7.100a), then only the bending (axial) stress will develop, and hence the stress state is uniaxial with tensile stresses at the larger radius side and compressive stresses at the smaller radius side. The corresponding strain state is therefore

$$\varepsilon_1 = \varepsilon_2 = -\frac{1}{2}\varepsilon_1 \,. \tag{7.97}$$

Hence the width of the tension side of the strip will decrease and the width of the compressive side will increase. On the other hand, if the width of the bent strip is much larger than its thickness then in the middle regions of the strip a plane strain state will develop (Fig. 7.100b) with $\varepsilon_2 = 0$. If furthermore, the plane stress state is assumed with $\sigma_3 = 0$, it can be shown using the flow rule that $\sigma_2 = \sigma_1/2$. For this case of the plastic state, the flow stress and the equivalent strain is related to the axial components by

$$\varepsilon_1 = \sqrt{\frac{3}{2}}\bar{\varepsilon}\,,$$
$$\sigma_1 = \frac{2}{\sqrt{3}}\sigma_\mathrm{f}\,. \tag{7.98}$$

Even for a wide strip, at the ends an uniaxial stress state exists leading to a transverse curvature at both ends.

The elastic stress-strain relationship for the plane strain case is given by the generalized Hooke's law as

$$\sigma_1 = \frac{E}{1-\nu^2}\varepsilon_1\,, \tag{7.99}$$

where E is Young's modulus and ν is Poisson's ratio. Introducing the plane strain Young's modulus E', the elastic stress–strain relation gets

$$\sigma_1 = E'\varepsilon_1 \quad \text{with} \quad E' = \frac{E}{1-\nu^2} \,. \tag{7.100}$$

Figure 7.101a shows the axial strain distribution over the thickness of a strip. The true strain distribution is nearly linear. If the strains are large enough the material will plastify in the outer regions. Assuming that the material is perfectly plastic and the strip is wide, in the plastic regions the axial stress will be equal to the flow stress for plane strain as given by (7.98) (Fig. 7.101b). Assuming that the whole cross-section plastifies, the bending moment is given by

$$M = \frac{1}{2\sqrt{3}} W t^2 \sigma_\mathrm{f} \,. \tag{7.101}$$

After the moment is removed the bent part will spring back due to the elastic energy stored during bending (Fig. 7.102). The new radius of curvature will now be r'

$$r' = \left(\frac{1}{r} - \frac{2\sqrt{3}}{t} \frac{\sigma_\mathrm{f}}{E'} \right)^{-1} \,. \tag{7.102}$$

The residual stresses after unloading are given for the plastified region by (Fig. 7.101c)

$$\sigma_1^{\text{residual}} = \frac{2}{\sqrt{3}} \sigma_\mathrm{f} \left(1 - \frac{3y}{t} \right) \,. \tag{7.103}$$

The springback factor is defined by

$$\text{springback factor} \equiv \frac{r}{r'} \tag{7.104}$$

and is given for various materials and two relative bending radii in Table 7.31.

The basic failure mode in bending is fracture at the tensile side of the sheet. The smallest radius a sheet can be bent without failure is considered as its bendability. The bendability is highest if the bending axis is transverse to the rolling direction.

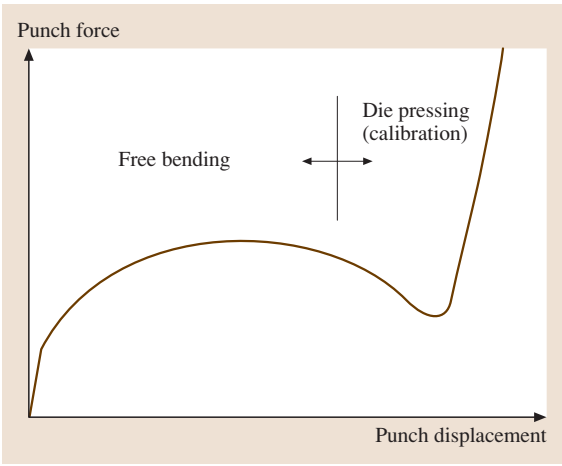

Fig. 7.103 Force–displacement curve in die bending

A typical force displacement curve for die bending (Fig. 7.97) is given in Fig. 7.103. The force increases during free bending and starts to drop as the sheet overbends. The steep increase at the end of process is as the bent sheet is pressed towards the die by the punch for calibrating the part.

Stretch Forming and Deep Drawing

Industrial sheet forming processes such as the manufacturing of automobile panels involve both stretch forming as well as deep-drawing processes. Stretch forming and deep drawing are similar processes in the sense that they shape a sheet using a rigid punch and a rigid die. On the other hand, the differ fundamentally in the sense that in stretching the sheet is fixed at its circumference, and hence the whole in-plane deformation is achieved by thinning of the sheet, whereas in deep drawing the sheet is allowed to be drawn at its circumference so that the shape change of the sheet is achieved under rather unchanged sheet thickness.

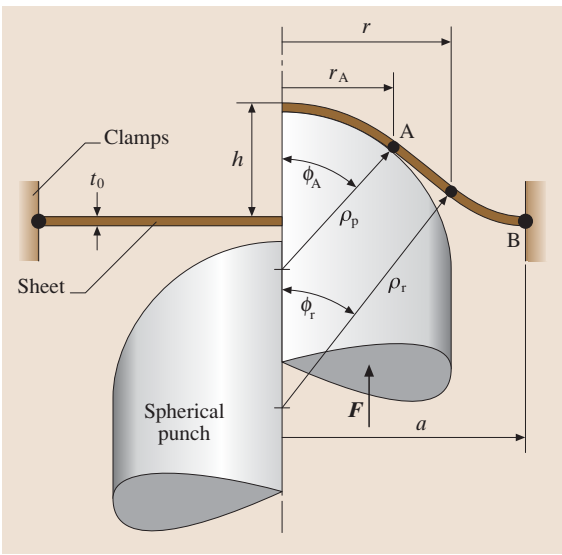

Fig. 7.104 Stretch forming with a spherical punch (after [7.52])

Stretch Forming. A circular sheet blank with diameter $2a$ being clamped firmly at its rim is stretched by a spherical punch with radius ρ_p (Fig. 7.104).

Using the membrane equation (7.87) it can be shown that the pressure between the punch and the sheet is

$$p_c = 2\frac{T_f}{\rho_p}\,, \tag{7.105}$$

and the punch force for a given contact angle ϕ_A is found as

$$F = T_f(2\pi\rho_p)\sin^2\phi_A\,. \tag{7.106}$$

Recall that the force resultant T_f is assumed constant and is therefore given as

$$T_f = \sigma_{f0}t_0 = \text{const.}\,, \tag{7.107}$$

where t_0 is the initial sheet thickness and σ_{f0} the initial flow stress.

The shape of the stretched sheet is given by the variable radius of curvature of the unsupported sheet region

$$\rho_r = \frac{r^2}{r_A\sin\phi_A}\,. \tag{7.108}$$

Deep Drawing. In the deep-drawing process an initially flat sheet (the blank) is formed by the rigid punch into the die cavity (Fig. 7.105). In order to prevent wrinkling of the blank a blank holder is usually used. Since the material in the blank is drawn in, the circumferential stresses are compressive here. The strain state at the rim is given by

$$\begin{aligned}
\varepsilon_\theta &= \ln\left(\frac{r_0'}{r_0}\right) \quad \text{(circumferential strain)}\,,\\
\varepsilon_t &= -\frac{1}{2}\varepsilon_\theta \quad \text{(thickness strain)}\,,\\
\varepsilon_r &= -\frac{1}{2}\varepsilon_\theta \quad \text{(radial strain)}\,.
\end{aligned} \tag{7.109}$$

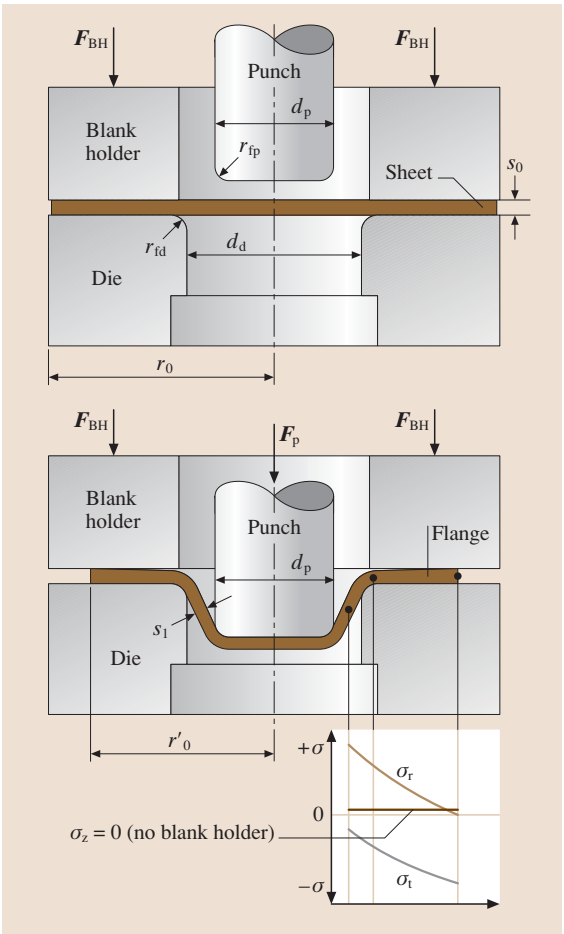

Fig. 7.105 Principle of deep drawing

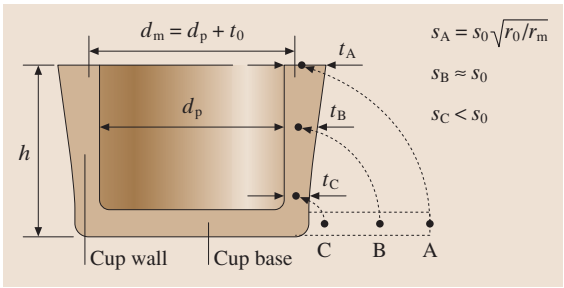

Fig. 7.106 Deep drawn cup (after [7.50])

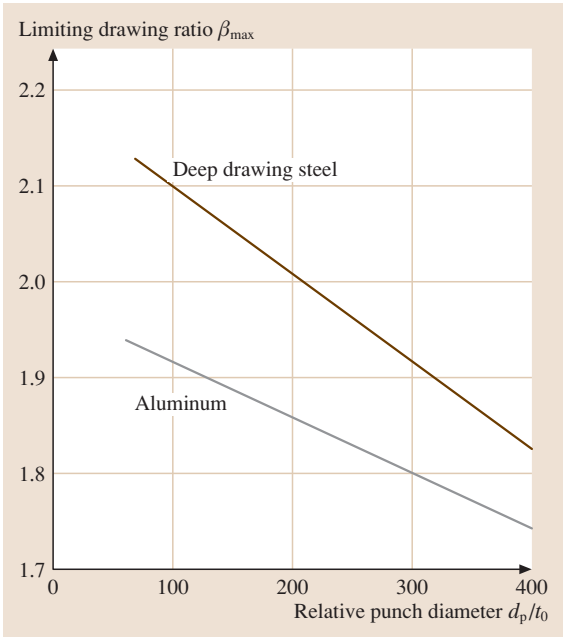

Fig. 7.107 Effect of relative punch diameter on the limiting drawing ratio

The wall thicknesses of the drawn cup are given in Fig. 7.106. Assuming that the mean thickness of the cup wall is equal to the initial sheet thickness, the drawn cup height is given as

$$h \approx \frac{\left(r_0^2 - r_m^2\right)}{2r_m} \tag{7.110}$$

with an error of ±5%.

The limiting drawing ratio β_{max} is an indicator of the drawability of a material and is defined as

$$\beta_{max} = \frac{d_{0,max}}{d_m} , \tag{7.111}$$

where $d_{0,max}$ is the largest blank diameter that can be drawn into a cup with mean diameter of d_m without failure. By membrane theory the ideal limiting drawing ratio is

$$\beta_{max} \leq e \approx 2.72 . \tag{7.112}$$

In reality, the limiting drawing ratios are 1.8 to 2.0 for aluminum sheets and 1.9 to 2.2 for steel sheets (for $d_0 = 100$ mm). This is because various process parameters are not considered in the simplifying membrane theory. One such factor is the dimension of the blank or equivalently the punch. As the relative punch diameter increases the limiting drawing ratio decreases (Fig. 7.107). Furthermore, as the normal anisotropy r_n increases the limiting drawing ratio increases; however, as the planar anisotropy Δr increases β_{max} decreases. Similarly, as the hardening

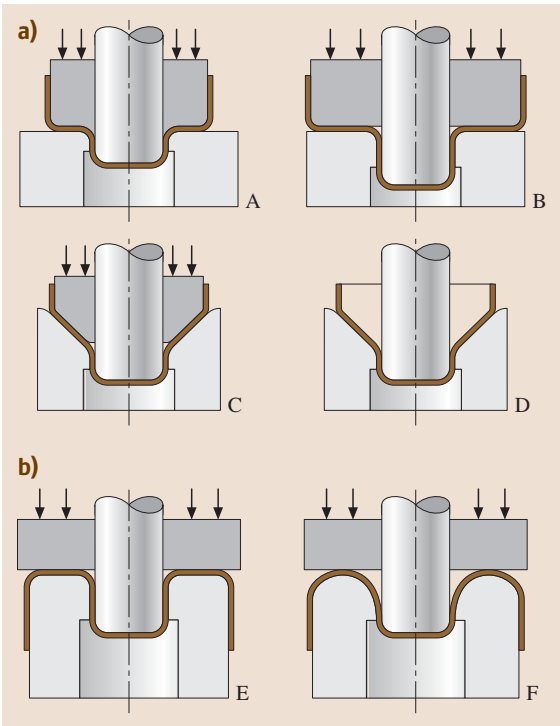

Fig. 7.108a,b Redrawing process to increase the overall drawing ratio: **(a)** direct redrawing, **(b)** inverse redrawing

exponent n increases β_{max} increases, but as friction between the blank and the die increases, β_{max} decreases.

To increase the drawing ratio cups can be drawn successively. This can be achieved by direct redrawing or reverse redrawing (Fig. 7.108). In direct redrawing the outer surface of the initially drawn cup remains the outer surface in the redrawn cup, whereas the same surface gets the inner surface in the reversely redrawn cup. Redrawing can be done either with annealing between the draws or without annealing. By the redrawing technique the total drawing ratio achieved without annealing between the draws is up to 6.5 for deep-drawing steel. Hereby, the first draws is conducted at a drawing ratio of 2.0 and all the following draws at a drawing ratio of 1.3.

The height of a drawn cup can be increased by reducing the wall thickness of the drawn cup by ironing (Fig. 7.74c). This process is also used to make the wall thickness of a cup uniform. This is virtually a drawing process and must be considered bulk forming.

Typical failure modes in deep drawing are given in Fig. 7.109. Tearing occurs if the drawing force can not be transmitted by the cup bottom; this is the failure type controlling the limiting drawing ratio. The limiting drawing force is

$$F \leq a\mathrm{UTS}\pi d_p t_0 \,, \qquad (7.113)$$

where a is a correction factor (for steel 1.05 to 1.55, for aluminum 0.99 to 1.22, for brass 0.92 to 1.27) and UTS is the ultimate tensile strength of the sheet material. Wrinkling is caused by compressive stresses that occur in the flange of the workpiece. If the clearance between the punch and the die is large, wrinkles can also occur in the cup wall. If the sheet thickness is large enough ($d_0/t_0 < 25$ to 40) the sheet has sufficient buckling resistance. For thinner sheets, wrinkles in the flange are prevented by a blank-holder. It is suggested to use a blank-holder pressure of 1 to 2% of the flow stress of the workpiece material.

The working window for the deep-drawing process is sketched in Fig. 7.110. The working window can be enlarged by reducing the flow stress of the workpiece in the flange region, by reducing friction in the flange and at the die radius, by increasing the strength of the material at the cup base/wall transition, and by increasing friction at the cup base region.

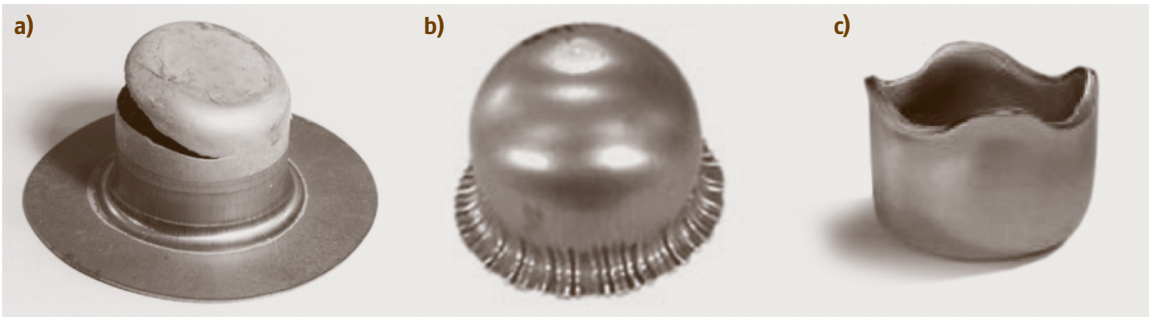

Fig. 7.109a–c Typical failure modes in deep drawing: **(a)** Tearing, **(b)** wrinkling (courtesy T. Altan, ERC), **(c)** earing (courtesy Hydro Aluminium Deutschland GmbH)

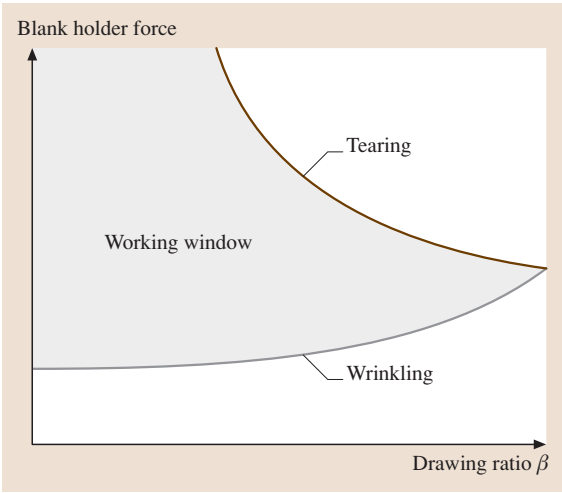

Fig. 7.110 Working window in deep drawing (after [7.52])

The drawing force during deep-drawing (see Fig. 7.111) can be estimated by

$$F = 2\pi r_m \left\{ \left[\underbrace{\sigma_{fm,flange} t_0 \ln\left(\frac{r'_0}{r_m}\right)}_{\text{ideal force}} + \underbrace{\frac{\mu F_{BH}}{\pi r'_0}}_{\text{flange friction}} + \underbrace{\frac{\sigma_{fm,die\text{-}ring} t_0^2}{2r_{fd} + t_0}}_{\text{bending/unbending}} \right] \underbrace{e^{\mu\phi}}_{\text{die-ring friction}} \right\} \sin\alpha \,, \quad (7.114)$$

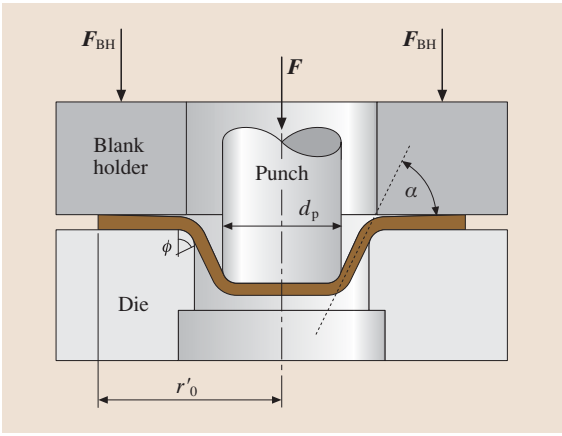

Fig. 7.111 Deep drawing parameters

The typical force–displacement in deep drawing shows a maximum as the blank radius reduces to around 77% of the initial value (Fig. 7.112). This is the result of the decreasing flange volume and the increasing flow stress in the flange as the punch advances. If the clearance between the punch and the die ring is smaller than the increased sheet thickness towards the rim of the cup, there will be an additional increase in the force due to ironing after the force maximum is reached.

Forming of complex three-dimensional sheets is a combination of stretch forming and deep drawing. The critical issue is to control the material flow within the sheet part during forming. This is achieved basically by four methods.

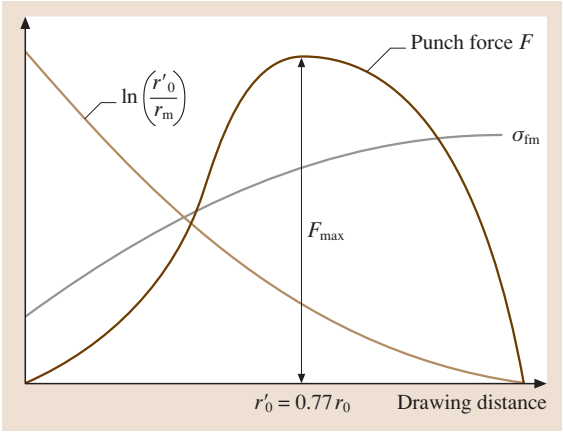

Fig. 7.112 Typical force–displacement curve for deep drawing

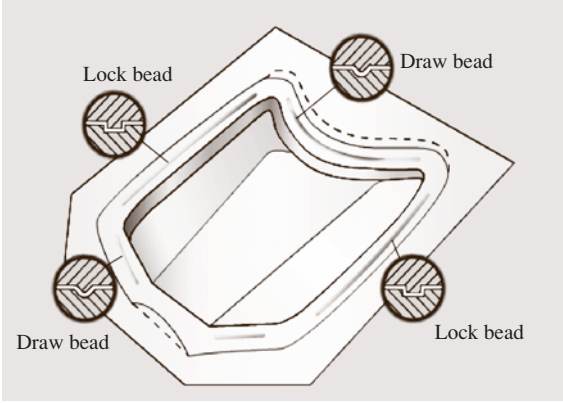

Fig. 7.113 Deep drawing of complex parts using draw beads and lock beads

1. Designing the blank geometry appropriately.
2. Using draw beads or lock beads (Fig. 7.113) that prevent partially or completely the draw-in of the material.
3. Regulating the blank-holder force. Advanced deep drawing dies have segmented blank-holders to adjust the blank-holder force locally.
4. Regulating the type, amount, and distribution of the lubricant during sheet forming.

Hydroforming

Hydroforming is characterized by the replacement of a rigid tool through a pressure medium such as water or oil. There are two broad groups of these processes: Sheet hydroforming and tube hydroforming. Sheet hydroforming processes are basically of two types: processes in which the die is replaced by a pressurized fluid (called hydromechanical deep drawing, the hydromech process, the aquadraw process, hydraulic counter-pressure deep drawing, or just hydroform) and processes in which the punch is replaced by a pressurized fluid (called high-pressure sheet forming or just fluid forming).

High-Pressure Sheet Forming (Fluid Forming). The high pressure sheet forming process consists of two stages (Fig. 7.114): The free bulging stage and the cavity filling stage. Compared to conventionally deep-drawn parts, hydroformed parts have better tolerances and repeatability. Besides, parts made from blanks of different thickness and materials (tailored blanks) can be produced using the same tools. Another advantage is the low springback and low residual stress levels in the product. On the other hand, due to the free bulging the depths of the parts are limited. Also the cycle time is relatively slow, and dies cannot be changed as quickly as conventional dies.

For the given typical process in Fig. 7.114, the internal pressure at the end of the free bulging state can be estimated by the membrane theory as

$$p \approx 4\sigma_{f0} t_0 \frac{r_d}{a^2 + r_d^2} . \qquad (7.115)$$

The maximum height for the free bulging stage is given by

$$h_{max} = \frac{a}{\sqrt{5}} \approx 0.447a . \qquad (7.116)$$

The pressure to fill the cavities is approximately

$$p = \sigma_{f0} t_0 \left(\frac{1}{a} + \frac{1}{r_d} \right) . \qquad (7.117)$$

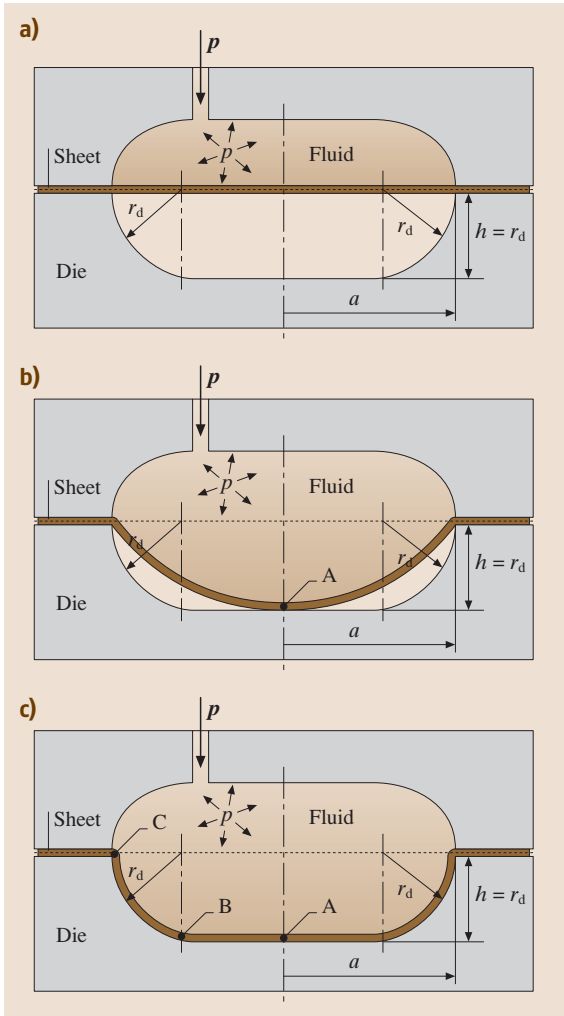

Fig. 7.114a–c Principle of high pressure sheet forming: **(a)** Beginning of process, **(b)** end of free bulging, **(c)** end of cavity filling (after [7.52])

The contact pressure in the interface of the sheet and the rigid die between point B and C is estimated by

$$p_{contact} \approx \frac{\sigma_{f0} t_0}{a} . \qquad (7.118)$$

Hydromechanical Deep Drawing. The working principle of hydromechanical deep drawing is given in Fig. 7.115 [7.53]. First, the press is opened and the water container is filled in the home position. After the insertion of the blank, the press closes, and the blank holder grips the blank. The blank holder pressure, set

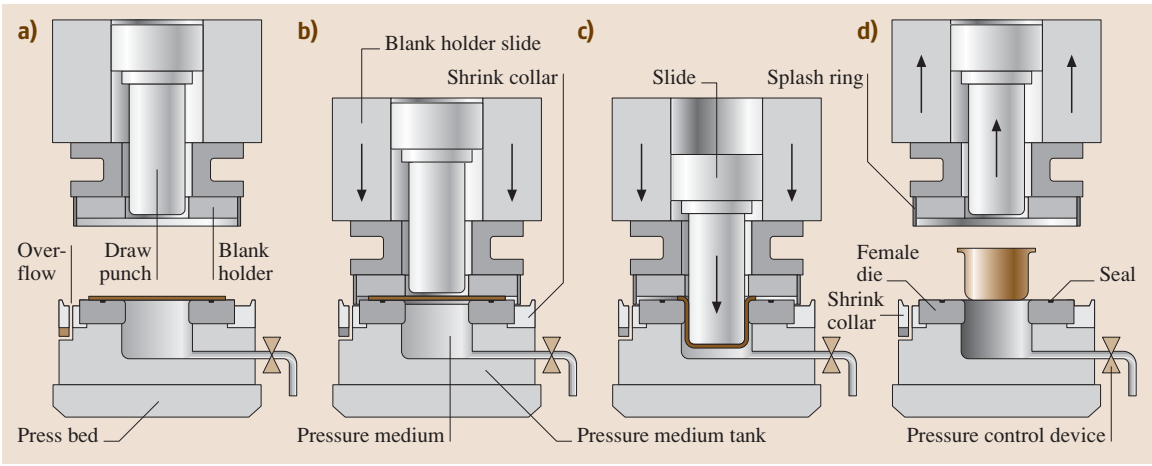

Fig. 7.115a–d Principle of hydromechanical deep drawing (after [7.53])

at the press, seals the pressure chamber, and the actual forming process is initiated. The medium pressure builds up as a result of penetration of the draw punch into the water container. During deformation, the sheet metal is pressed against the draw punch. During the forming phase, the control system, which is linked to the pressure chamber, controls the application of the hydraulic pressure in function of the draw depth.

After reaching the mechanically limited draw depth, the pressure in the chamber is released and the press travels back to its home position.

Advantages of hydromechanical deep drawing are the higher limiting drawing ratio ($\beta_{max} = 2.7$) as compared to mechanical deep drawing ($\beta_{max} = 2.0$), the better surface quality, and the lower springback of the product. Pressures for various materials during hydromechanical deep drawing are given in Table 7.32.

Tube Hydroforming. Tube hydroforming is a cold forming process in which a tube is pressurized internally and simultaneously compressed axially and/or radially [7.53]. The tube is thereby expanded and pressed against a die. The process steps can be illustrated by the manufacturing of a T-fitting (Fig. 7.116): A special hydraulic press is equipped with a two-part multiple purpose die. Depending on the workpiece, the dies have two seal punches (horizontal cylinders) positioned axially relative to the tube ends and a counterpressure punch. The tubular preform is in the bottom die and the die is closed. The ends of the tube are sealed by the axial punches, and the tube is filled with pressure medium. In the actual forming process, the punches compress the tube, while the pressure medium is fed to inflate the part until the part wall rests against the die contour. Pressures can reach values up to 4000 bar. The counterpressure punch additionally controls the material flow. The calibration pressure forms the workpiece in such a way that its contour corresponds to that of the die accurately and reproducibly. The die is finally opened and the formed component is ejected.

Currently, tubes with maximum dimensions given as in Fig. 7.117 are possible to form by tube hydroforming. Typical achievable product dimensions are given in Fig. 7.118.

Tube hydroforming is limited by three failure modes (Fig. 7.119): buckling, wrinkling, and bursting.

Table 7.32 Pressures during hydromechanical deep drawing

Material	Pressure range (bar)
Aluminum	50–200
Steel	200–600
Stainless steel	300–1000

7.2.6 Forming Machines

Metals are plastically formed by usually at least two tools. These tools have to be moved with certain kinematics and with certain forces. This is achieved by a forming machine. Since various metal forming processes need various load-stroke characteristics, the forming machines used have to be selected accordingly. Besides satisfying the mechanical requirements, forming machines must also provide a long uptime, i. e. the time they are used for forming, and they should ensure

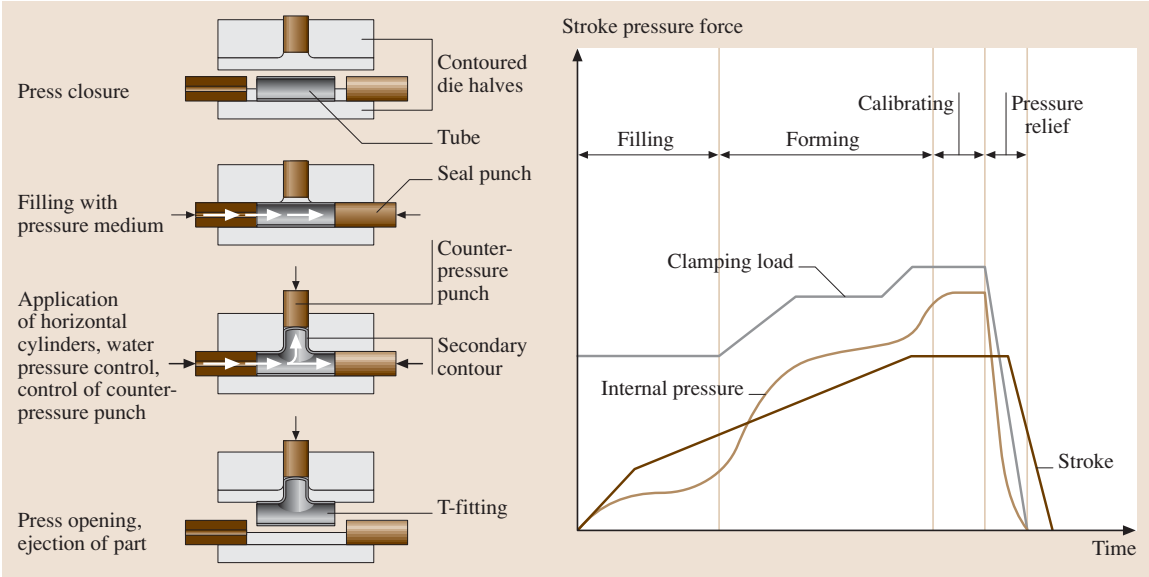

Fig. 7.116 Principle of tube hydroforming and process control (after [7.53])

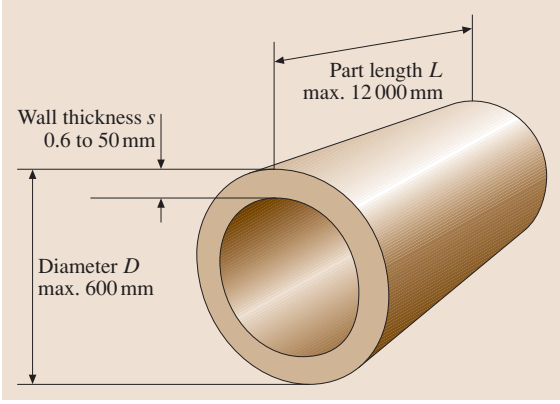

Fig. 7.117 Current limits on workpiece geometry for tube hydroforming (after [7.53])

long tool lives. The latter depends, for instance, on the precision of the guidance of the slides.

The largest group of forming machines is presses. These are machines with linear relative motion between the two tools. Other forming machines include rolling machines, wire or tube drawing machines, and magnetic or explosive forming machines. Here only presses will be discussed.

Parameters of Forming Presses

The various requirements of the forming process such as necessary force, moment, energy, etc. must be matched with the capabilities of the forming press. This can be achieved by comparing characteristic parameters of the forming press with those of the forming process. Basically four groups of parameters can be identified [7.22, 23]: energy and force parameters, transient parameters, accuracy parameters, and other parameters.

Energy and Force Parameters. For a feasible forming process the nominal ram force provided by the machine F_{nom}, must be larger than or equal to the necessary maximum forming force F_{form} and the available energy of the forming machine E_{nom} must be larger than or equal to the necessary process work W_{proc}. Practically, however, equality makes no sense due to the inherent fluctuations of the forming loads; on the other hand, due to economic utilization of the usually expensive forming machines F_{nom} and E_{nom} should be as close as possible to F_{form} and W_{proc}, respectively. The necessary process work is given by

$$W_{proc} = W_{form} + W_{el} + W_{fr} + W_{aux} \,, \qquad (7.119)$$

where W_{form} is the work necessary to plastically deform the metal (including the frictional work at the tool/workpiece interface), W_{el} is the work to elastically deform the press frame and the tools, W_{fr} is frictional work consumed in the various guides and bearings, and finally W_{aux} is the work consumed by auxiliary equipment such as blankholders, ejectors etc.

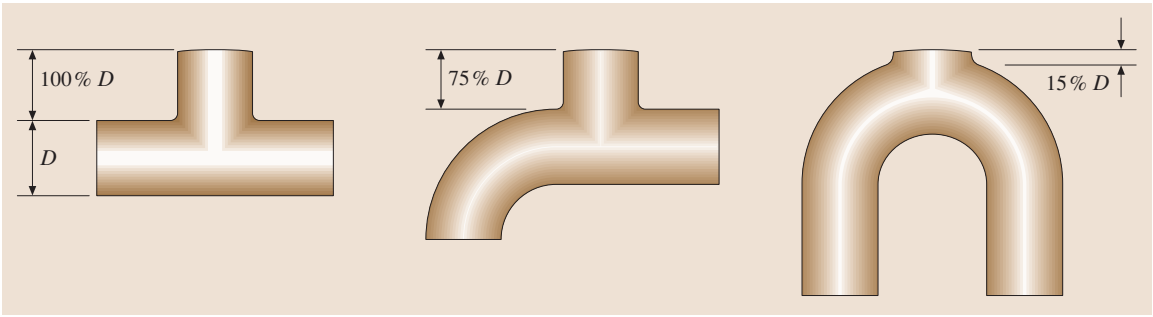

Fig. 7.118 Producible product geometries by tube hydroforming (after [7.53])

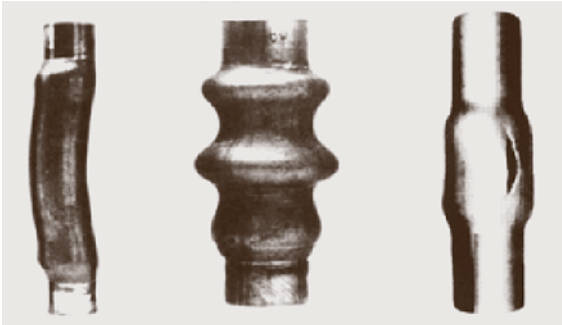

Fig. 7.119 Failure modes in tube hydroforming (after [7.54])

The elastic work absorbed by the press frame and the tools is given by

$$W_{el} = \frac{1}{2}\frac{F_{form}^2}{C}\,, \qquad (7.120)$$

where C is the stiffness of the forming press including the tools. As long as $C > dF_{form}/ds$ (with s the ram stroke), the elastic energy spent until the maximum forming load is reached can be recovered afterwards. The not recovered elastic energy leads to vibrations in the drives and in the machine frame. Hence, the higher C is, the higher the chance that the elastic energy can be recovered and vibrations can be reduced.

Presses can be classified according to the basic physical parameter controlling the action of the press as stroke controlled, force controlled, and energy controlled presses (Fig. 7.120): *Energy controlled forming machines* provide a certain amount of energy (E_{nom}) for the process. If this energy is consumed the press stops. If the required energy for the process is larger than the available one multiple strokes can be executed (Fig. 7.120a). Hence the basic characteristic parame-

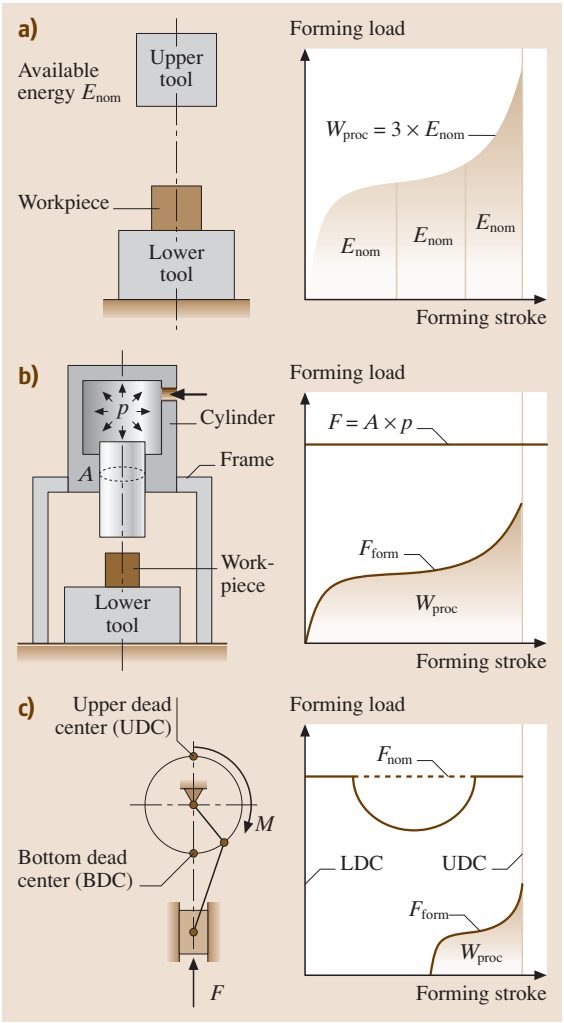

Fig. 7.120a–c Basic types of forming presses: **(a)** Energy controlled forming presses, **(b)** load controlled forming presses, **(c)** stroke controlled forming presses

ter of energy controlled presses is the nominal energy E_{nom}. Hammers and screw presses are two typical representatives of this group. Different from hammers, screw presses have drives and frame elements under load, so that for these in addition to the nominal energy also a nominal force has to be specified for which these machine elements are designed. *Force controlled presses* provide independent of the stroke a given force that is the obtained by the hydraulic pressure p multiplied by the cylinder cross-sectional area A (Fig. 7.120b). The basic parameter for these presses is therefore the maximum allowable force F_{nom}. The typical representative of this group is the hydraulic press. Finally, *stroke controlled presses* (Fig. 7.120c) provide ram force for each ram position depending on the kinematics of the mechanical drive. The characteristic parameters, therefore, are the ram force as a function of the stroke and the maximum ram force F_{nom}. Typical representatives are crank and toggle presses.

Transient Parameters. The basic time-dependent parameters are the effective stroke rate, the contact time of the tools with the workpiece under the forming load, and finally the speed of the press. The effective stroke rate determines the economic efficiency of the press. This parameter is related to the failing height in case of hammers, to the speed during the load free stroke in case of hydraulic presses and to the speed and total stroke in case of crank presses. The contact time under pressure is especially important for warm and hot forming processes since it determines the cooling amount of the workpiece. Typical contact times for various machines are given in Table 7.33 For stroke controlled presses the contact time under pressure is larger the softer the frame and tool system are (i. e. the lower C is). Another important parameter is the speed of the ram of the press. This directly influences the strain rates during forming. Especially in warm and hot forming, the higher the strain rates, the higher the flow stress, and hence the higher the forming loads. In hammers the speed is given during the forming process by the power balance, whereas for stroke driven presses the ram speed is a function of the ram position. For the latter, it must be noted that the true ram speed depends on the stiffness of the frame-tool system.

Accuracy Parameters. The accuracy parameters of presses are related to geometric errors of the workpiece, such as position errors during impact, eccentricity of the product, dimensional errors in product height, the angle of twist of the product, etc. These errors are caused either by inaccuracies of the presses in the idle state, such as excessive clearance of the guides or skewness of the lower die and upper die leading to position errors during impact, or by inaccuracies of the press under load, such as elastic deformations leading to height errors in the tool. The latter errors are strongly dependent on the stiffness of the press, so that this characteristic parameter is the key parameter for the press specification. In presses generally the frame, the upper tool, the lower tool, and the drive system deflect elastically. In the case of hammers, only the lower tool deflects elastically.

Table 7.33 Order of magnitude for contact times for various press types (after [7.22, 23])

Press type	Contact times under pressure (s)
Hammers	10^{-3}–10^{-2}
Screw presses (with fly-wheel)	10^{-2}–10^{-1}
Stroke controlled presses	10^{-1}–5×10^{-1}
Hydraulic presses	10^{-1}–1

Other Parameters. Finally, parameters such as stroke length, tooling space, space requirements of the press, weight of the press, and necessary power supply can be listed as other characteristic parameters.

Energy Controlled Presses

Energy controlled presses provide a certain predetermined amount of energy for the forming process. Force as well as displacement is not controlled directly. There are basically two types of energy controlled presses: Hammers and screw presses.

Hammers. There are basically three types of hammers (Fig. 7.121): Drop hammers provide the energy by a freely falling ram including the upper die. In double-acting hammers the ram is accelerated by a fluid such as steam, air, or hydraulic oil acting through a cylinder and piston. Finally, in counter-blow hammers upper and lower dies are accelerated towards each other. The first two types transmit the forging force to the ground, whereas for the counter-blow hammer the ground is practically not effected by the forming load.

The properties of these hammers are given in Table 7.34. Hammers are basically used in hot forging operations, so that the impact speeds are important for determining the strain rates for the forming process.

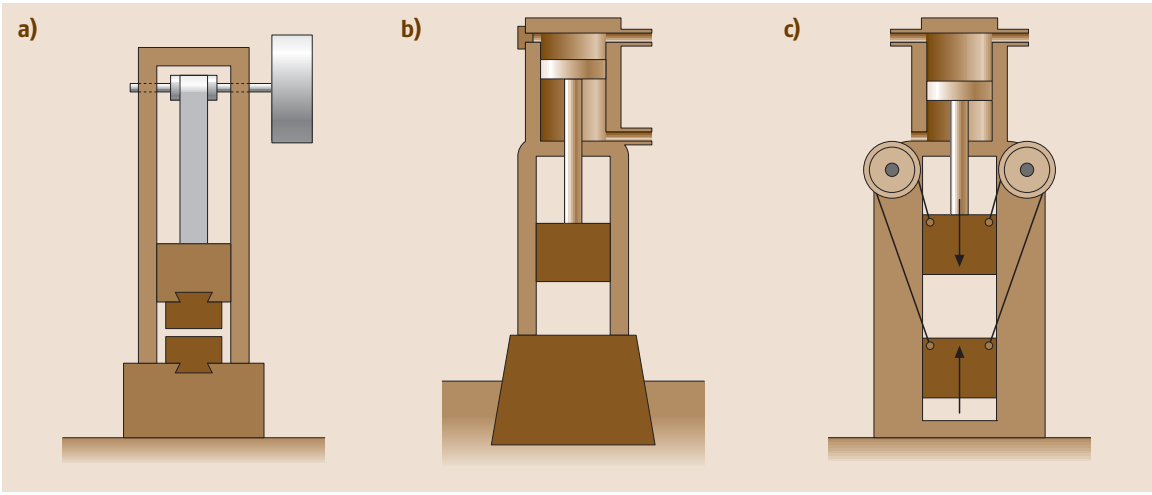

Fig. 7.121a–c Basic types of hammers: (a) Drop hammer, (b) double-acting hammer, (c) counter-blow hammer

Furthermore, the contact time of the dies with the workpiece is important to determine the cooling of the workpiece. The contact time for hammers is 10^{-3} to 10^{-2} s and is the shortest contact time among all press types. The maximum nominal energy of the hammer cannot be completely used for forming due to energy losses such as friction at the slides and elastic deformations of the dies. For small loads and large displacements about 80 to 90% of the nominal energy can be used, whereas for high loads and small displacements only 20 to 50% of the nominal blow energy is available for the forming process.

Screw Presses. Screw presses have two basic types (Fig. 7.122): presses with axially moving screw drives and presses with stationary screw drives (also called Vincent presses). The angular kinetic energy of the flywheel is transferred to the screw that either moves the upper ram (Fig. 7.122a) or the lower die (Fig. 7.122b). In the case of Vincent presses, the frame of the press is not under load during forming. The available energy is given by the flywheel rotational speed ω (in rad/s) and its moment of inertia I as

$$E = \frac{1}{2} I \omega^2 \,. \tag{7.121}$$

This energy is used for forming, for overcoming friction in the slides, and for elastically deforming the frame of the press.

The contact time of the dies with the workpiece is longer for screw presses than for hammers and is between 10^{-2} to 10^{-1} s. The impact speed of the dies on the workpiece ranges between 0.7 to 1 m/s. The maximum nominal energy ranges from 800 to 7500 kN m and the maximum nominal press loads from 20 000 to 140 000 kN, depending on the drive to accelerate the

Table 7.34 Properties of various hammers (after [7.38])

Property	Drop hammers	Double-acting hammers	Counterblow hammers
Maximum drop height	1.3–2 m	about 1.3 m	–
Acceleration of ram	$< g$	$> g$	$> g$
Impact speed of ram	3–5 m/s	3–9 m/s	5–14 m/s
Maximum nominal energy E_N	80–160 kN m	200 kN m	1000 kN m
Blow energy equation	mgh	$mgh + pAh$	$\frac{1}{2}(m_1 + m_2)v^2$
Parameters	m: mass of ram, g: gravitational acceleration, h: drop height, p: pressure in cylinder, A: cross-sectional area of cylinder, m_1: mass of upper ram, m_2: mass of lower ram, v: speed of each ram		

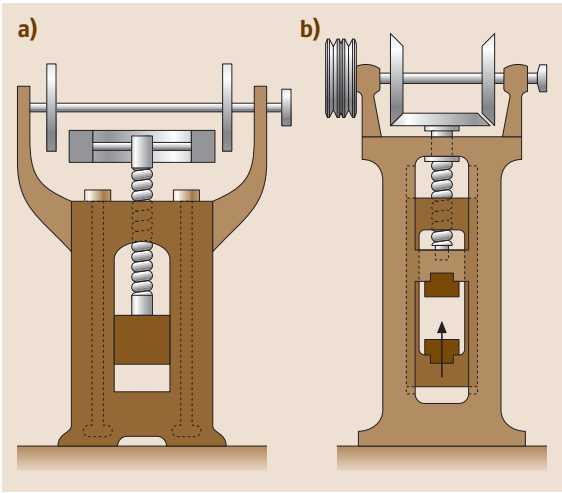

Fig. 7.122a,b Basic types of screw presses: **(a)** Friction screw press, **(b)** Vincent friction screw press

flywheel (friction, gear, electrical, or hydraulic drives). Impact loads are between 40 000 to 300 000 kN.

Compared to hammers screw presses have a lower noise level. Because of the lower hitting speed the strain rates are lower, yet the cooling time of the workpiece under pressure is longer. Also for the same energy, screw presses have a flywheel mass that is about 1/6th of the mass of the upper die of a hammer. Furthermore, the accuracy of screw presses is higher than the accuracy of hammers. A disadvantage of screw presses is, however, that their stroke rate is lower than that of hammers. Screw presses are, therefore, also used in cold calibration operations and coining in addition to hot forging.

Stroke Controlled Presses

Stroke controlled presses are also simply called mechanical presses. They all utilize a flywheel to store the necessary forming energy. Figure 7.123 shows a typical eccentric press. A slider crank mechanism is used to transfer the energy of the flywheel through the crank, the connecting rod, and finally the slide to the workpiece. A slight variation of the eccentric press is the crank press, where a crank link is used instead of an eccentric shaft. The presses are sometimes differentiated by the fact that the total stroke of the crank press cannot be changed whereas the total stroke of the eccentric press is adjustable [7.42].

For crank presses the ratio of the crank length to coupler length r/ℓ takes values between 1/15 to 1/4, so

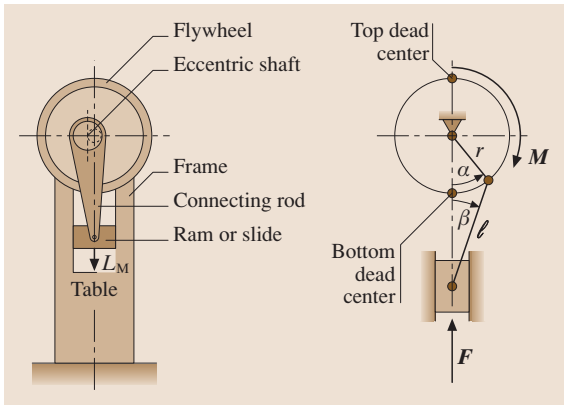

Fig. 7.123 A typical eccentric press and its mechanism

that the included angle between the coupler link and the press axis β is less than 6°. For this case, the axial ram force acting on the slider is given by

$$F(\alpha) \approx \frac{M}{r \sin \alpha} , \tag{7.122}$$

where M is the torque supplied by the crank and r is the crank radius. The nominal force of a mechanical press is given for a crank position at 30° to its bottom dead center

$$F_{\text{nom}} = F(\alpha = 30°) . \tag{7.123}$$

This is the highest allowable forming force for the given press. All the mechanical elements of the press are designed for this load. For various crank angles the current allowable force and the theoretical available force is shown in Fig. 7.124. The crank angle dependence can be converted to the stroke of the press s as measured from the bottom dead center using

$$s = r \left[(1 - \cos \alpha) + \frac{1}{2} \left(\frac{r}{\ell} \right) \sin^2 \alpha \right] . \tag{7.124}$$

If the total stroke of the press is denoted by S $(= 2r)$, then the stroke for which the nominal force is available corresponds to 7.3% of S for $r/\ell = 0.1$. Beyond this rather small stroke the available ram force decreases rapidly.

A another force-stroke characteristic is given for knuckle-joint (toggle) presses (Fig. 7.125). The six-link mechanism employed in this press provides the nominal force over a much smaller stroke than the crank presses, so that they are suitable basically for processes with force maximums toward the end of the stroke re-

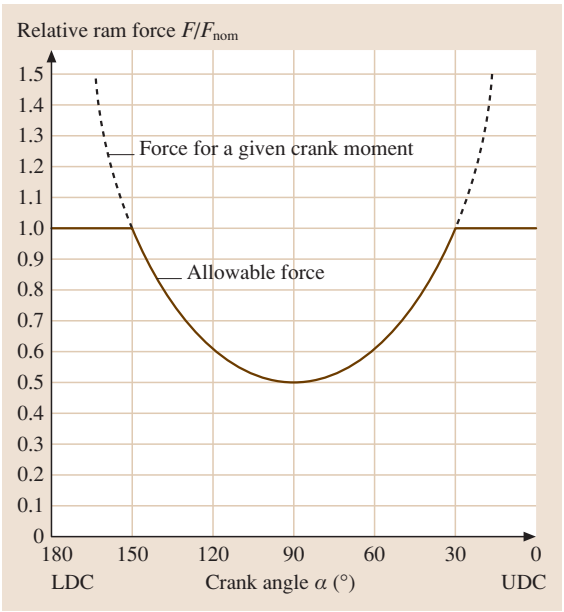

Fig. 7.124 Allowable press force as a function of crank position

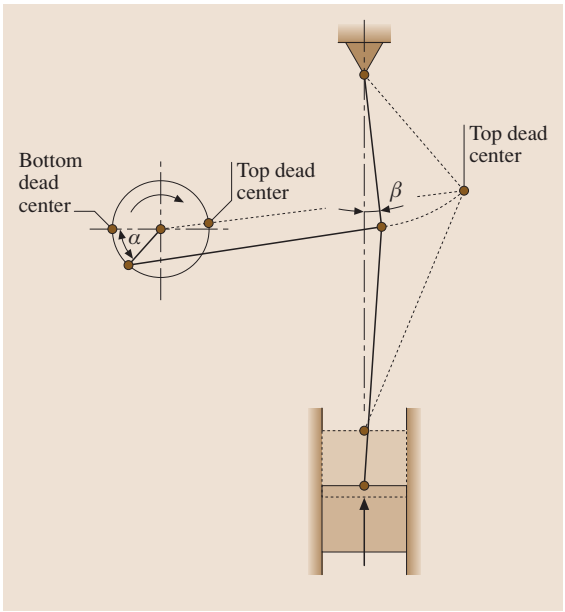

Fig. 7.125 Mechanism of a knuckle-joint press

quiring also short strokes. Despite this disadvantage, the velocity characteristic of toggle presses is superior to crank presses since they are faster over a long stroke but slower towards the dead centers, i. e. in the forming regime, than crank presses (Table 7.35).

A recent development in press technology is the servomotor press [7.42]. One or multiple servomotors are used to drive a crank or toggle mechanism. The obvious advantage of the servomotor press is the almost limitless control of the press. Current limitations are the available motor torques and the hence forming forces, since the forming energy must be supplied instantaneously. Despite this disadvantage 1000 t presses are expected to be available in near future.

Force Controlled Presses

Hydraulic presses supply the nominal forming force independently from the stroke. Figure 7.126 shows the basic working principle of a hydraulic press: A pump converts the electrical energy into hydraulic energy that is converted finally to mechanical energy. A cylinder in the die closure phase is pressurized by hydraulic fluid from a reservoir with high flow rates. This fluid is usually oil. This oil is compressible such that a 0.7 to 0.8% volume change occurs per 100 bar pressure. After the dies are closed control of the cylinder is overtaken by the slide control for the forming action. The cylinder is returned by reversing the fluid flow into the lowering cylinder. Hydraulic presses have the advantage that the whole cycle of die-closure/forming/punch reversal can be programmed efficiently and individually. Therefore, these press types are appropriate for many forming processes, such as sheet forming, cold forging, and especially for hot forging and hot extrusion.

The basic characteristic parameter of a hydraulic press is the nominal forming force that is obtained by

Table 7.35 Properties of mechanical presses (after [7.38])

Property	Eccentric or crank press	Knuckle-joint press
Stroke	10–300 mm	3–12 mm
Nominal load	1000–16 000 kN	1000–16 000 kN
Stroke rate	10–100 strokes/min	20–200 strokes/min

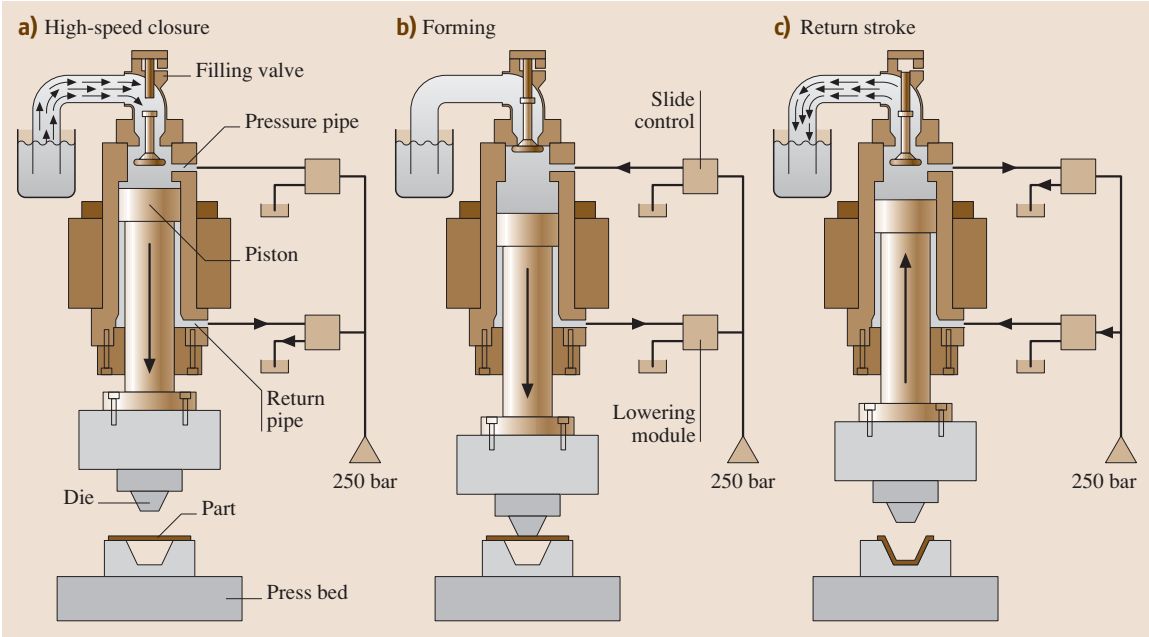

Fig. 7.126a–c Working principle of a hydraulic press: **(a)** High-speed closure, **(b)** forming, **(c)** return stroke (after [7.53])

the hydraulic pressure p and the cross-sectional area of the cylinder A

$$F_{\text{nom}} = pA \,. \tag{7.125}$$

The hydrostatic pressure is up to 320 bar. In contrast to mechanical presses there is no energy reservoir, so that the necessary energy during forming must be supplied instantaneously by the pump. This pump power P is given by

$$P = \frac{1}{\eta_{\text{total}}} p\dot{V} \,, \tag{7.126}$$

where $\dot{V}$ is the volumetric flow rate of the fluid and η_{total} is the total efficiency of the hydraulic system including mechanical and electrical losses. The maximum flow rates are around 185 l/min.

7.3 Machining Processes

In material removal processes surplus material is removed from a solid object (workpiece) in the form of small pieces (e.g. chips) by means of tools, thus generating surfaces by relative motions between the workpiece and tool provided by the machine tool.

The material removal processes that will be discussed in this section can be divided into three subgroups:

- Cutting with geometrically well-defined tool edges
- Cutting with geometrically undefined tool edges
- Nonconventional machining (chipless) processes

Cutting is accomplished with the mechanical action of a tool on a workpiece. In chipless machining material particles are removed from a solid object by nonmechanical means.

7.3.1 Cutting

Fundamentals

During a cutting process particles of material are mechanically removed as chips from a blank or workpiece by the cutting action of a tool. In machining with geometrically well-defined tool edges the number of cutting

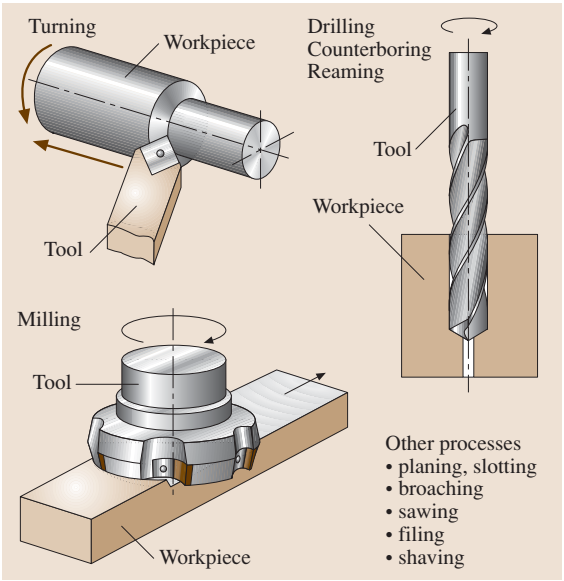

Fig. 7.127 Cutting processes (machining with geometrically well-defined tool edges) [7.55]

edges, the geometry of the tool and the position of the cutting edges in relation to the workpiece are known and describable (as opposed to cutting with geometrically undefined tool edges, e.g. grinding).

Figure 7.127 [7.55] illustrates important processes of this group. The processes differ according to the cutting motion (cutting speed v_c), the feed motion (feed rate v_f), and the resulting effective motion (effective cutting speed v_e). Feed and cutting direction vectors span the working plane. The angle between the two vectors is called the feed motion angle φ, while the angle between the effective direction and the cutting direction is called the effective cutting speed angle η. The following equation applies for all processes

$$\tan \eta = \frac{\sin \varphi}{\frac{v_c}{v_f} + \cos \varphi} \,. \qquad (7.127)$$

The mechanical process of separation of material parts from the workpiece, i. e. chip formation, can be described by the example of an orthogonal process (two-dimensional deformation). The wedge is described by the rake angle γ, the clearance angle α, and the edge radius r_B. The wedge penetrates into the working material, which is plastically deformed. Figure 7.128 [7.56] shows the zones of plastic deformation in continuous chip formation. Five effective zones can be distinguished.

The primary shear zone comprises the actual area of chip formation by shearing. In the secondary shear zones in front of the rake and flank face, friction forces act between the tool and the workpiece causing plastic deformation of these material layers. In the zone in front of the deformation area, chip formation results in stresses that lead to plastic and elastic deformations. In the pressure and cutting zone, the material is deformed and separated under high compressive stresses.

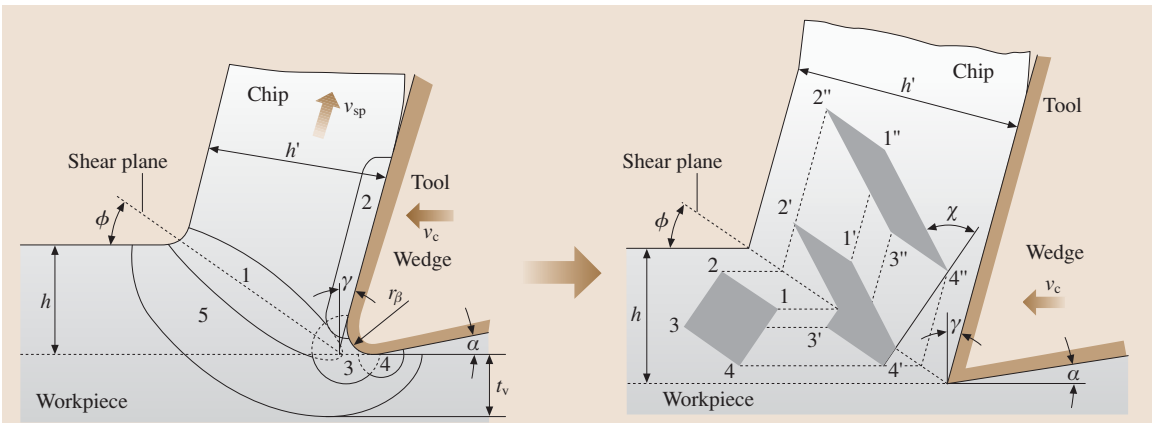

Fig. 7.128 Effective zones in chip formation and derived model of deformation in the shear plane

In the course of these processes the undeformed chip thickness h gives way to the chip thickness h' with the resultant chip compression ratio being $\lambda_h = h'/h$. The shear plane comprises the shear angle ϕ with the cutting speed vector. The deformation angle χ characterizes the shearing of a small part that has passed through the shear plane.

The following chip types can be distinguished: in continuous chip formation the chip slides off over the rake face at a constant speed in a stationary flow. Periodical changes in the intensity of the deformation may occur; mainly at higher cutting speeds. Lamellae are formed in the chip that can reach as far as material separation and the formation of chip segments.

Segmented chip formation is the discontinuous formation of a still continuous chip that, however, shows recognizable differences in the degree of deformation along the direction of flow. Especially negative tool orthogonal rake angles, but also greater undeformed chip thicknesses, as well as very slow and very fast cutting speeds can result in segmented chip formation. The chip formation is uneven.

Discontinuous chip formation occurs in working materials that possess only a small ability to deform, such as cast iron with graphite lamellae. The parting surface between the chip and the workpiece proceeds irregularly.

Built-up edges can form in ductile, work-hardening materials at low cutting speeds and sufficiently continuous chip formation. Parts of the working material, that have been strongly deformed and cold-hardened in the area of the compression zone weld under high pressure at the rounded cutting edge to the chip surface, thus becoming a part of the cutting tip.

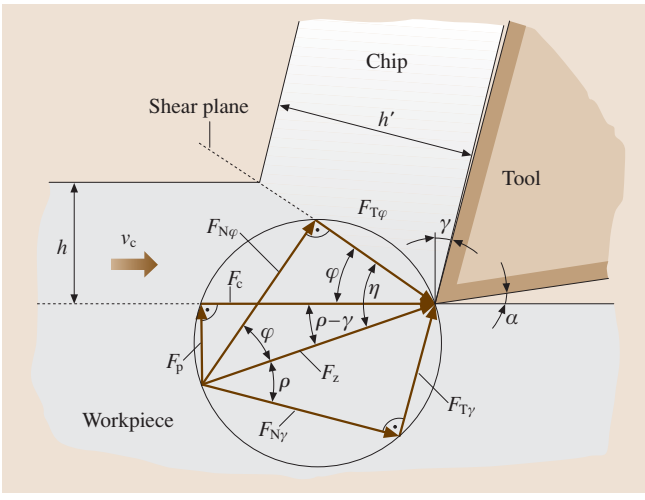

Fig. 7.129 Ernst and Merchant's force circle

The forces acting on the tool in orthogonal cutting can be represented by Ernst and Merchant's force circle as shown in Fig. 7.129 [7.57]. The resultant force F_z has two components, F_c and F_p. The cutting force F_c in the direction of the tool path determines the amount of work done in cutting. The thrust force F_p, together with F_c, produces deflections of the tool. The resultant force has two components on the shear plane: $F_{T\varphi}$ is the force required to shear the metal along the shear plane, and $F_{n\varphi}$ is the normal force on this plane. Two other force components on the face of the tool are also represented: the friction force $F_{T\gamma}$ and the normal force $F_{N\gamma}$. From the geometries within the circle the following relationships can be derived.

The frictional force on the tool rake face

$$F_{T\gamma} = F_p \cos\gamma + F_c \sin\gamma \,. \tag{7.128}$$

The coefficient of friction at the tool-chip interface

$$\mu \quad = \frac{F_p + F_c \tan\gamma}{F_c - F_p \tan\gamma} \,. \tag{7.129}$$

The shear stress in the shear plane, where $A_0 = hw$ is the undeformed chip cross-section and w is the width of the cut

$$\tau = \frac{F_c \sin\varphi \cos\varphi - F_p \sin^2\varphi}{A_0} \,. \tag{7.130}$$

In the chip formation zone the cutting energy applied E_c is completely converted. It can be calculated from

$$E_c = F_c l_c \,, \tag{7.131}$$

where F_c is the cutting force and l_c is the travel length in cutting direction.

The cutting energy is composed of deformation and shear energy E_φ, friction energy at the rake face E_γ, friction energy at the flank face E_α, surface energy for the formation of new surfaces E_τ and kinetic energy due to chip deflection E_M.

The energy converted during machining one unit of volume is

$$e_c = \frac{E_c}{V_w} \,, \tag{7.132}$$

where e_c is the specific energy and V_w is the volume of material removed.

Like E_c, itself, its individual components can be expressed in relation to V_w.

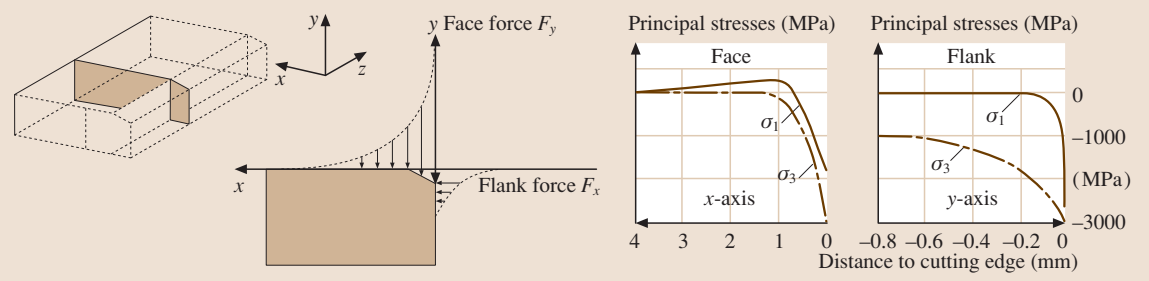

Fig. 7.130 Load distribution due to mechanical stress perpendicular to the major cutting edge

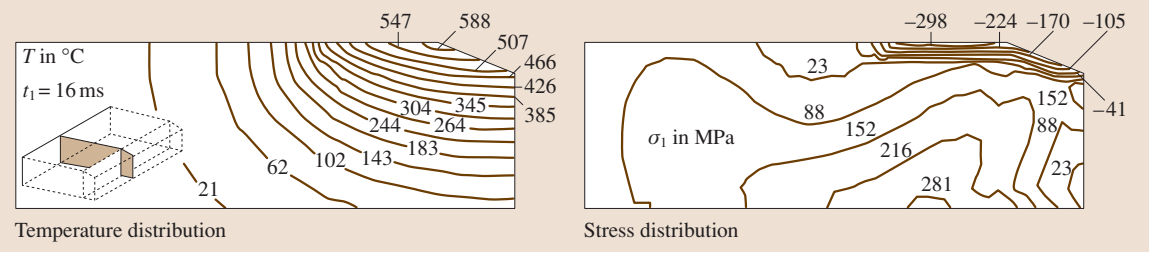

Fig. 7.131 Temperature and stress distribution during constant heat flow to the ceramic cutting tool

From the specific energy e_c the specific cutting force k_c can be derived as a characteristic value for calculating the cutting force

$$k_c = \frac{F_c}{A} = \frac{F_c}{hb}\,, \qquad (7.133)$$

where A is the undeformed chip cross-section, b is the undeformed chip width, and h is the undeformed chip thickness

$$e_c = \frac{E_c}{V_w} = \frac{P_c}{Q_w} = \frac{F_c v_c}{A v_c} = k_c, \qquad (7.134)$$

where P_c is the cutting power, Q_w is the material removal rate and F_c is the cutting force.

Estimation shows that the largest amount of cutting energy is converted into deformation and frictional energy. Thus the specific cutting force k_c can be seen as an energy-related variable (the application and determination of k_c will be dealt with in more detail in the section *Turning*). The energy introduced into the chip formation zone is almost entirely converted into heat, the minor amount being transformed into residual stress in the chip and in the workpiece (spring energy). Due to this process high temperatures in the cutting edge arise, introducing mechanical and thermal load into this area. Surface forces beneath the rake and flank face surfaces, and the principal stresses that can be calculated thereby are shown in Fig. 7.130 [7.56].

Figure 7.131 [7.56] represents the temperature distribution on a highly loaded ceramic indexable insert and the resulting thermally induced tensile stresses. These tensile stresses are particularly critical for high-temperature ceramic cutting materials. Mechanical and thermal loads supported by chemical reactions may cause significant wear.

The characteristics of worn cutting tools can be described by different types of wear (Fig. 7.132) [7.56]:

- Fractures and cracks. These arise in the area of the cutting edge because of mechanical or thermal overload.
- Mechanical abrasion (frictional wear) is mainly caused by hard inclusions such as carbides and oxides in the working material.

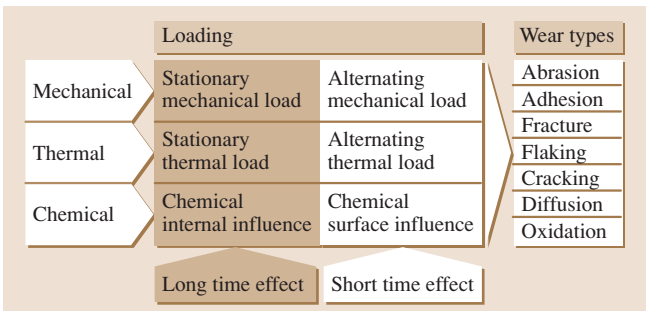

Fig. 7.132 Loading and wear types of cutting tools

- Plastic deformation occurs if the cutting material offers inadequate resistance to deformation but provides sufficient toughness.
- Adhesion is the shearing off of pressure welding areas between the working material and the chip, whereby the point of shearing is located in the cutting material.
- Diffusion occurs at high cutting speeds and mutual solubility of the cutting material and the working material. The cutting material is weakened by chemical reactions, dissolves and is removed.
- Oxidation also occurs only at high cutting speeds. By contact with oxygen in the air the cutting material oxidizes and the structure is weakened.

The machinability of a workpiece is determined by the composition of the workpiece material, its structural configuration in the machined area, its previous casting or forging process, and its heat treatment. Machinability is evaluated considering the following criteria:

- Tool wear
- Surface quality of the workpiece
- Machining forces
- Chip form

For the evaluation of an individual criterion the machining task must be considered.

Turning

Turning is defined as machining with a continuous (usually circular) cutting motion and any desired feed motion in a plane perpendicular to the cutting direction. The turning axis of the cutting motion keeps its position relative to the workpiece independently of the feed motion. Figure 7.133 [7.58] shows some important turning processes.

In the following, longitudinal cylindrical turning is taken as an example of a turning process. Terminology, names, and designations for geometrical descriptions of the cutting processes can be found in ISO 3002/1. Figure 7.134 [7.56] shows the surfaces and cutting edges defined for the cutting tip.

The angles represented in Fig. 7.135 [7.59] serve to determine the position and shape of the tool in three dimensions: the tool cutting edge angle κ is the angle between the primary cutting edge plane and the working plane. The tool included or edge angle ε is the angle between the primary and secondary cutting edge planes and is given by the cutting edge geometry. The tool cutting edge inclination λ is the angle between the cutting edge and the reference plane and is apparent when looking down onto the primary cutting edge. The clearance angle α, wedge angle β, and rake angle γ can be measured in the tool orthogonal plane and make up 90° in sum. The values of the relevant tool angles are determined from approximate value tables in relation to

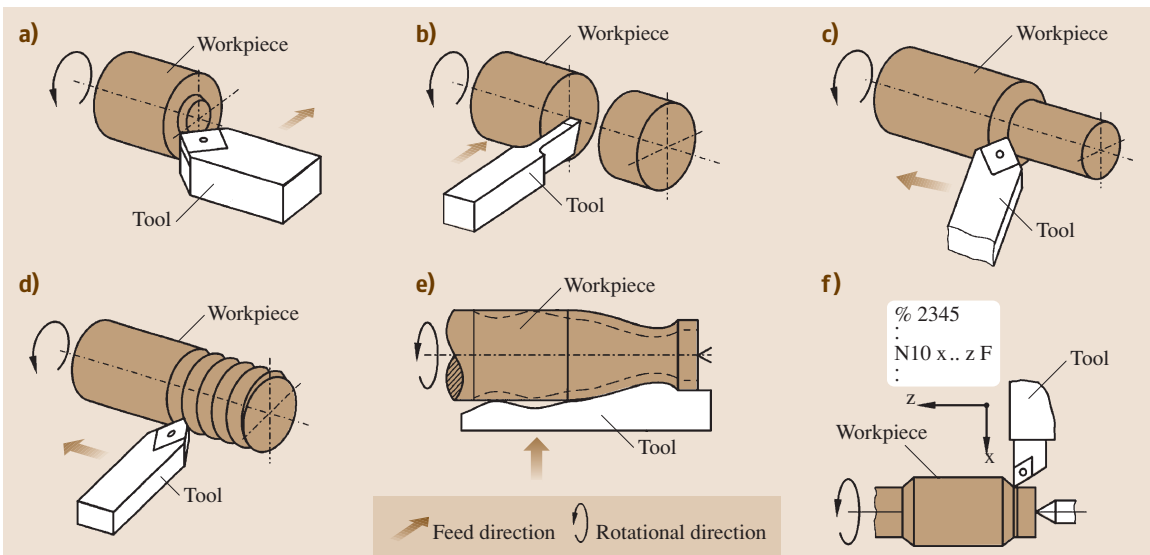

Fig. 7.133a–f Turning processes: **(a)** Facing, **(b)** parting-off, **(c)** longitudinal turning, **(d)** thread turning, **(e)** profile turning (tool contour is duplicated in workpiece), **(f)** form turning [7.58]

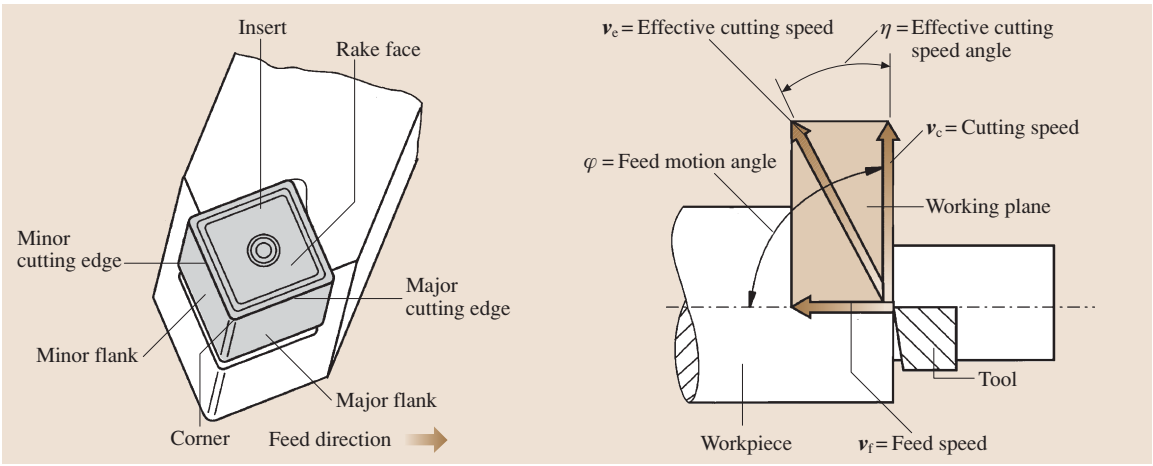

Fig. 7.134 Terminology at cutting tip and directions of motion of tool (ISO 3002/1)

the workpiece and cutting materials and the machining process. The tool cutting edge angle κ influences the shape of the undeformed chip cross-section to be removed and thus the power required for the machining process (Fig. 7.136) [7.56].

The bulk volume Q' of the chips flowing over the rake face of the tool varies depending on chip type and form. The characteristic parameter is the chip volume ratio RZ specifying the relationship between the removed chip volume in a given time Q' (bulk chip volume) and the material removal rate Q_w. In this case

$$RZ = \frac{Q'}{Q_w}\,, \tag{7.135}$$

$$Q_w = a_p F_c = a_p f D \pi n\,. \tag{7.136}$$

The chip volume ratio RZ characterizes the *bulkiness* of the chips. It serves to determine the machine tool working spaces, the chip conveying devices, and chip spaces in the cutting tools. The chip volume ratio can amount to very different values according to the chip form (Fig. 7.137) [7.60]. The more brittle the material, the lower this value. Brittleness can be influenced via the composition of the material. For steel, higher sulfur contents (more than 0.04%, free cutting steel with 0.2% S) have a beneficial effect. However, this may impair the toughness of the material in the transverse direction, depending on the form of the dispersed sulfides. Chip breakers ground into the chip surface, sintered in, or attached with the clamping system of inserts cause additional chip deformation, i. e. an additional material load in the chip. The chip is bent by contact with the cut surface of the workpiece or the flank face of the tool and breaks (secondary chip breaking in contrast to segmented or discontinuous chip formation, where the chips leave the chip formation zone as small fragments). Favorable chip forms can also be achieved by selecting the appropri-

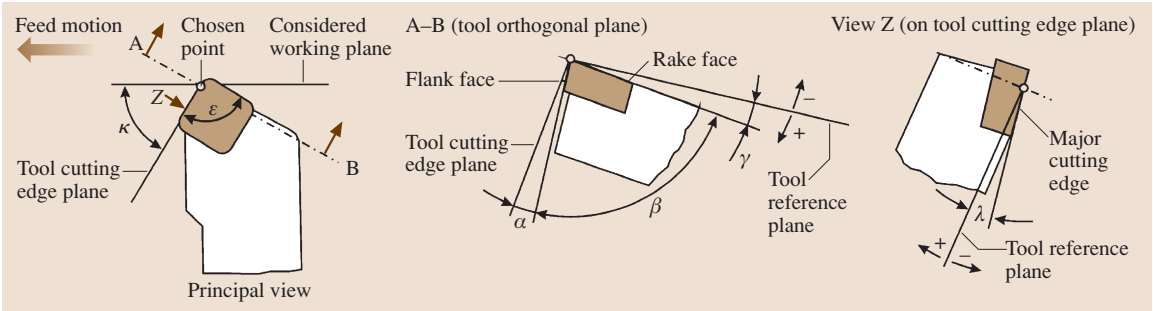

Fig. 7.135 Single point cutting tool angles (DIN 6581)

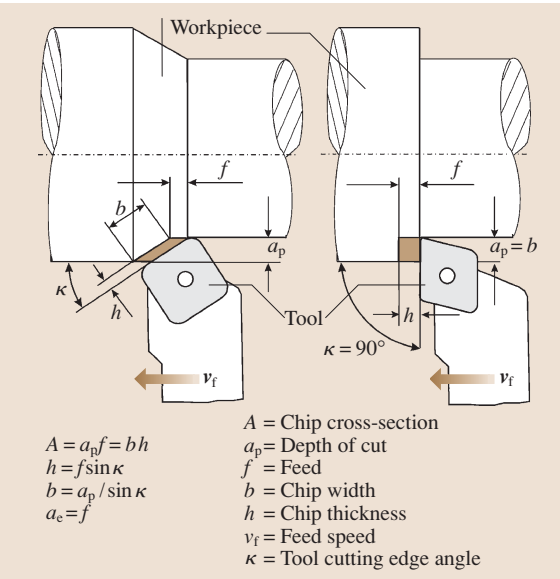

Fig. 7.136 Cut and chip variables in turning

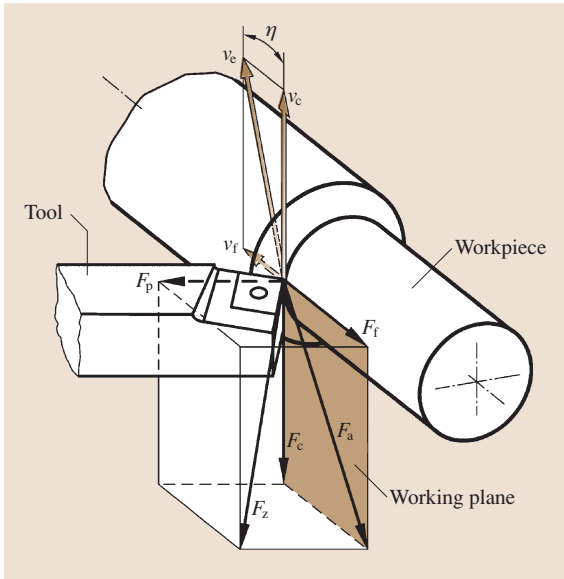

Fig. 7.138 Components of cutting force (after [7.62])

ate machine setting data such as feed rate and depth of cut [7.61].

Each material provides resistance towards the penetration of the tool during chip removal. This has to be overcome by means of a force, the machining force F. This force is analyzed by resolving it into its three components (Fig. 7.138) [7.62]. The active force F_a is formed by the cutting force F_c in the direction of the cutting motion together with the feed force F_f. The passive force F_p does not contribute to power conversion because no motion between the tool and the workpiece takes place in its direction. Thus

$$F_z = F_a + F_p = F_c + F_f + F_p \,. \tag{7.137}$$

The cutting force related to the area of the undeformed chip is defined as the specific cutting force k_c and depends on a variety of factors

$$k_c = \frac{F_c}{hb} = \frac{F_c}{a_p f} \,. \tag{7.138}$$

It is known from experiments that the specific cutting force k_c is a function of the undeformed chip thickness h. From the logarithmic representation (Fig. 7.139) [7.56] it can be seen that

$$k_c = k_{c1.1} \left(\frac{h}{h_0} \right)^{-m_c} \,. \tag{7.139}$$

Here $k_{c1.1}$ is the unit specific cutting force, i. e. k_c at $h = 1$ mm (indices 1.1 due to $k_{c1.1} = F_c/1.1$ at $b = h = 1$ mm). The quantity m_c indicates the increase and is the exponent of the specific cutting force. This equation is named in honor of the initial researcher Kienzle's cutting force formula [7.63] and can also be written as

$$F_c = k_{c1.1} b h^{1-m_c} \,. \tag{7.140}$$

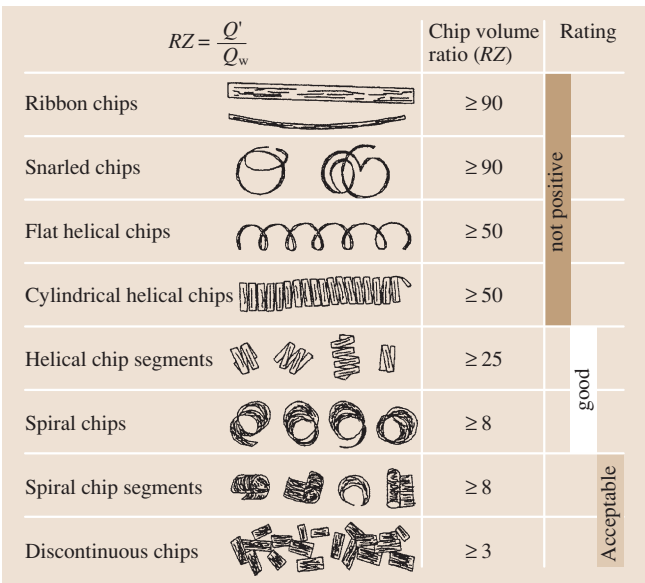

Fig. 7.137 Chip shapes, their related chip volume ratio and rating

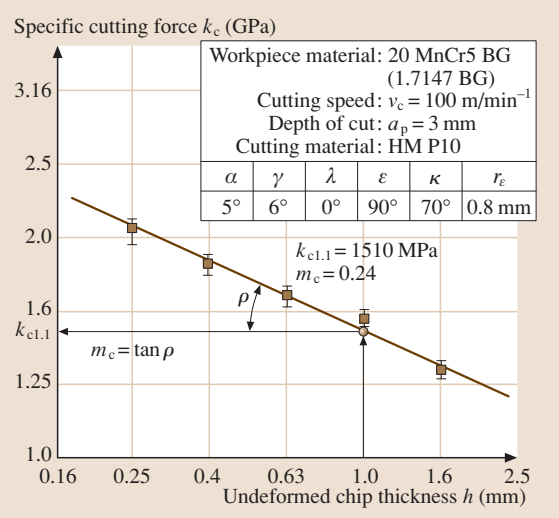

Fig. 7.139 Specific cutting force as a function of undeformed chip thickness

$k_{c1.1}$ and $1 - m_c$ are listed for various ferrous materials in Table 7.36. A direct comparison of the $k_{c1.1}$ values of different materials to indicate the machinability or the energy required for machining is not acceptable, as the exponent m_c can vary significantly. From $m_c < 1$ it follows that at a given cross-sectional area the cutting force and power requirements increase with decreasing undeformed chip thickness. This can be explained physically by the higher share of friction at decreasing undeformed chip thicknesses (see the section *Fundamentals*).

In addition to the working material and the undeformed chip thickness, k_c depends on further factors as well. Therefore additional influencing factors will be specified. The correction factors considering the cutting speed K_v, the rake angle K_γ, the cutting material K_{CM}, the tool wear K_{TW}, the cooling lubricant K_{CL}, and the workpiece shape K_{WS} are given in Table 7.37.

The passive force F_p (Fig. 7.138) [7.62], which is not relevant for the power balance due to its perpendicular orientation, is of importance for the size and form accuracy of the system – machine/workpiece/tool/fixture. Passive force F_p and feed force F_f can be merged to a thrust force F_D. For thin undeformed chip cross-sections (bh), the resultant cutting force is perpendicular to the primary cutting edge. From this it follows that

$$\frac{F_f}{F_p} = \tan\kappa \,. \tag{7.141}$$

For normal values of h and b it can be approximated that

$$F_D \approx (0.65\text{–}0.75)F_c \,, \tag{7.142}$$

wherein F_f and F_p have to be determined.

The exponential functions corresponding to the cutting force formula can be used for a more exact determination. Exponents and unit specific cutting force are given in Table 7.36.

The surface finish is determined by the profile of the cutting edge that is creating the workpiece surface and by the feed. From the shaping of the cutting edge corner radius r_ε, the theoretical maximum roughness $R_{z,th}$ according to EN ISO 4287 can be geometrically determined as

$$R_{z,th} = \frac{f^2}{8r_\varepsilon} \,. \tag{7.143}$$

This value should be regarded as a minimum for the surface roughness, which increases due to vibrations, especially at higher rotational and cutting speeds, on the formation of built-up edges (see the section *Fundamentals*), and with the progressive wear of the cutting edge.

The tool is subject to mechanical stress due to the machining force, thermal stress due to heating, and chemical attack due to the interaction of the cutting material, the workpiece material, and the surrounding medium. This results in wear on the cutting tool (see the section *Fundamentals*). Typical forms of wear are illustrated in Fig. 7.140 [7.64]. In addition, cutting edge wear, rounding of the cutting edge, and scoring may occur on the secondary cutting edge. The type of wear that determines the end of tool life (tool life criterion) is determined by the respective use. Weakening of the cutting edge by crater wear or an increase in the share of friction in the resultant force due to flank wear are critical in roughing. Cutting edge wear leads to changes in workpiece dimensions, and flank wear or scoring impair surface quality and determine the end of tool life in finishing. Often the lifetime end is set at $V_B = 0.4$ mm or $KT = 0.1$ mm. The flank is divided into three zones for more precise identification of the wear.

For a specific cutting-material–workpiece-material combination and a given tool life criterion, the tool life depends mainly on the cutting speed according to an exponential function (Taylor's equation shown on a straight line on a log–log graph) [7.65]

$$\frac{T}{T_0} = \frac{v_c^k}{C} \,. \tag{7.144}$$

Table 7.37 Correction factors for cutting force calculation

Cutting speed correction factor	$K_v = \frac{2.023}{v_c^{0.153}}$ for $v_c < 100\,\text{m/min}$ $K_v = \frac{1.380}{v_c^{0.07}}$ for $v_c > 100\,\text{m/min}$
Rake angle correction factor	$K_\gamma = 1.09–0.015\angle°$ (steel) $K_\gamma = 1.03–0.015\angle°$ (cast iron)
Cutting material correction factor	$K_{CM} = 1.05$ (HSS) $K_{CM} = 1.0$ (cemented carbide) $K_{CM} = 0.9–0.95$ (ceramic)
Tool wear correction factor	$K_{TW} = 1.3–1.5$ $K_{TW} = 1.0$ for sharp cutting edge
Cutting fluid correction factor	$K_{CL} = 1.0$ (dry) $K_{CL} = 0.85$ (non-water soluble coolant) $K_{CL} = 0.9$ (emulsion-type coolant)
Workpiece shape correction factor	$K_{WS} = 1.0$ (outer diameter turning) $K_{WS} = 1.2$ (inner diameter turning)

Here, T_0 and v_c are reference values. T_0 is normally set at $T_0 = 1$ min. C is the cutting speed for an operating period of $T_0 = 1$ min.

The Taylor straight line is plotted on the basis of a wear/tool life turning test according to ISO 3685. With these tests suitable settings for high-speed steel,

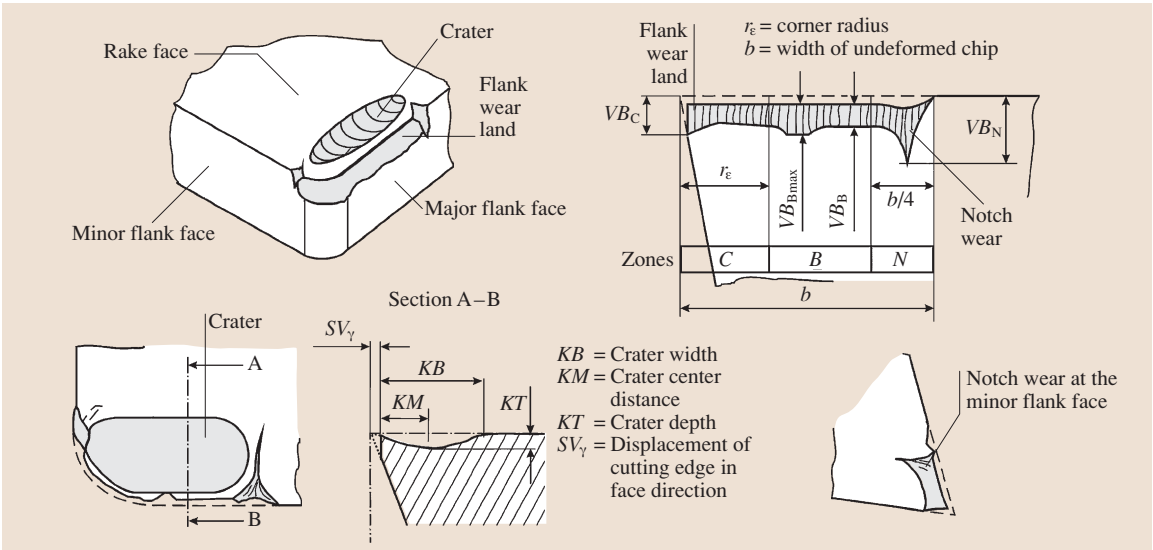

Fig. 7.140 Forms of wear in turning (ISO 3685)

hard metals of all machining application categories, and ceramic inserts have been determined. It is usually sufficient to determine the width of the flank wear land VB and/or the crater depth KT, as well as the distance from the crater center to the point of the cutting tip. Table 7.38 normal values of the gradient exponent k and the cutting speed C for a tool life of $T = 1$ min and a width of wear land of $VB = 0.4$ mm shows for various materials.

For metal cutting machines the optimum cutting speed must be established to meet economical criteria (Fig. 7.141) [7.56]. The optimum cutting speed in relation to time is expressed by

$$v_{c,opt} = C(-k-1)t_{CT}^{1/k} \,. \qquad (7.145)$$

Optimization of the cutting speed to minimize unit costs takes into account not only the tool changing time t_{CT} but also the tool costs per cutting edge K_{CT} and the

Drilling and Reaming

Drilling is a metal cutting process with a rotary cutting motion (primary motion). The tool, i. e. the drill, performs the feed motion in the direction of the rotational axis. Figure 7.142 [7.55] shows common drilling processes. With drilling into solid metal either through holes or blind holes can be produced. The tool is usually a twist drill. Drilled holes are either enlarged with twist drills or with countersinks or counterbores having two or more cutting edges. Step drills produce stepped holes. They usually have multiple cutting edges; for manufacturing reasons, not every cutting edge has to support all parts of the contour (e.g. one cutting edge may break the edge of a step, while the adjacent one produces a planar surface). Centre drills are special profile drills with a thinner spigot and a short, stiff drill section in order to attain a good centering effect. Trepanning cutters produce an annular cut into solid material with the coincidental formation of a solid cylinder or plug. Taps are used to cut internal threads. Reaming is a hole enlarging process with a small undeformed chip thickness, for producing holes of precise size and shape with a high-quality surface.

For drilling holes with diameters of 1–20 mm and with drilling depths up to five times the diameter, the twist drill is the tool most commonly used (Fig. 7.143) [7.55]. The twist drill consists of the shank and the cutting section. The shank is used to locate and clamp the drill in the machine tool. It is straight or tapered. If a high cutting torque is to be transmitted, tangential flat surfaces transmit the force. The cutting section has a complex geometry, which can be modified to adapt the drill to the respective machining task. Essential parameters are the profile and the web thickness, the flute geometry and the helix angle, i. e. the pitch of the flutes, the ground drill-point, and the drill-point angle. Especially the ground drill-point and the drill-point angle can be determined by the user. The profile of the twist drill is designed in such a way that the flutes provide the maximum space for chip removals while ensuring that the drill is capable to adequately withstand torsional stresses. These are the two main requirements. A further de-

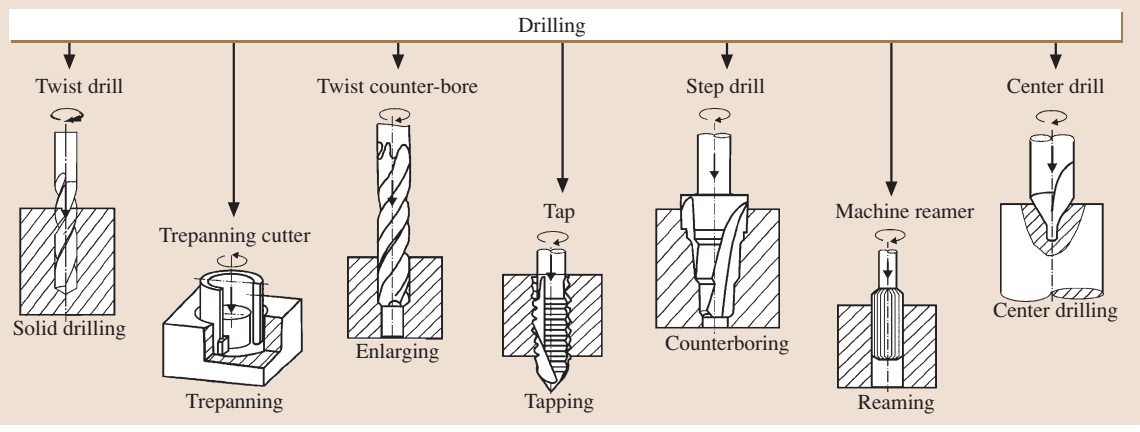

Fig. 7.142 Drilling processes (DIN 8589)

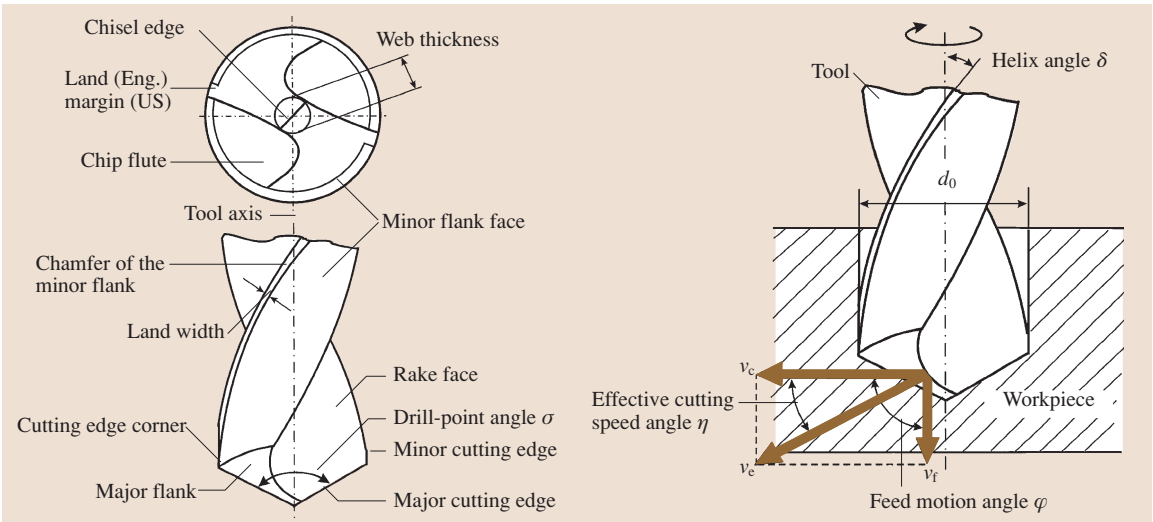

Fig. 7.143 Terminology and mode of operation of twist drills (DIN 8589)

mand on the drill may be the production of favorable chip forms. This has led to a diversity of special profiles and allows the adaption of the drilling process to particular constraints. Working material also has to be removed from the area in front of the core of the twist drill; with the special boundary condition that the cutting speed v_c in the center is zero. This is achieved by the chisel edge, which connects the major cutting edges.

Along the major and minor cutting edges, the rake angle γ as an important factor influencing the drilling process is not constant but already decreases in front of the major cutting edge from the outside towards the inside. In Fig. 7.144 [7.56], the rake angles at three positions on the major cutting edge and chisel edge, respectively, are shown.

At the outer diameter the rake angle is almost identical to the helix angle δ and decreases in direct proportion to the diameter. Close to the chisel edge, the rake angles on the major cutting edge are already strongly negative. Here the workpiece material has to be displaced in radial direction. As shown in the left

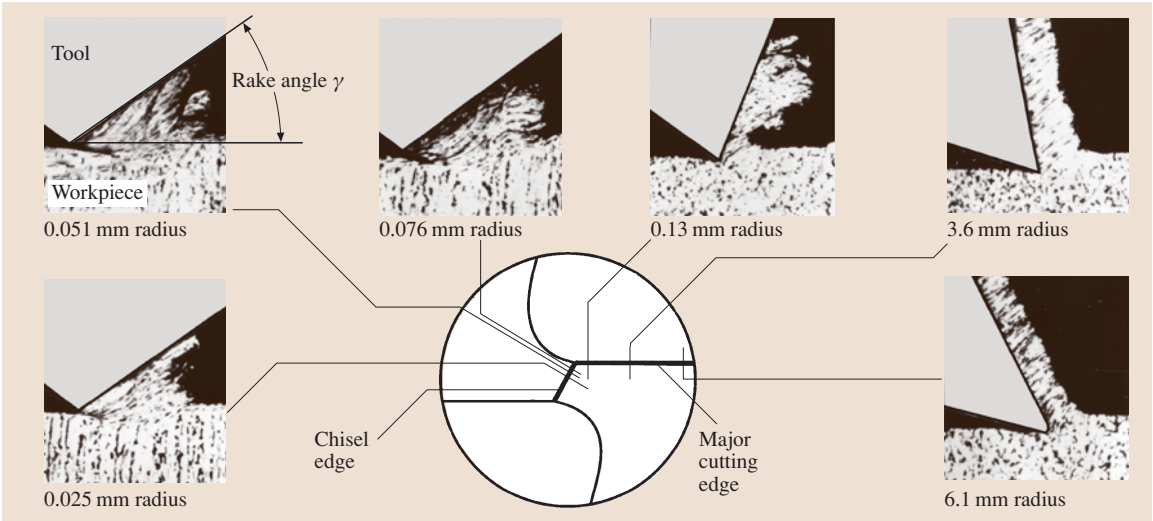

Fig. 7.144 Rake angles at different position on a drill tip

of Fig. 7.144 all rake angles on the chisel edge are negative. These negative rake angles and the material displacement effect generate high pressures in the area of the chisel edge. To diminish this effect, twist drills are pointed. The center of the drill is tapered by profile grinding in the direction of the flute and towards the drill tip on a conical or similar surface. In this way, the rake angle at the chisel edge is increased and/or the chisel edge is shortened.

The most important type of wear concerning the twist drill is flank wear at the corners. This wear, which is mainly caused by abrasion, generates an increase in the torsional load on the drill, as higher machining forces are present in the corner area. This torsional load may cause the drill to break. Worn twist drills are therefore reground until the damaged area of the secondary cutting edge is removed.

Cutting Forces. The forces and moments in drilling are calculated on the basis of Kienzle's approach [7.63, 66]. Figure 7.145 [7.56] illustrates the cutting geometry and the forces implied in drilling processes. The forces arising per cutting edge, which are assumed to act in the middle of the cutting edge, are divided into their components F_c, F_p and F_f. The cutting forces F_{c1} and F_{c2} generate the cutting moment via the lever arm r_c, the cutting moment M_c

$$M_c = (F_{c1} + F_{c2}) r_c \,, \tag{7.147}$$

$$F_{c1} = F_{c2} = F_{cZ} \,, \tag{7.148}$$

$$M_c = F_{cZ} 2 r_c \,. \tag{7.149}$$

F_f is the sum of the feed forces F_{f1} and F_{f2},

$$F_f = F_{f1} + F_{f2} \,, \tag{7.150}$$

$$F_{f1} = F_{f2} = F_{fZ} \,, \tag{7.151}$$

$$F_f = 2 F_{fZ} \,. \tag{7.152}$$

In the ideal case, i. e. with a symmetrical drill, the passive forces F_{p1} and F_{p2} cancel each other out. If there are symmetry deviations, F_{p1} and F_{p2} generate interference forces, which impair the quality of the hole. The cutting force per cutting edge results in

$$F_{cZ} = b h^{(1-m_c)} k_{c1.1} \,, \tag{7.153}$$

$$h = F_z \sin\kappa \,, \tag{7.154}$$

$$b = \frac{d_0 - d_i}{2 \sin\kappa} \,. \tag{7.155}$$

By analogy, the feed force is

$$F_f = b h^{(1-m_c)} k_{f1.1} \,. \tag{7.156}$$

Over G-22	–	–	0.48	535	0.53	381

Values are given in Table 7.39. The feed forces are strongly dependent on the shape of the chisel edge. They can be lowered significantly by web thinning [7.56]. Wear causes them to reach twice their original value or more.

Surface quality in drilling with twist drills corresponds to roughing with $R_z = 10-20\,\mu m$. The surface roughness can be reduced by reaming with increased dimensional accuracy. The application of solid cemented carbide drills provides another solution. When drilling solid metal, surface qualities, dimensional accuracy, and accuracy of shape like those obtained with reaming are achieved. Most of the drilling tools are further improved by suitable coatings.

Short-Hole Drilling. Short-hole drilling with drilling depths of $L < 2D$ covers a large proportion of bolt hole drilling, through hole drilling and tapping. For this, short-hole drills with indexable inserts may be used for diameters from 10 to over 120 mm. Their advantage compared with twist drills is the absence of a chisel edge, and the increase in cutting speed and feed rate achieved with indexable cemented carbide or ceramic inserts. Due to the asymmetrical machining forces, the use of short-hole drills requires rigid tool spindles similar to those found on common machining centers and milling machines. The higher rigidity of the tool enables pilot drilling of inclined or curved surfaces with accuracy of IT7.

Milling

Classification of Milling Processes. In milling, the necessary relative motion between the tool and the workpiece is achieved by means of a circular cutting motion of the tool and a feed motion perpendicular to or at an angle to the axis of rotation of the tool. The cutting edge is not continuously in engagement with the workpiece. Therefore, it is subject to alternating thermal and mechanical stresses. The complete machine-tool–workpiece-fixture system is dynamically stressed by the interrupted cutting action.

Milling processes are classified according to DIN 8589 on the basis of the following:

- The nature of the resulting workpiece surface
- The kinematics of the cutting operation
- The profile of the milling cutter

Milling can be used to produce a practically infinite variety of workpiece surfaces. A distinguishing feature of a process is the cutting edge (major or minor) that produces the workpiece surface (Fig. 7.146): in face milling the minor cutting edge is located at the face of the milling cutter, while in peripheral milling the major cutting edge is located on the circumference of the milling cutter.

A distinction can be made on the basis of the feed direction angle φ (Fig. 7.147): in down-milling the feed direction angle φ is $> 90°$, thus the cutting edge of the milling cutter enters the workpiece at the maximum undeformed chip thickness, while in up-milling the feed direction angle φ is $< 90°$, thus the cutting edge enters at the theoretical undeformed chip thickness $h = 0$. This initially results in pinching and rubbing.

A milling operation may include both up-milling and down-milling. The principal milling processes are summarized in Fig. 7.148.

Plain Face Milling with End Milling Cutters. The kinematics of cutting and the relationship of the cutting

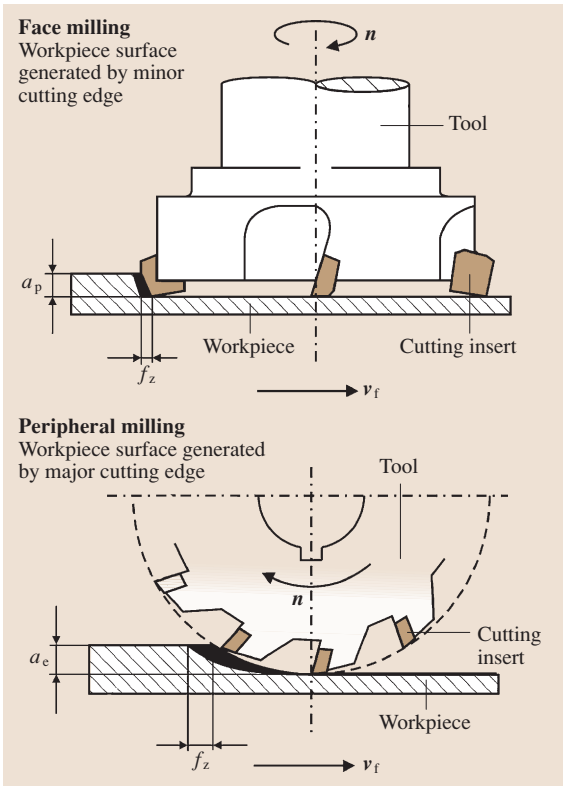

Fig. 7.146 Comparison of face milling and peripheral milling

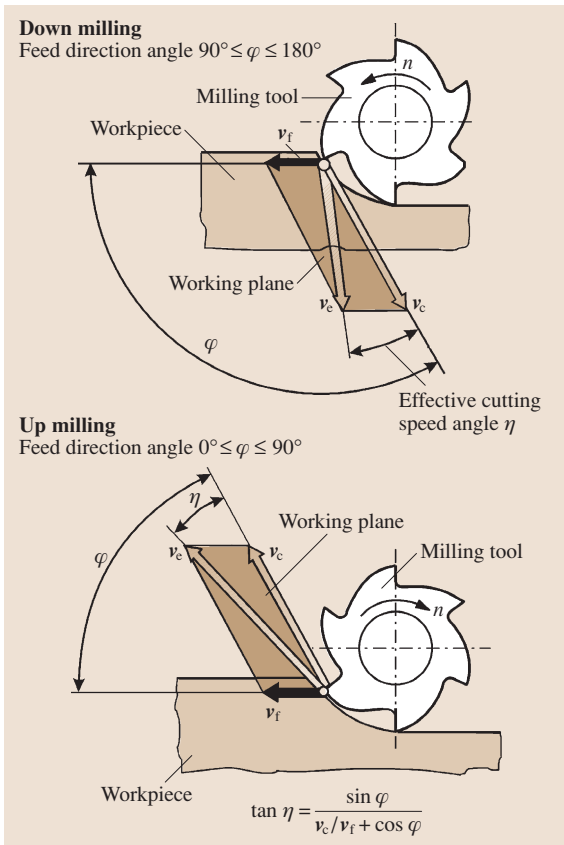

Fig. 7.147 Comparison of down and up milling (DIN 6580E)

forces during milling will be discussed with reference to plain face milling with an end milling cutter.

Kinematics of Cutting in Milling. To describe the process, it is necessary to distinguish between the tool-workpiece engagement variables and the cutting variables. The engagement variables, which are expressed in relation to the working plane, describe the interaction of the cutting edge and the workpiece. The working plane is described by the cutting speed vector v_c and the feed velocity vector v_f. In milling the engagement variables are (Fig. 7.149): depth of cut a_p, measured at a right angle to the working plane, cutting engagement a_e, measured in the working plane at right angles to the feed direction, and feed of the cutting edge f_z, measured in the feed direction.

For a full description of the kinematics of cutting, the following data are required: milling cutter diameter D, number of teeth z, tool excess x_e, and the cutting edge geometry (side rake angle γ_f, back rake angle γ_p, side clearance angle α_f, back clearance angle α_p, entry angle κ_r, angle of inclination λ_s, cutting edge radius r, and chamfer).

Due to the interrupted cut, the entry and exit conditions of the cutting edge, and the types of contact, are especially important for milling processes. The types of contact describe the nature of the first and last contacts of the cutting edge with the workpiece. They can be determined from the entry angle φ_E, the exit angle φ_A, and the tool geometry. Generating the first point of contact with the cutting edge tip should be avoided.

From the engagement variables the cutting variables can be derived, which indicate the dimensions of the layer of material to be removed from the workpiece. The cutting variables are not identical to the chip variables, which describe the dimensions of the resulting chips. The cutting edges describe cycloids in relation to the workpiece. As the cutting speed is significantly higher than the feed velocity, they can be approximated by cir-

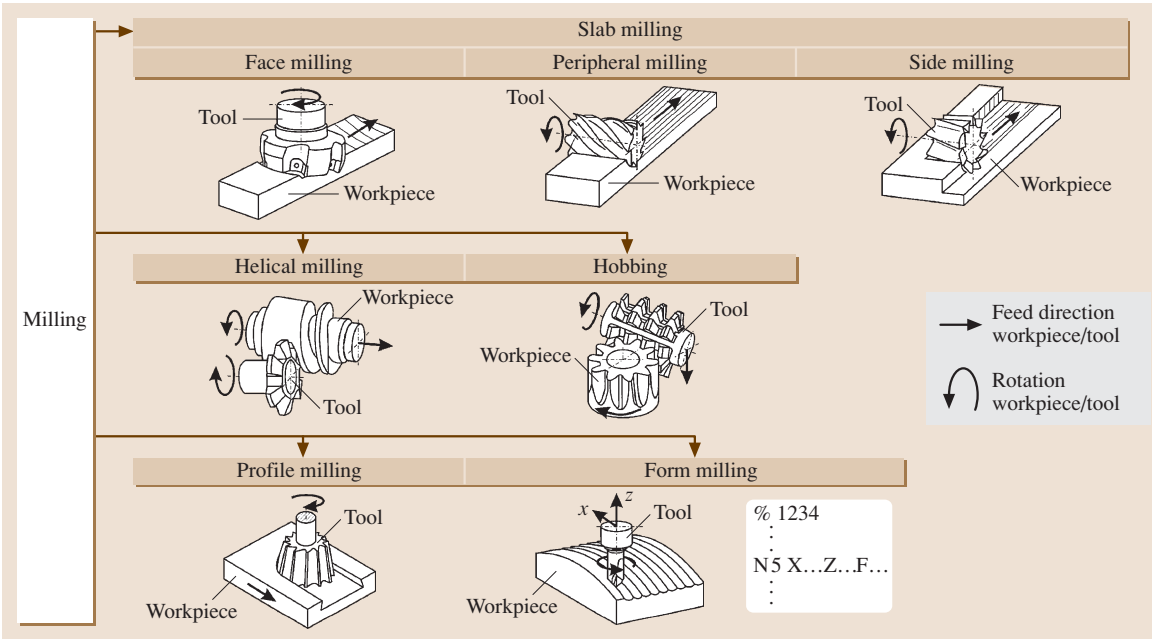

Fig. 7.148 Milling processes (DIN 8589)

cular paths. Taking this into account, the undeformed chip thickness is (Fig. 7.149)

$$h(\varphi) = f_z \sin\kappa \sin\varphi \,. \tag{7.157}$$

With the undeformed chip width $b = a_p / \sin\kappa$, the undeformed chip cross-section is

$$A(\varphi) = bh(\varphi) = a_p f_z \sin\varphi \,. \tag{7.158}$$

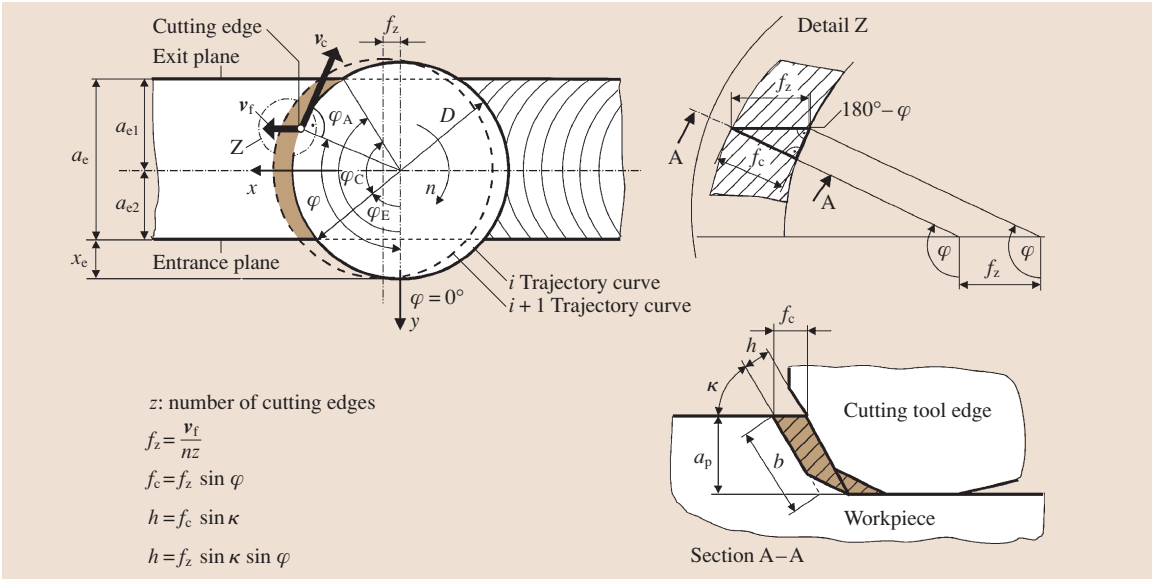

Fig. 7.149 Tool–workpiece engagement variables in plain face milling

The time-related chip volume is $Q = a_c a_p v_f$. The undeformed chip thickness is a function of the entry angle φ and is thus not constant as in turning. The evaluation of the milling process is based on the mean undeformed chip thickness

$$h_m = \frac{1}{\varphi_c}\int_{\varphi_E}^{\varphi_A} h(\varphi)\,\mathrm{d}\varphi = \frac{1}{\varphi_c} f_z \sin\kappa(\cos\varphi_E - \cos\varphi_A)\,. \qquad (7.159)$$

Cutting Force Components. The machining force required for chip formation has to be absorbed by the cutting edge and the workpiece. According to DIN 6584, the machining force F can be resolved into an active force F_a, which lies in the working plane, and a passive force F_p, which is perpendicular to the working plane. The direction of the active force F_a changes with the entry angle φ. The components of the active force can be expressed in relation to the following directions (Fig. 7.150).

- Direction of cutting speed v_c: the components cutting force F_c and perpendicular cutting force F_{cN} relate to a co-rotating system of coordinates (tool-specific components of the active force).
- Direction of rate of feed v_f: the components feed force F_f and perpendicular feed force F_{fN} relate to a fixed system of coordinates (workpiece-specific components of the active force).

For converting the active force from the fixed system of coordinates into a co-rotating system, the following equations apply

$$F_c(\varphi) = F_f(\varphi)\cos\varphi + F_{fN}(\varphi)\sin\varphi\,, \qquad (7.160)$$
$$F_{cN}(\varphi) = F_f(\varphi)\cos\varphi + F_{fN}(\varphi)\cos\varphi\,, \qquad (7.161)$$
$$F_x(\varphi) = F_f(\varphi)\,, \qquad (7.162)$$
$$F_y(\varphi) = F_{fN}(\varphi)\,. \qquad (7.163)$$

This transformation is important if, for instance, the cutting force F_c is to be measured with a three-component force-measuring dynamometer that holds the workpiece. Figure 7.150 shows the pattern of the components of the active force in the tool- and workpiece-specific systems of coordinates for plain face milling with an end milling cutter.

Prediction of Cutting Force Components. Kienzle's machining force equation [7.63] can also be applied to milling. For the machining force components cutting force F_c, perpendicular cutting force F_{cN} and passive force F_p the calculation is

$$F_i = Ak_i\,, \qquad (7.164)$$

where $i = \mathrm{c}, \mathrm{cN}, \mathrm{p}$. A is the undeformed chip cross-section and k_i is the specific machining force. Owing to the wide range of undeformed chip thicknesses that is covered by milling (the undeformed chip thickness depends on the engagement angle φ), Kienzle's relationship only applies to certain areas. The undeformed chip thickness range of $0.001\,\mathrm{mm} < h < 1.0\,\mathrm{mm}$ is divided into three sections (Fig. 7.151). For each section,

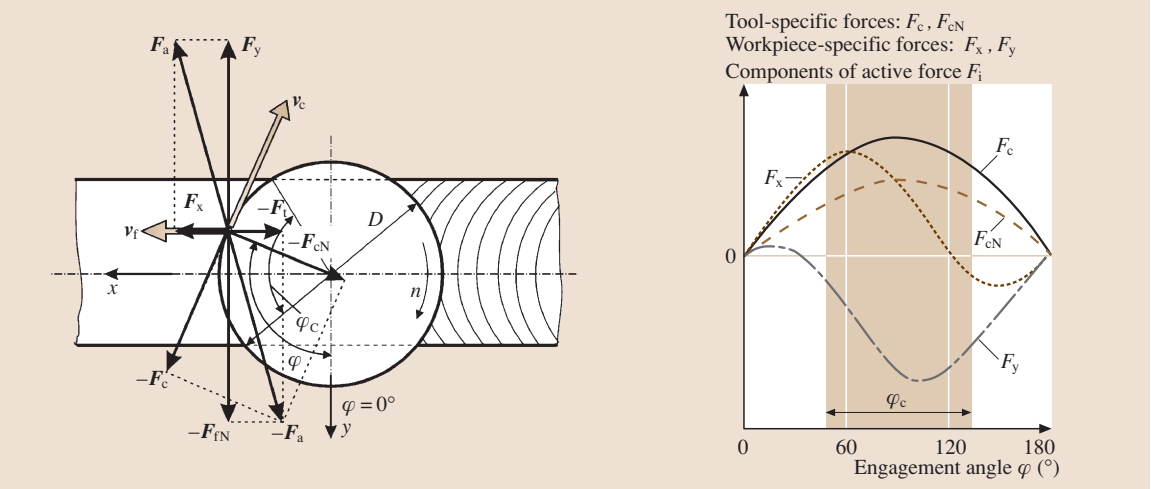

Fig. 7.150 Components of cutting force in plain face milling

a straight line can be determined, depending on, the unit specific cutting force k_i and its exponent m_i. For the specific cutting force the following equations apply

$$k_i = k_{i1.0,01} h^{-m_{i0,01}} \quad \text{for} \quad 0.001\,\text{mm} < h < 0.01\,\text{mm}\,, \tag{7.165}$$

$$k_i = k_{i1.0,1} h^{-m_{i0,1}} \quad \text{for} \quad 0.01\,\text{mm} < h < 0.1\,\text{mm}\,, \tag{7.166}$$

$$k_i = k_{i1.1} h^{-m_i} \quad \text{for} \quad 0.1\,\text{mm} < h < 1\,\text{mm}\,, \tag{7.167}$$

where $i = \text{c, cN, p}$.

Thus the cutting force for milling with an end milling cutter is

$$F_i = b k_{i1.1} h^{1-m_i}\,, \tag{7.168}$$

where $i = \text{c, cN, p}$.

The corresponding component of the cutting force can be calculated for milling if unit specific cutting force k_i and its exponent m_i for the workpiece/cutting material combination and the cutting conditions are available. The machining indices for axial plane face milling with a milling head are given in Table 7.40 for a number of workpiece materials and cutting conditions [7.63]. Often, though, to estimate the cutting force during milling, values obtained from turning will have to be used.

The milling machine capacity is designed on the basis of the average machining force

$$F_i = b k_{i1.1} h_m^{1-m_i} K_{\text{pro}} K_\gamma K_\text{v} K_{\text{TW}} K_{\text{CM}}\,, \tag{7.169}$$

where $i = \text{c, cN, p}$.

In this equation, h_m is the mean undeformed chip thickness, $K_{\text{pro}} = 1.2\text{–}1.4$ is the correction factor for the manufacturing process (the factor takes into account the fact that the machining indices were obtained from turning tests), K_γ is the correction factor for the rake angle (see the section *Turning*), K_v is the correction factor for the cutting speed, K_{TW} is the correction factor for tool wear, and K_{CM} is the correction factor for the cutting material. Experimental research on plain face milling has proven that the influence of wear on the machining force components cannot be ignored.

Vibrations. Depending upon the elasticity frequency response of the complete milling machine-milling cutter-workpiece-fixture system, the metal cutting forces generate vibrations that may affect surface quality and tool life. According to their origin, these vibrations are divided into separately excited and self-excited vibrations [7.67, 68].

–4°	–7°	6°	23°	–6°	75°

ε	Chamfer
90°	45° × 0.06 mm

Fig. 7.151 Specific cutting force in plain face milling

In the case of separate excitation, the complete system vibrates at the frequency of the exciting external forces. Due to the intermittent cutting action of milling the cutting edges are not constantly in engagement. With a multiple-edged milling cutter, the number of cutting edges in engagement at any time should be taken into account. Depending on the ratio a_c/D, z_{iE} cutting edges are in engagement, the following relationship being valid

$$z_{\text{iE}} = \frac{\varphi_\text{c}}{2\pi} z\,, \quad \text{where} \quad \frac{\varphi_\text{c}}{2} = \frac{a_\text{c}}{D}\,. \tag{7.170}$$

The mean cutting force acting on the milling cutter and thus on the spindle of the milling machine is

$$F_{\text{cm}} = z_{\text{iE}} F_{\text{cmz}}\,, \tag{7.171}$$

where F_{cmz} is the mean cutting force of a single cutting edge. Superimposed on the mean cutting force is a dynamic force element. The larger the value of z_{iE} the smaller the force amplitude; if z_{iE} is an integer, the cutting force amplitude is at a minimum. The dynamic force element leads to separately excited vibrations between the workpiece and the milling cutter.

In the case of self-excitation, the complete machining system vibrates at one or more eigenfrequencies, without an external interference force affecting the system. Special importance is attached to self-excited vibrations that arise because of the regenerative effect which are also referred to as *regenerative chatter*. The chatter is caused by variations in cutting force due to changes in undeformed chip thickness [7.67]. Chatter can be influenced by varying the cutting speed, depth of cut, feed rate, and cutting edge geometry.

Tool Wear in Milling. Due to the intermittent cutting action in milling, the cutting material is subject to alternating thermal and mechanical stresses. As a consequence, not only face and flank wear but also cracking in the cutting tip may determine tool life. Figure 7.152 depicts the tool life travel per tooth based on the flank wear of the primary cutting edge of an end ball nose milling cutter for different cutting tool materials [7.56]. As shown especially with the development of cubic boron nitride (CBN), the wear behavior of milling tools could be significantly improved, thus allowing finish-machining of hardened materials by milling [7.69–71]. Suitable data for cutting parameters are accessible via catalogues of all major milling tool manufacturers. Depending on the cutting conditions, surface roughness values comparable to those obtained in grinding are achieved. In grinding, the accuracy of shape is achieved by spark-out. As there has to be a minimum undeformed chip thickness in milling, shape defects occur, which

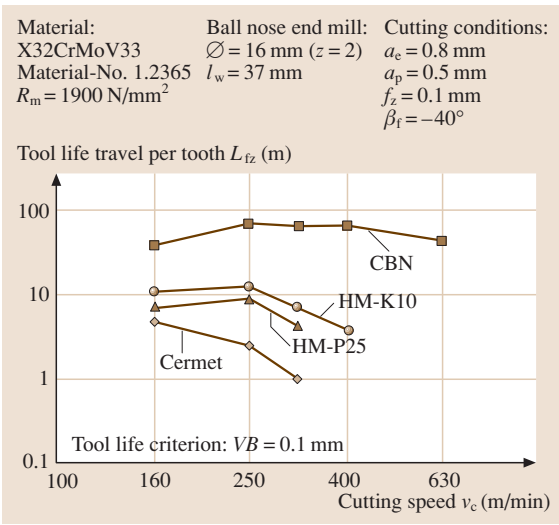

Fig. 7.152 Milling tool wear depending on cutting tool material and speed (after [7.56])

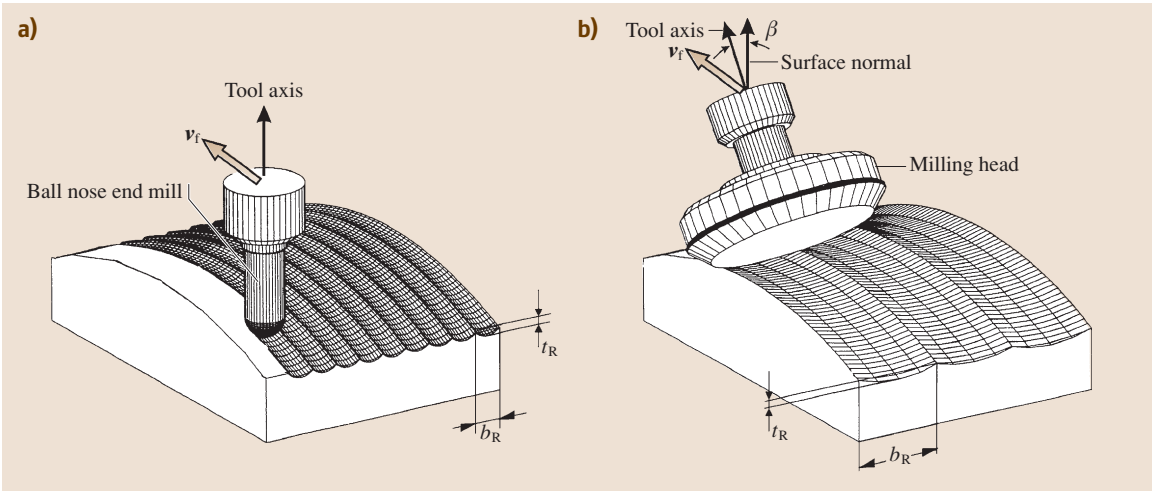

Fig. 7.153a,b Form milling by (a) 3-axis milling and (b) 5-axis milling

can be attributed to the following influencing variables: environment, operating behavior of the milling machine, inhomogeneity in material hardness, heat absorption of the workpiece due to metal cutting, and a change of residual stresses in the edge zone of the workpiece.

Form Milling. Hollow-mold tools such as deep-drawing tools are manufactured by both chip-removal and chipless machining processes. Milling plays a dominant role as a controlled shaping process. The essential characteristic in form milling is the number of actively controlled axes, a distinction accordingly being made between three-axis milling and five-axis milling (Fig. 7.153). In five-axis milling, not only the tip but also the axial direction of the milling cutter is continuously and simultaneously controlled relative to the workpiece coordinate system. The profile of the milled grooves determines the productivity and quality of the process (small final finishing with a small profile depth being desired). It is formed by machining a curved surface in parallel lines and depends on the milling cutter geometry, the workpiece geometry, and the method of work. For a given groove depth t_R, five-axis milling with an end milling cutter produces significantly larger groove widths b_R than three-axis milling with a convex ball nose end milling cutter.

Other Processes: Planing and Shaping, Broaching, Sawing

Planing and Shaping. According to a German standard a distinction can be made between planing and shaping. Chip removal is accomplished during the working stroke with a single-point cutting tool. The following return stroke resets the tool to its original position. The feed is performed intermittently, usually at the end of a return stroke.

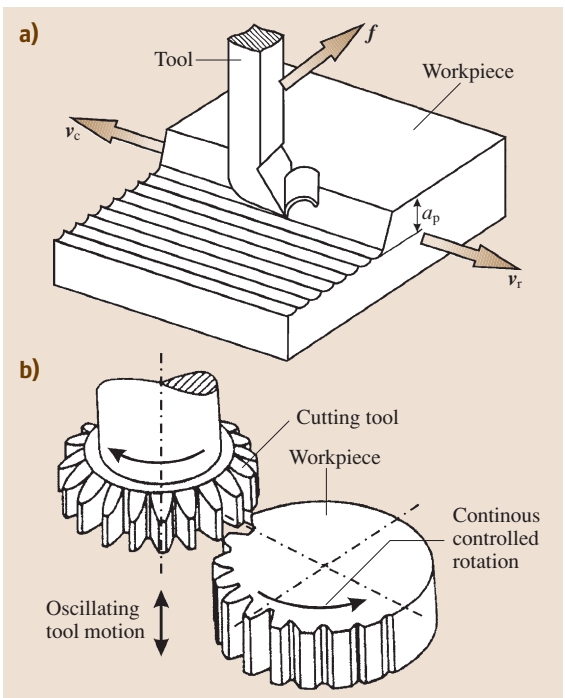

Fig. 7.154 (a) Planing and (b) gear shaping

In planing, the workpiece performs the cutting motion with the cutting speed v_c and the return motion with v_r. Feed f and depth of cut a_p are accomplished by the tool (Fig. 7.154a). In shaping, the tool performs the cutting and return motion, while feed and engagement are accomplished by the workpiece or the tool.

The reciprocating motion of the workpiece (in planing) or the tool (in shaping) produces high inertia forces and limits the cutting speed. As a guideline for the cutting speed, for machining steels the ranges $v_c = 60–80$ m/min (roughing) and $v_c = 70–100$ m/min (finishing) are well established for cemented carbide tools. Frequently used special methods are manufacturing by planing or shaping (Fig. 7.154b) to produce involute gears [7.72].

Broaching. In broaching material is removed using a multiple-pointed tool, the teeth of which are one behind the other and are successively stepped by one layer of the material to be removed. Thus no feed motion is required, as it is *built into* the tool. The cutting motion is usually linear or, under certain circumstances, helical or circular.

The advantages of the process are the high productivity and the possibility of finishing workpieces with a single tool because high surface finish and dimensional accuracies with tolerances up to IT7 can be achieved. Due to the high cost of the tools, the main areas of use are series and mass production; a new tool is required for each workpiece shape.

A basic distinction is made between internal broaching and external broaching. In internal broaching, the broach is pushed or pulled through a hole, while in external broaching the tool moves along the surface.

Broaches are divided into roughing, finishing, and calibrating teeth sections (Fig. 7.155). Normal undeformed chip thicknesses in flat broaching of steels are $h_z = 0.01–0.15$ mm for roughing and $h_z = 0.003–0.023$ mm for finishing. Broaching of cast materials is carried out up to a thickness of $h_z = 0.02–0.2$ mm in the roughing section and $h_z = 0.01–0.04$ mm in the finishing section.

Cutting speeds are restricted by the hardness of the chosen cutting material at high temperature and by the efficiency of the machine. The cutting material most commonly used, high-speed steel (HSS), permits only low cutting speeds owing to its hot hardness of approximately 600 °C. Cutting speeds of $v_c = 1$ to 30 m/min are used, with speeds of up to 70 m/min in exceptional cases. The capacity of the process can be increased by using TiN-coated HSS or cemented carbide. Due to these developments broaching of case-hardened steel workpieces with cemented carbide tools has also become possible [7.73]. High cutting speeds require high drive power outputs to accelerate and decelerate the tool and the broach slide, causing a disproportionate increase in equipment costs. Vibration problems might also occur, especially with thin internal broaches.

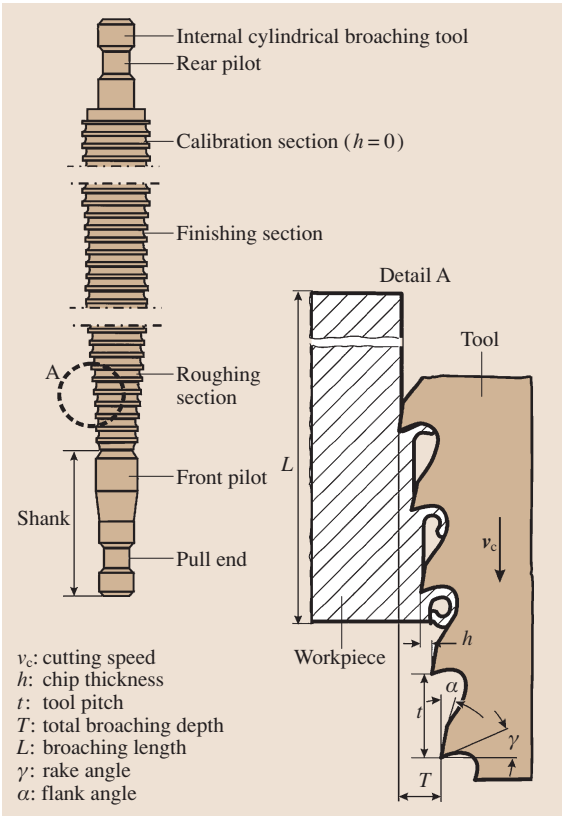

Fig. 7.155 Internal cylindrical broaching tool and process characteristics

In broaching, mainly mineral oils are used as cutting fluid for lubricating and cooling in the contact zone, but above all to prevent the formation of built-up edges and to carry away the chips. They usually contain EP (extreme pressure) additives, which are nowadays mostly chlorine-free.

Besides the above-mentioned internal and external broaching operations also special process configurations like gear scraping or turn broaching are used in industry [7.72].

Sawing. Sawing is metal cutting with a multiple-pointed tool having a small width of cut for severing

or slitting workpieces. The rotational or linear principal motion is performed by the tool. The teeth of the tool are offset in alternate directions. Thus the kerf is widened in relation to the saw blade, thus reducing friction between tool and workpiece (Fig. 7.156).

Band sawing is sawing with a continuous, usually straight cutting motion of a rotating endless band. The motions and cutting parameters are shown in Fig. 7.156A.

The normal cutting speeds for high-speed steels lie within the range of $v_c = 6$ to 45 m/min with feed rates per tooth of $F_z = 0.1$ to 0.4 mm. If bands with inserted cemented carbide teeth are used, the cutting speed can be increased to 200 m/min for steels and up to 2000 m/min for light metals.

In reciprocating sawing (hack sawing), a tool of finite length clamped in a holding frame is used. The feed motion is carried out intermittently only as the tool advances or at a constant perpendicular force.

Circular sawing is sawing with a continuous cutting motion using a circular saw blade. In terms of kinematics and metal cutting technique, circular sawing resembles peripheral milling.

Cutting Tool Materials

Cutting tools consist of the cutting tip, the holder, and the shank. Holders and shanks are designed according to constructional and organizational requirements, such as mating dimensions of the machine, the nature and extent of tool storage and tool changing, or the geometry of the workpiece. The cutting tip is responsible for chip removal. It is subject to mechanical and thermal stresses and chemical attack. The tip consequently wears.

A basic dualism applies to all cutting materials. Harder and more wear-resistant materials are typically less tough and stable under periodically changing loads, as well as under unstable cutting conditions and in intermittent cutting. Materials that cope better with variable mechanical or thermal stresses, are often less resistant to wear. The perfect cutting material combining both features is yet to be developed (Fig. 7.157).

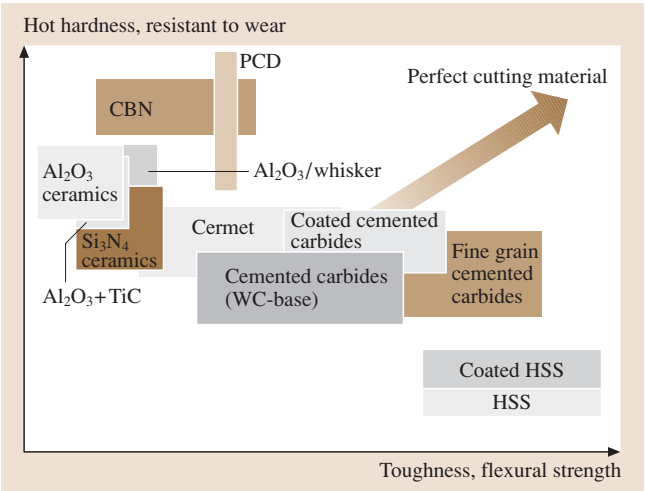

Fig. 7.157 Schematic representation of cutting tool materials (after [7.72])

To overcome this restricting dualism, various cutting materials are manufactured as composite materials. Coating with hard-wearing carbides or oxides produces a separation of functions; the physically (PVD – physical vapor deposition) or chemically (CVD – chemical vapor deposition) vapor-deposited layers provide wear protection and enhanced tribological performance. The tougher substrate performs the supporting function, even under dynamic load conditions. Examples of these coatings include TiN and TiAlN. The latter is applied in dry machining applications due to its higher hardness and enhanced thermal stability compared with TiN [7.74]. Multilayer coatings are also increasingly employed due to their superior tribological performance compared with single layer coatings [7.75].

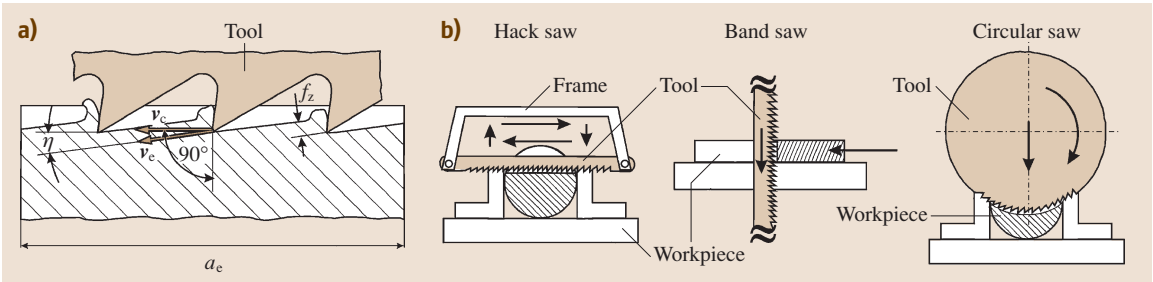

Fig. 7.156 (a) Process kinematics of band sawing and (b) different sawing variants

The primary cutting tool materials include: alloy steels, high-speed steels (HSS), cemented carbides, ceramics and superhard cutting materials (e.g. diamond and cubic boron nitride).

High-Speed Steels. High-speed steels are usually used for drilling, milling, broaching, sawing, and turning tools. Their hot hardness (up to approximately 600 °C) is far superior to that of tool steels (Fig. 7.158). Their hardness results from their basic martensitic structure and from interspersed carbides: tungsten carbides, tungsten-molybdenum carbides, chromium carbides, and vanadium carbides.

The through-hardenability of tools with large cross-sections is increased with molybdenum and/or by alloying with chromium. Tungsten increases the wear resistance and tempered strength, vanadium increases the wear resistance (but is difficult to grind when hard) and cobalt increases the high-temperature hardness. High-speed steels are traditionally manufactured by casting but can also be manufactured by powder metallurgy (PM). PM steels provide enhanced edge strength and cutting edge durability. They are used for thread-cutting and reaming tools. PM high-speed steels with high vanadium contents are easier to grind than their cast high-speed steel counterparts. Their acceptance is only limited because of their higher cost.

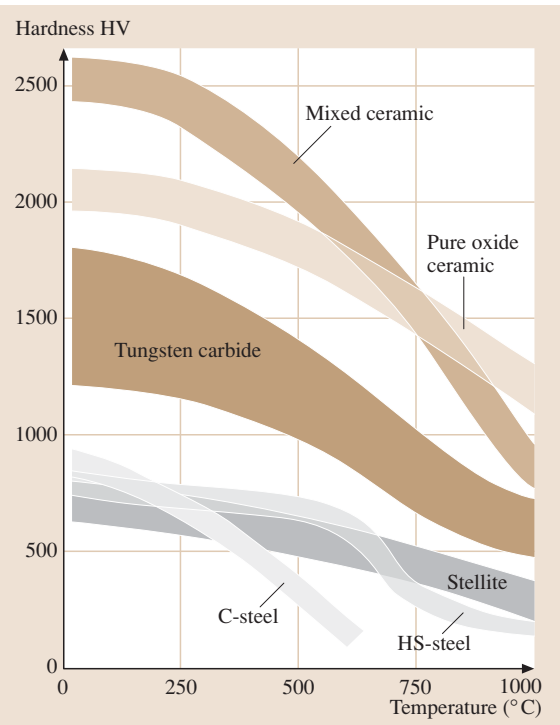

Fig. 7.158 Hot hardness of cutting materials

Coated HSS. High-speed steels are usually coated by physical vapor deposition (PVD), which is reactive ion plating performed at low temperatures in order to stay below the tempering temperature during the process. Simple shapes such as indexable inserts can be treated by chemical vapor deposition (CVD) followed by rehardening. Coated tools (drills, taps, hobs, form turning tools) can have a significantly increased tool life compared to uncoated tools.

A coating of single layers or multilayers deposited on the cutting tools improves its performance. The most frequently used coating materials are titanium carbide (TiC), titanium nitride (TiN), titanium-aluminum nitride (TiAlN), and titanium carbonitride (TiCN).

Coated HSS provides increased hot hardness and wear resistance combined with a high ductility and bending strength of the tool. Tool life can be increased up to 2–2.5 times at increased cutting speed by 20–40%. The most important physical-mechanical properties and parameters obtained by PVD processes are shown in Table 7.41.

The application areas of coatings for cutting tools strongly depend on their properties. TiN has high thermodynamic stability; it is chemically passive to ferrous materials. It combines high hardness and sufficient plasticity. TiN coated HSS tools are mainly used for operations in continuous cutting, e.g. turning, drilling, etc. with the application of cutting fluid.

TiCN provides higher hardness than TiN, and it shows high resistance against oxidation at increased temperatures. TiCN coating is mostly used for milling at increased cutting speeds.

TiAlN has high hardness and increased resistance against oxidation. This material is recommended for high-speed machining combined with flood type application of cutting fluid.

CrN and TiCrN possess high hardness at a rather high level of plasticity. They have high resistance against corrosion and oxidation. HSS tools coated with CrN and TiCrN are recommend for finishing and semifinishing operations at milling with the application of cutting fluid.

Cemented Carbides. Cemented carbides are two-phase or multiphase alloys manufactured by powder metallurgy with a metallic binder. The materials used are

Table 7.41 Properties of some coatings of HSS tools

Properties	Coating materials				
	TiN	TiCN	CrN	TiCrN[a]	TiAlN[a]

tungsten carbide (WC: α-phase), titanium carbide and tantalum carbide (TiC, TaC: γ-phase). The binder is cobalt (Co; β-phase) with a content of 5–15%. Nickel and molybdenum binders (Ni, Mo) are also used in so-called *cermets* (also cemented carbides). A higher β-phase content increases toughness, while a higher α-phase content increases wear resistance and a higher γ-phase content enhances wear resistance at high temperature. Cermets have high edge strength and cutting edge durability. They are suitable for finishing under stable cutting conditions. The manufacturing of cemented carbides by powder metallurgy permits considerable freedom in the choice of constituents (in contrast to casting).

Cemented carbides retain their hardness up to over 1000 °C (Fig. 7.158). They can therefore be used at higher speeds (by a factor of three or more) than high-speed steels. According to standards (DIN 4990/ISO 513) cemented carbides are classified into the metal cutting application groups P (for long-chipping, ductile ferrous materials), K (for short-chipping ferrous materials), M (for ductile cast iron and for ferritic and austenitic steels), N (for nonferrous metals such as aluminum and copper alloys), S (for superalloys and titanium alloys), and H (for hardened materials, such as steels and cast irons). Each group is subdivided due to toughness and wear resistant grades by adding a number. For example, P02 stands for very hard-wearing cemented carbide and P40 stands for tough cemented carbide. The metal cutting application groups do not correspond to grades of cutting tool material, but to the application areas of the finished cutting tools.

Most cemented carbide cutting tools are coated with titanium carbide (TiC), titanium nitride (TiN), aluminum oxide (Al_2O_3), or chemical or physical combinations of these substances. The coatings are applied by CVD or PVD techniques. They are used to achieve longer tool lives or higher cutting speeds. They broaden the range of use of a grade. Coated cemented carbides should not be used for nonferrous metals, high-nickel ferrous materials or, because of the edge rounding caused by the coating process, for precision or ultra-precision machining (cermets are better suited for this purpose). Intermittent cutting and milling requires coatings of especially high bonding strength, which can be influenced by process control during coating.

The application areas of carbides fall into six groups as shown in Table 7.42. The classification is based on the properties of each grade and the machining conditions, type of material being machined, and chip formation.

Ceramics. Ceramic cutting tool materials are single-phase or multiphase sintered hard materials based on metal oxides, carbides, or nitrides. In contrast to cemented carbides, no metallic binders are needed and the material provides high hardness even at temperatures above 1200 °C. Ceramic inserts are generally suitable for machining at high cutting speeds, usually exceeding 500 m/min.

The use of aluminum oxide ceramic is restricted by its lower bending strength and fracture toughness compared with cemented carbide. In intermittent cutting with alternating mechanical and thermal stresses, microcracking, crack growth with microchipping or total fracture can occur. This effect greatly depends on the nature and composition of the ceramic. The change from single-phase materials (Al_2O_3) to multiphase materials has improved toughness considerably: today Al_2O_3 containing 10–15% ZrO_2 (transformation toughening), Al_2O_3 with TiC (dispersion strengthening) or Al_2O_3 reinforced with SiC whiskers (high

Table 7.42 Classification of cemented carbides according to ISO 513:2004-07

Groups of cutting carbide materials			Subgroups of application		Hardness, wear resistance, cutting speed	Toughness, bending strength, feed speed
Designation	**Colour**	**Material machined**

H	Grey	Hard materials: tempered steel, high-strength pig-iron, chilled cast pig-iron	H01 H10 H20 H30	H05 H15 H25	↑	↓

toughness) are used. The main field of application is the turning of flake graphite cast iron at high cutting speeds, though the turning of steel is also feasible. Additions of up to 40% TiC to the Al_2O_3 ceramic (black mixed ceramic) increase toughness and edge strength. These are used for hard machining and the finishing of cast iron.

Silicon nitride (Si_3N_4) exhibits many excellent cutting material qualities (high strength, hardness, oxidation resistance, thermal conductivity, and resistance to thermal shock) owing to strong covalent bonding of the elements. Here, fracture toughness is not a primary limiting factor in selecting application areas. Sintered Si_3N_4 ($\rho = 3.1\,g/cm^3$, $R_m = 650\,MPa$), hot-pressed Si_3N_4 ($\rho = 3.2\,g/cm^3$, $R_m = 700\,MPa$) and the material system Y-Si-Al-O-N are all used as cutting tool materials. The manufacture and use of Si_3N_4 is currently limited by the sintering auxiliaries (e.g. magnesium oxide, yttrium oxide), which determine the glassy phases in the cutting material. When machining steel or ductile cast iron, failure occurs due to severe

Table 7.43 Properties of oxide ceramics

wear. Si_3N_4 is suitable for turning and milling of gray cast iron, for highly intermittent cutting actions, and for the turning of high-nickel content materials. The properties of some oxide ceramic materials are given in Table 7.43.

Superhard Cutting Tool Materials. Superhard cutting tool materials include polycrystalline diamond (PCD), polycrystalline cubic boron nitride (PCBN), monocrystalline diamond (MCD), and various forms of chemical vapor deposition diamonds (both thin-film coatings and self-supporting thick-films). The polycrystalline diamond is typically manufactured as a *backed* 0.5–2.0 mm layer of superhard composite on a cemented carbide substrate. PCD is used to machine nonferrous metals, including metal-matrix composites (MMC), wood, composites, stone, and certain cast irons. Due to a well-defined maximum operating temperature of between 700–800 °C, it cannot be used for machining of steels. PCBN is manufactured as either a carbide-backed or solid material. Different grades of PCBN are used for the machining of gray, white, and high-alloy cast irons, and hardened steels. Coatings on PCBN tools are becoming increasingly popular as with cemented carbides. Monocrystalline diamond tools are used for high-precision and ultra-precision machining of aluminum, copper, electroless nickel, glass, plastic, and silicon where, for example, surface finish requirements of several nm and form errors of less than 0.1 µm are common [7.76]. Being a single crystal material, it is possible to produce an extremely sharp cutting edge, within the range of 10–100 nm. Thick-film CVD diamond is generally considered as lying between monocrystalline and polycrystalline diamond, in terms of properties and behavior in application.

In Table 7.44 conditions of cutting parameters and application areas of PCB and PCD tools are shown.

Table 7.44 Application of and cutting parameters for PCB and PCD tools

Work material	Cutting speed (m/min)	
	Turning	Milling
PCB		
Structural and tool steels (without thermal treatment) (< 30 HRC)	–	400–900
Hardened steels (35–55 HRC)	50–200	200–400

WC-Co carbides	15–30	15–45

Tooling

The design of tools has to take all possible impacts into account which can occur during the specific process, comprising mechanical, thermal and chemical loads, as well as flexibility, changeability, maintenance, and costs. Therefore solid tools, tools with brazed tips, and tools with indexable inserts are in use.

In turning the toolholders have to be mounted to the different types of turrets on a lathe, taking into account tool changing time and collision contours. In the case of driven tools like milling shank type cutters have to be clamped in specific toolholders, which are used as interface between the actual cutting tool and the main spindle of the milling machine (Fig. 7.159). The stiffness of the cutters and the toolholders is important for the required surface quality and has a strong influence on the probability of chatter in milling.

In the case of high performance or high speed cutting conditions significant attention has to be paid to the quality of the machine–tool-interface regarding unbalance, stiffness, and damping [7.77, 79]. The machine facing side of these toolholders is standardized. Most often short tapers, steep-angle tapers, or hollow shank tapers are used. The toolholders are fixed in the main spindle by mechanical or hydraulic power.

A number of different toolholder systems are available on the market. This system, the machine tool and the tool changer determine the possible chip-to-chip time in case of a change of the tool [7.80].

Microcutting

Micromanufacturing is defined as the production of components with feature sizes in the range of 1–500 µm. Microcutting is therefore a process used for the production of components of micron dimensions with submicron form accuracy and surface roughness to within a few tens of nanometers [7.81, 82], achieved by mechanical removal of material using defined edge tools. Common microcutting operations include microturning, microdrilling, and micromilling. Examples of features produced by microcutting are shown in Fig. 7.160 while microcutting tools are shown in Fig. 7.161.

The scale of the tool cutting edge geometry, often simplified as a single radius of curvature, is generally similar to the scale of the undeformed chip thickness (as indicated in Fig. 7.162b). The result is a *size-effect* due to a more negative *effective rake angle* as the undeformed chip thickness is reduced. There is also an increase in friction, elastic and ploughing energies, relative to the energy expended in material removal, and therefore an increase in specific cutting

Shank type tool clamping devices	 Precision collet chuck	 Hydraulic expansion-chuck	 Heat shrink chuck

energy. The increasing negative rake produces hydrostatic stresses in the near surface enabling ductile mode machining of brittle materials (optical glasses, ceramics, etc.) [7.83]. An isotropic material size-effect also pertains whereby the material strength approaches the theoretical value due to the reduction in dislocation density in the cutting zone as the undeformed chip thickness decreases.

The work material microstructure may also affect the microcutting process performance. For example, the grain size and anisotropy of polycrystalline (PC) metals and alloys can affect the surface finish. Figure 7.162b shows a simplified model of this mechanism. The modulus of elasticity E of a PC material varies in different atomic lattice directions. After the cutting tool has passed, as shown, the grains return to equilibrium positions (the *springback effect*) but to different surface levels due to the differences in the crystal orientations and modules of elasticity.

Tool materials for microcutting must be of high hardness. Diamond tools are generally used for cutting nonferrous metals, ceramics, semiconductors, and glasses. Tungsten carbide is used for ferrous-based metals where diamond tools are limited due to their wear conditions (graphitization, oxidation, diffusion, and carbide formation). Single crystal diamond cutting tools are preferred for microcutting as they can have cutting edge *radii* in the order of 10 nm. With polycrystalline tools, such as tungsten carbide-based tools, the achievable edge sharpness is limited by the grain size. Ferrous alloys have recently been machined with single crystal diamond tools using ultrasonic elliptical vibration cutting to lower cutting temperatures [7.85].

The mechanics of tool and machine tool design must be considered in microcutting. Small diameter tools for microdrilling and micromilling require very high spindle speeds. Furthermore the precision of a machine tool has to be increased in order to maintain a given relative dimensional tolerance. As a component and associated load are reduced in scale, the structural stiffness will decrease, and the natural frequency and internal stresses will increase. Finally, the ratio of total surface area to workpiece (feature) volume is increased in microcomponents, making the surface integrity of the component more significant in comparison with bulk properties.

High-Speed Cutting

The development of high-efficiency machine tools and new cutting tool materials facilitated the application of high-speed cutting (HSC) in metal working.

The main objective of HSC application is to the reduce machining time and increase the removal rate. High cutting speeds lead to lower cutting forces, higher machining accuracy, and improved surface quality compared to traditional cutting [7.86].

The HSM concept was initially developed for the aerospace industry, especially for machining titanium alloys, but was soon adapted by other industrial branches using different materials. At present, a range of materials are being machined with HSM, including nickel-based alloys, titanium, steel, cast iron,

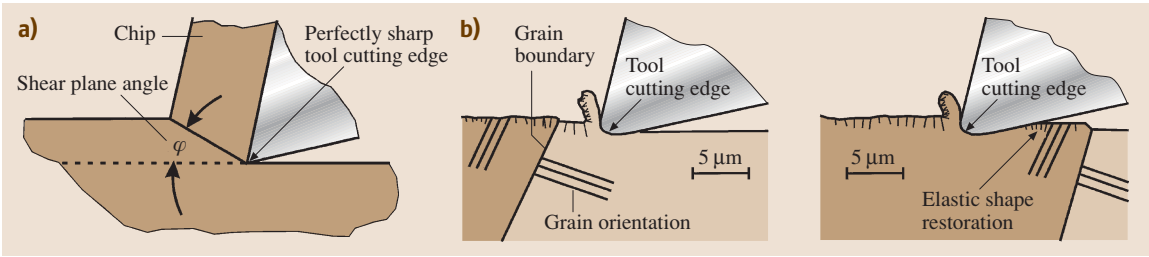

Fig. 7.162 (a) Conventional orthogonal cutting and (b) microcutting showing finite tool cutting edge geometry and workpiece anisotropy

aluminum, and reinforced plastics. The industries using HSM include the aerospace, automotive, and tool/die industries, just to mention the most important users, primarily for manufacturing parts made from aluminum, titanium, and steel alloys. There are a number of extremely important challenges affecting high speed machining, namely the need for hard machining, environmentally friendly hard machining, and the machining of free form (sculptured) surfaces, high material removal rates, increased productivity and quality.

In aerospace the wing spar and stringer components are made from high-grade aerospace aluminum materials. Typically at least 85% of the aluminum billet is turned into chips, which requires excellent off-line work preparation to eliminate machine tool loading time waste, powerful chip-management, and cutting fluid management systems. It is extremely important in the aerospace industry that the HSM technology does not induce residual stresses into the machined component, thus it drastically reduces the problem otherwise caused by fatigue. It is also important that thin walls can be machined easily without deformation.

There are a number of major automotive industries in the world, who also use HSM for making their strategic components in combination with hard cutting to replace the very expensive grinding technology.

In the tool/die industry tools and dies are normally made of difficult-to-machine alloys, which have to be heat treated for high production performance. This represents an extremely high challenge for high speed machining, including machine tools, cutting tools, and technology alike.

In HSM the maximum cutting speed depends upon the workpiece material, the type of cutting operation, and the cutting tool used.

Salomon proposed to use high cutting speeds when machining various materials [7.87]. This idea was based on the hypothesis that when the cutting speed increases to a critical value, the cutting temperature decreases. Some research has been carried out with cutting speeds within the range of $v_c = 47\,000–132\,000\,\mathrm{m/min}$. The most general definition of HSM is the economical utilization of resources and functions to remove the greatest amount of material in the shortest time span by mechanical means.

The achievable maximum cutting speed largely depends on the available high-speed spindle technology and tool technology, including the tool diameter. The high-speed range lies between 800 and 10 000 m/min, depending on the cutting material, productivity, and accuracy [7.88].

In principle, the higher the cutting speed, the more energy is required to remove material [7.89]. The generated heat causes a softening of the material, thus the energy requirement is reduced. During high-speed machining friction and the length of the contact area between the chip and the rake face of the tool reduces contact time. This results in corresponding heat distribution in the cutting system and decreased intensity of heat flow to the tool and workpiece.

The increased productivity of processes using HSC is attributed to the improved material removal rate. Reduction of cutting forces, thermal emission level at the cutting area and thermal-mechanical effect on the machined surface, as well as its elastic form recovery allows considerable improvement of quality and accuracy of machined parts.

HSC has a number of competitive advantages over traditional machining:

- Substantially increased material removal rate
- Excellent surface finish with superb surface integrity
- Low cutting forces, which allow for the machining of thin wall sections
- High frequency system that does not cause any vibration during machining

Table 7.45 Examples of high-speed cutting technologies

Material	Cutting tool	Machining operation	Cutting speed (m/min)
Al-alloys Mg-alloys	Coated carbides, PCD	Milling	1000–7000
High-temperature steel, graphite, copper	Coated carbides, cutting ceramics, PCB	Milling	350–2000
Reinforced plastics, nonferrous metals	Coated cermets	Drilling	100–300

- *Cold* machining, whereby the chips take away most of the heat generated in the process
- Increased accuracy of machining

Table 7.45 shows some high-speed cutting applications.

The efficiency of high-speed cutting becomes apparent when cutting hardened steels with hardness above 45 HRC. HSC of hardened steels and refractory materials is only possible at a small depth of cut and with small wear land of the cutting tool. Machine tools for high-speed cutting should have high rigidity, be equipped with high pressure or minimum quantity lubrication system.

In any case the definition of high cutting speed is material dependent. In Fig. 7.163 an attempt is presented to deduce the area of high cutting speed v_{HSC} from material properties. Extensive research has led to the conclusion the tensile strength of the workpiece material is suitable for a definition of v_{HSC} by means of an empirical equation [7.90].

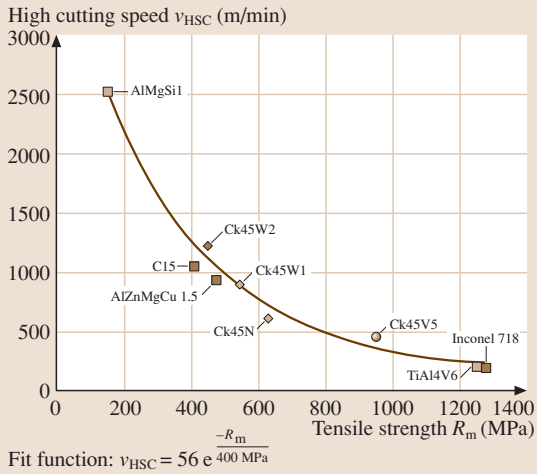

Fig. 7.163 Material depending definition of HSC (after [7.90])

High-Efficiency Machining (HEM). High-efficiency machining means cutting a part in the least amount of time, which is the real target function in machining. High-efficiency machining can be achieved by a variation in the feed rate. Typically, high-speed machining is accomplished with very small axial cut depths in order to achieve good surface finish and avoid damage to the cutter, workpiece, or spindle. Feed rate optimization software can be employed to achieve better cutting efficiency with greater axial depths at high feed rates similar to those of HSM and to protect the cutter in those few places where the chip load momentarily increases. Constant chip load tool paths allow optimum use of the cutter's strength and the machine's speed and power. The software detects conditions under which the chip load would be too high and adjusts the feed rate to a more reasonable level. It returns to the higher feed rate when it is suited [7.91].

Thin-walled components are used widely in the aerospace industry. However, thin-walled components very easily deflect under the cutting forces during the cutting process, which results in compromised machining precision and efficiency. Some solutions have been proposed for the control of machining deflection, such as the NC compensation approach by a tilting tool.

Using this method, the machining deflections are analyzed by FEM. Then the feed rate is adjusted to the degree of deflection by CNC compensation in order to cut off the excessive material due to the deflection. Thus, the thin-walled component can be machined with high precision and high efficiency on a 5-axis CNC machining center.

Hard Machining

Machining of steels of hardness beyond 45 HRC is often required in metal cutting; it is called hard machining. Therefore hard machining, turning, milling, and drilling, are viable alternatives to grinding.

Hard machining is characterized by a low friction coefficient in the cutting area, the application of a rel-

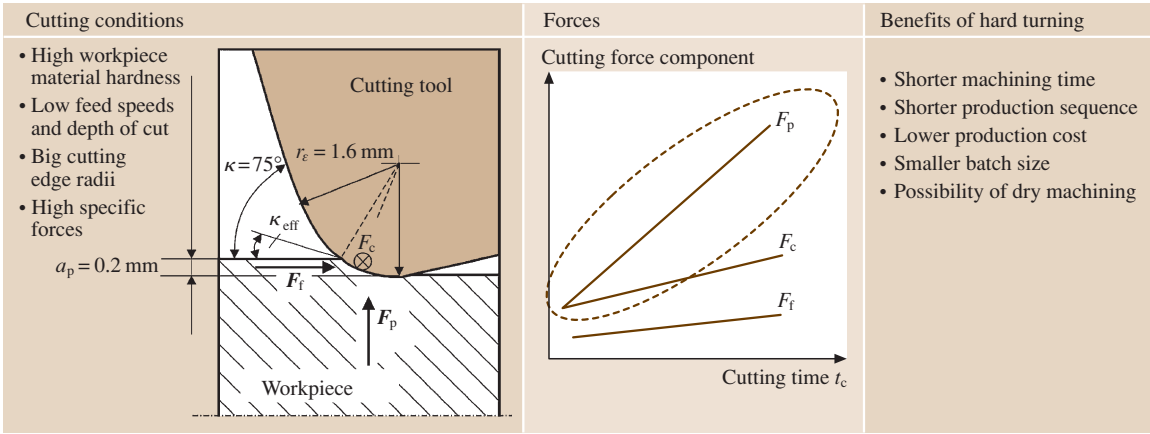

Fig. 7.164 Principle and benefits of hard turning (after [7.92])

atively high cutting speed, low feed and depth of cut, which result in reduced chip–tool contact length. Due to the redistribution of the generated heat which causes a softening of the material and to the high compression load on the workpiece material, machining efficiency increases. The major breakthrough of this technology was connected with the introduction of suitable cutting tool materials as ceramics and CBN for turning and coated tungsten carbides for milling and drilling. These developments made hard machining a serious competitor for grinding and electro discharge machining. As an example of successful application of hard machining the conditions and benefits of hard turning are presented in Fig. 7.164. Important to mention is the fast rising and dominating passive or back force F_p, which needs an excellent lathe with superior stiffness to compete with grinding. Also the possibility to apply dry machining is a major benefit, allowing all costs and problems related to cutting fluids to be avoided.

7.3.2 Machining with Geometrically Nondefined Tool Edges

Fundamentals

Machining with geometrically nondefined tool edges is cutting by the mechanical action of cutting edges on the material. The cutting edges are formed by grains of hard material randomly shaped and arranged. They are either bonded together into a tool (grinding, honing) or are used loose (lapping, abrasive blasting). The cutting edge geometry is not described with reference to a single grain. The individual cutting edge is geometrically nondefined. The processes are divided into the following subgroups:

- Grinding with rotating tools
- Belt grinding
- Honing
- Lapping
- Free abrasive grinding/abrasive tumbling
- Machining by abrasive blasting

The common factor in these processes is that the grains of hard material generally form several cutting edges. The important cutting edge angles for chip formation, the clearance angle α, the rake angle γ, and the wedge angle β are only indicated by means of statistical parameters such as mean values or distributions. On average, sharply negative rake angles and large contact and friction zones are formed between the grain and the workpiece. The cutting edges penetrate only a few micrometers into the material. The undeformed chip thickness distribution depends on the positioning of the cutting edges in the mixture of grains (microtopography of the cutting zone) and the geometry of the machined workpiece surface. Not only chip removal but also elastic and plastic deformations without chip removal take place.

High normal forces result between tool and workpiece at the predominantly negative rake angles of the cutting edges. They lead to elastic deformations in the machine (stretching of the frame and deflection of the spindle), the tool, and the workpiece. The amplitude of deformations may be comparable to the normal small feed motions. Therefore a distinction should be made between the theoretical and the actual feed motion (Fig. 7.165).

Machining processes with geometrically nondefined tool edges are frequently used as final machining

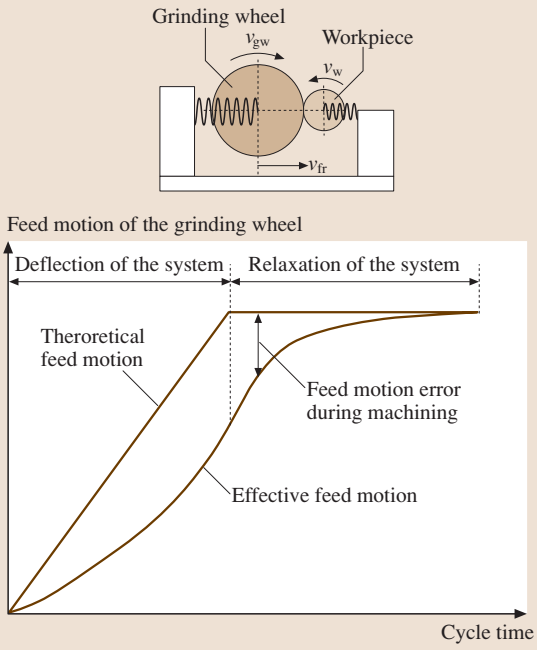

Fig. 7.165 Feed motion errors in grinding due to elastic deformations in the machine tool–workpiece-system

processes for workpieces subject to exacting quality requirements. Figure 7.166 shows a comparison of various precision machining processes with regard to operational results and efficiency. It can be seen that the grinding processes achieve high rates of material removal, while honing and lapping are able to produce the best surface qualities.

The chip formation mechanism when using geometrically nondefined tool edges differs from that of machining with geometrically well-defined tool edges (Fig. 7.167). In phase 1, the often sharply negative rake angle of the individual grains causes elastic deformation of the material. In phase 2 plastic deformation occurs, while in phase 3 the actual chip removal takes place. A large amount of friction occurs between the individual grains and the workpiece.

The mechanical energy supplied is almost exclusively converted into heat. Figure 7.168 shows a qualitative distribution of the heat flows around an individual grain. Most of the heat generated flows into the workpiece, while a small part finds its way into the grain, the bond and the surroundings (cooling lubricant, atmosphere). Temperature increases in the workpiece may harm its surface integrity. This is manifested in thermally induced residual stresses, structure changes or cracks, which influence the subsequent behavior of the workpiece in service. The use of abrasive materials (CBN, diamond) and bonds with superior thermal conductivity reduces the proportion of heat that penetrates into the workpiece [7.93, 94].

In machining with geometrically nondefined tool edges, the use of cooling lubricants is important for the end result. The cooling and lubricating effect can reduce tool wear. Furthermore, the temperature of the workpiece is reduced and the danger of thermal damage to its surface is decreased. The lubricants used are nonwater-miscible (oils) and water-miscible (emulsions, solutions) cooling lubricants, the effect of which can be further improved with additives (polar and extreme pressure (EP) additives to improve the lubri-

cating effect, antifoaming agents, biocides, and rust inhibitors). The cooling effect depends on physical parameters: specific heat capacity c in kJ/(kg K), heat transmission coefficient α in W/(m^{2}K), thermal conductivity λ in W/(m K), heat of evaporation I_d in kJ/kg, and surface tension σ in N/m. The lubricating effect is described by the tribological parameters of the cooling lubricant.

A comprehensive study on the main effects of coolant type, composition and application in grinding is presented in [7.95]. The correct selection and use of grinding fluids normally results in enhanced process performance, better workpiece quality, and longer tool life. Lower volumetric wear of the wheel and improved surface finishing are achieved when neat oil is used instead of water-based fluids. On the other hand, water-based fluids can reduce workpiece temperature, provide less risk of fire and are generally better suited for the working environment and the machine tool operator.

Grinding with Rotating Tools

Processes. Grinding can be performed in a large variety of motions. The six main classifications are related to the shape of the surfaces produced, namely surface, peripheral, thread, gear, profile, and form grinding. Figure 7.169 shows examples of various motion classifications and tool shapes.

Chip Formation. Material is removed by the penetration of abrasive grains into the workpiece material along a defined path. Owing to the generally unfavorable shape of the cutting edge, the actual chip formation is accompanied by friction and displacement processes. The process is evaluated by calculating statistical averages. Figure 7.170 shows in simplified terms how a comma-shaped chip is formed by the successive action of two cutting edges. While grain 1 has traveled the path AB, the center of the grinding wheel has moved from P_0 to P_1. The next grain 2 will travel the path CD. In this process, the thickness of an average chip increases from 0 up to h_{max}. A simple relationship for the average undeformed chip thickness $\bar{h}$ is obtained by applying the continuity relationship

$$v_{ft} a_e a_p = v_c C V_{sp} a_p \,, \tag{7.172}$$

$$\bar{h} = \frac{v_{ft}}{v_c} \frac{1}{\bar{b} C} \sqrt{\frac{a_e}{d_{eq}}} \,, \tag{7.173}$$

with $\bar{l} = \sqrt{a_e d_{eq}}$, $V_{sp} = \bar{l}\,\bar{b}\bar{h}$ and $d_{eq} = \frac{d_w d_s}{d_w \pm d_s}$ (+ external cylindrical grinding, − internal cylindrical grinding) or

$$\bar{h} = \sqrt{\frac{v_{ft}}{v_c} \frac{1}{rC} \sqrt{\frac{a_e}{d_{eq}}}} \quad \text{with} \quad r = \frac{\bar{b}}{\bar{h}} \,. \tag{7.174}$$

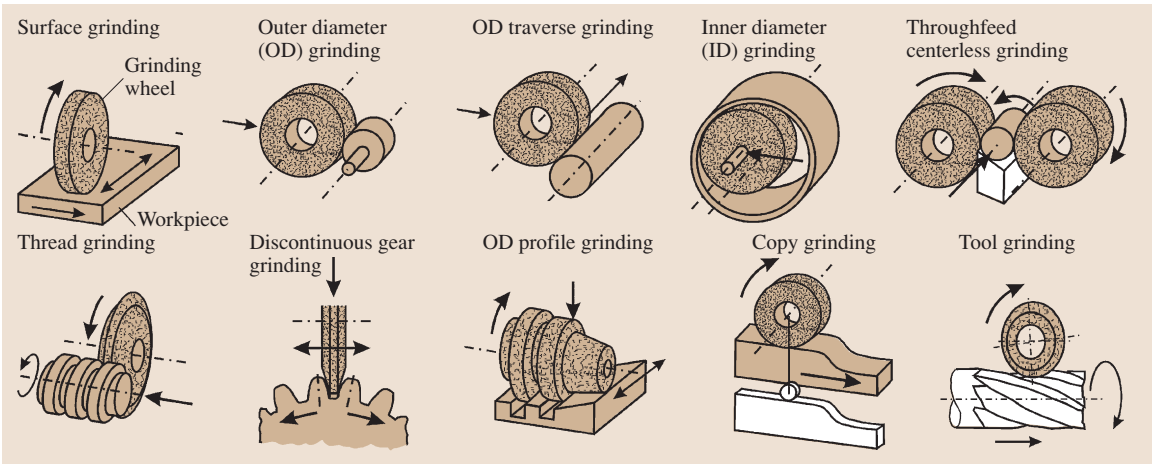

Fig. 7.169 Various grinding processes

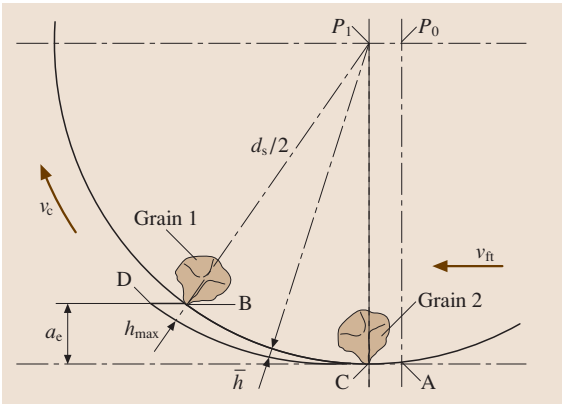

Fig. 7.170 Schematic chip formation in surface grinding

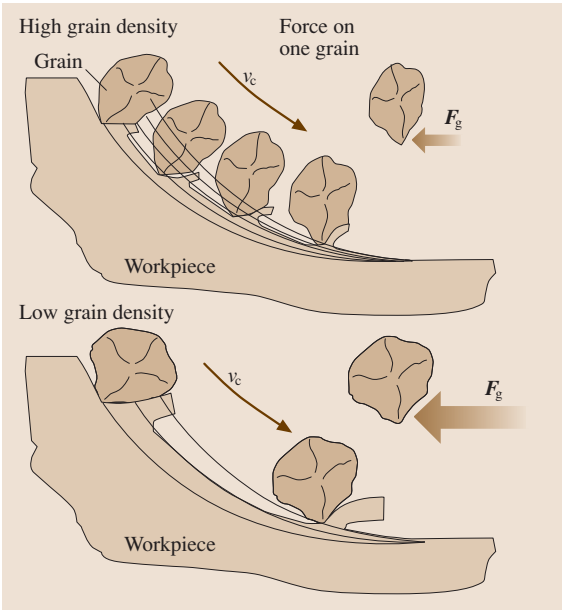

Fig. 7.171 Influence of grain concentration on the chip formation mechanism

The symbols are as follows: $\bar{h}$ is the average (undeformed) chip thickness, $\bar{l}$ is the average (undeformed) chip length, $\bar{b}$ is the average (undeformed) chip width, v_{ft} is the feed speed of the workpiece, v_c is the cutting speed, a_e is the depth of cut a_p is the width of engagement (width of grinding), d_{eq} is the equivalent grinding wheel diameter, d_s is the grinding wheel diameter, d_w is the workpiece diameter ($\rightarrow \infty$ in surface grinding), C is the number of active cutting edges per unit of surface area of the grinding wheel, and r is the ratio of average chip thickness to average chip width. The maximum chip thickness h_{max} is twice the average chip thickness $\bar{h}$.

The chip thickness is highly dependent on the concentration of abrasives on the grinding wheel surface C (Fig. 7.171). Higher grain density leads to thinner chips and consequently lower forces per grain. The grain density decreases with increasing grain size. The correction of these parameters can influence the wear mechanisms on a grinding wheel. Owing to technical difficulties in measuring the number and distribution of grains, the equivalent chip thickness h_{eq} is often used as a parameter for evaluating the grinding process [7.96]. This parameter is directly related to the grinding forces and

surface finishing

$$h_{eq} = a_e \left(\frac{v_{ft}}{v_c} \right) . \qquad (7.175)$$

Composition of Grinding Wheels. A grinding wheel consists of grains, bonding material (bond), and pores. The abrasive materials used are hard-brittle ones such as zirconium-corundum (ZrO_2 with Al_2O_3), corundum (Al_2O_3), silicon carbide (SiC), cubic boron nitride (CBN), and diamond (C); their hardness values are presented in Fig. 7.172. However, diamond is unsuitable for machining steel, as there is a high chemical affinity between diamond with its carbon-based cubic lattice structure and iron, which leads to rapid tool wear.

Sorting of the grains according to size is accomplished by screening. The basis of all standards is the mesh of the screens through which the abrasive grains pass. The average grain size is determined by the shape (angularity) of the individual grains. Below a certain grain size, sorting can be carried out by settlement out of a slurried suspension of water and grains. For conventional abrasives (e.g. SiC, Al_2O_3) the grain size is usually given in a mesh number; thus high numbers represent small grain sizes in the grinding wheel specification. The grain size for superabrasive wheels (only CBN and diamond) follows the FEPA specification related to the grit diameter.

The bonding material (bond) is chosen according to the requirements of the machining process and of the grain material. Inorganic (ceramic, silicate, magnesite), organic (rubber, synthetic resin, glue) and metallic bonds (bronze, steel, cemented carbide) are used; the most popular bonds are those made of ceramic or synthetic resin. In manufacturing a tool, its structure can be influenced to a certain extent by varying the proportions of grains, bond, and pore volume [7.97].

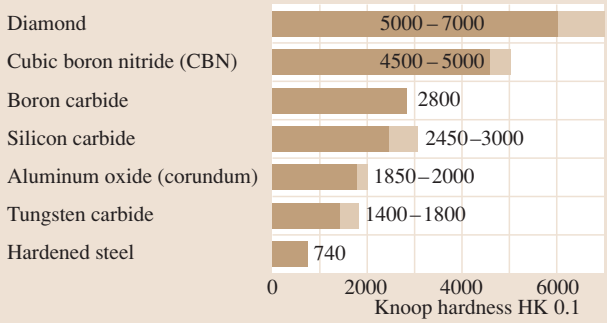

Fig. 7.172 Knoop hardness of various materials

Superabrasive wheels exhibit a particular construction. They consist of a core to which the grinding layer is applied. Usual layer thicknesses are 2–5 mm for resin or vitrified bonds. The core material can be made of metals or fibre reinforced plastics. Superabrasive wheels can grind at higher speeds due to the resistance of the core and the higher hardness of the grains. In the grinding wheel specification for superabrasives the average grain size is usually directly given in µm.

Electroplated bonds are mostly used in superabrasive wheels. They are very thin since they hold only one

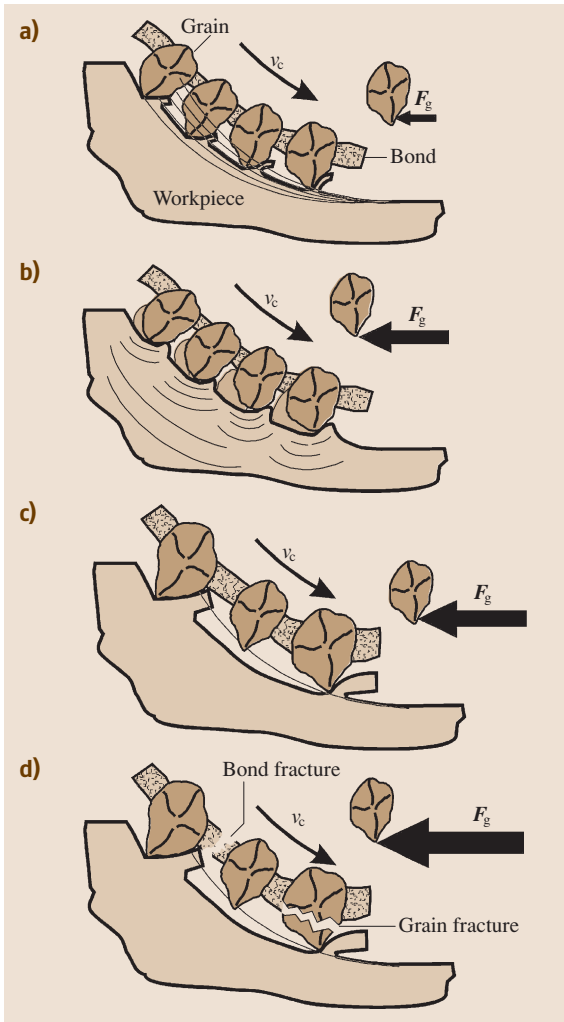

Fig. 7.173a–d Grinding wheel wear mechanisms: **(a)** Sharp wheel with low load per grain, **(b)** dulling and loading, **(c)** sharp wheel with high load per grain, **(d)** grain and bond fracture due to very high load

layer of abrasives. This kind of bond is used for grinding at high speeds due to its high wear and stress resistance. Electroplated wheels are recommended for rough and semifinish grinding. The final surface finish can be obtained with vitrified or resin bonds. The specification of a grinding wheel is standardized in DIN 69100 (for conventional wheels) and ISO 6104 (for CBN and diamond wheels).

Tool Wear. Grinding wheel wear may take place in the grains and the bond. The wear phenomena can be related to dulling or grain/bond breakage (Fig. 7.173). In dulling, wear flat areas are formed on the edges. They lead to increasing grinding forces and temperature. This normally happens when the abrasives are submitted to gentle grinding conditions. When the abrasive grains are under higher loads the grain/bond breakage mechanisms will lead to higher volumetric wear resulting in constant grinding forces and temperature. Surface finish quality may deteriorate and form errors may increase.

Grinding Wheel Conditioning. The purpose of conditioning is to give the grinding wheel the required profile and concentricity (profiling or truing), to produce the necessary grinding wheel topography with sharp grains (sharpening), and to clean the grinding wheel surface [7.98]. The first two operations summed up under the term dressing and are generally performed simultaneously by passing a dressing tool over the surface of the grinding wheel (Fig. 7.174). In some applications a separate sharpening step is necessary, which can be performed preprocess or in-process. It is often performed with special equipment with electrolyte supply (ELID = electrolytic in-process dressing) [7.99] or with contact erosion [7.100]. The main components of dressing tools are metallic bonds mixed with diamond particles; however, there are also single point diamonds, diamond-free steel and ceramic tools. They reach the end of their life when the diamond layer or the tool geometry is worn out.

A special variant of a rotating diamond form roll is called grinding with continuous dressing (CD grinding) (Fig. 7.175). Here, the dressing tool is in engagement during grinding and is continuously advanced radially to the grinding wheel. As a constant grinding wheel profile and a uniform grinding wheel topography with sharp cutting edges are permanently ensured, the material removal rate can be increased considerably [7.101]. With the aid of the machine control system, the dressing tool and the grinding wheel have to be advanced in relation to the workpiece in such a way that the decrease in the diameter of the grinding wheel is compensated. This technique is often used for pro-

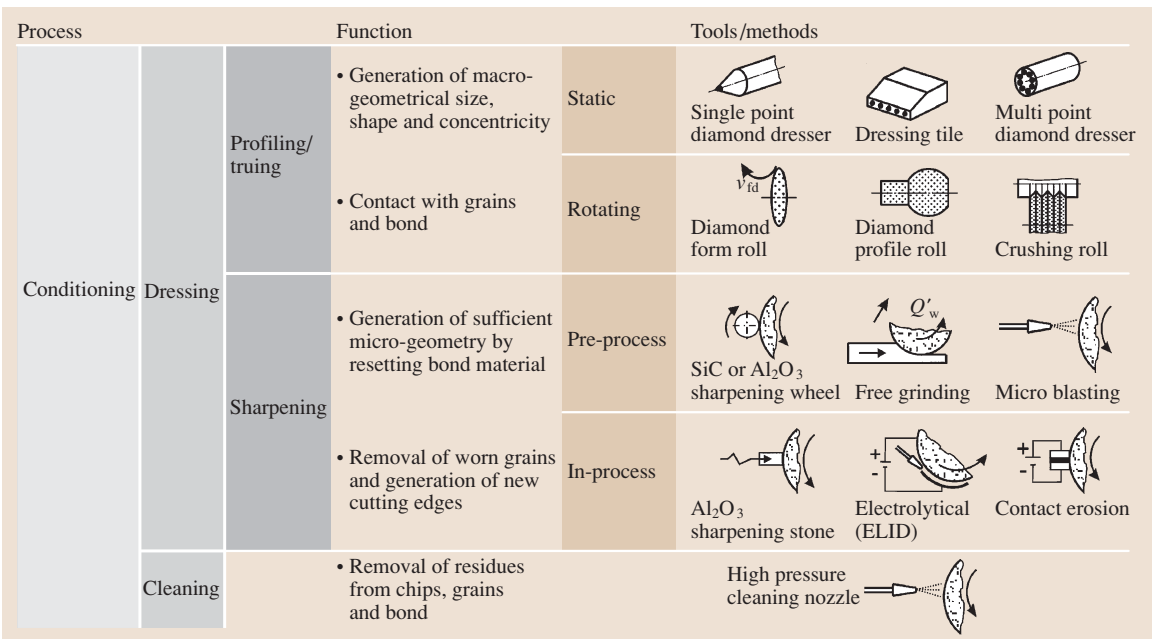

Fig. 7.174 Classification system for grinding wheel conditioning

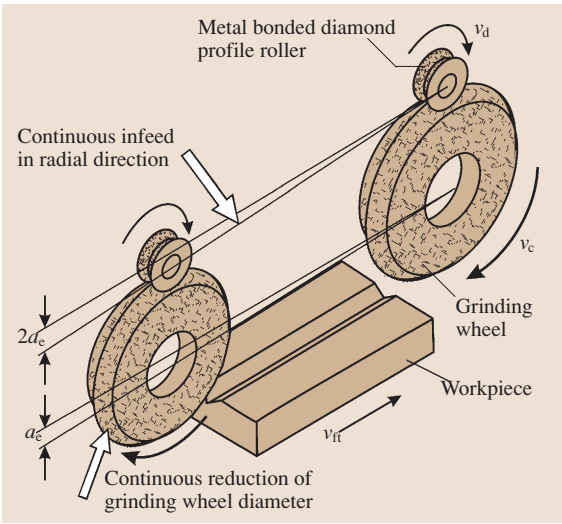

Fig. 7.175 Principle of grinding with continuous dressing (CD grinding)

file grinding of difficult to machine materials like the nickel-based alloys used for turbine blades.

Limits of the Grinding Process. Restrictions on the process arise if the original data, e.g. dimensional accuracy, accuracy of shape, surface quality or condition of workpiece surface integrity, do not lie within the required limits. The interaction of the various influencing variables, such as workpiece, machine setting data, tool, cutting fluid, etc., may be extremely diverse. Mechanical and/or thermal overstressing of the material in the grinding process may adversely affect the characteristics of a ground component [7.102]. Typical grinding defects due to poor process control are visible marks on the surface as a result of regenerative chatter [7.103], hardness and structure changes, tensile residual stresses, and probably even cracks in the workpiece [7.104] (Fig. 7.176). The latter defects can be summarized by the term grinding burn.

Development Trends in Grinding. Grinding has been continuously developed from a traditional precision machining process to improve dimensions, shape and surface quality into a very versatile and efficient manufacturing process. Creep feed grinding, high-speed grinding, grinding with continuous dressing (CD grinding), the growing use of superhard abrasives combined with CNC and sensor technologies have been extensively applied in industry [7.105–107]. With the development of advanced open CNC systems, the control of grinding processes is nowadays including intelligent routines. Sensors allow the detection of contact between grinding wheel and workpiece, collisions and wheel topographic conditions where necessary conditioning/dressing can be automatically activated [7.108]. Gear and other complex profile grinding processes have also been improved with the help of high performance interpolation routines able to increase productivity and quality with high process flexibility [7.109]. Even the fact that grinding might generate a high amount of heat is turned into a benefit by us-

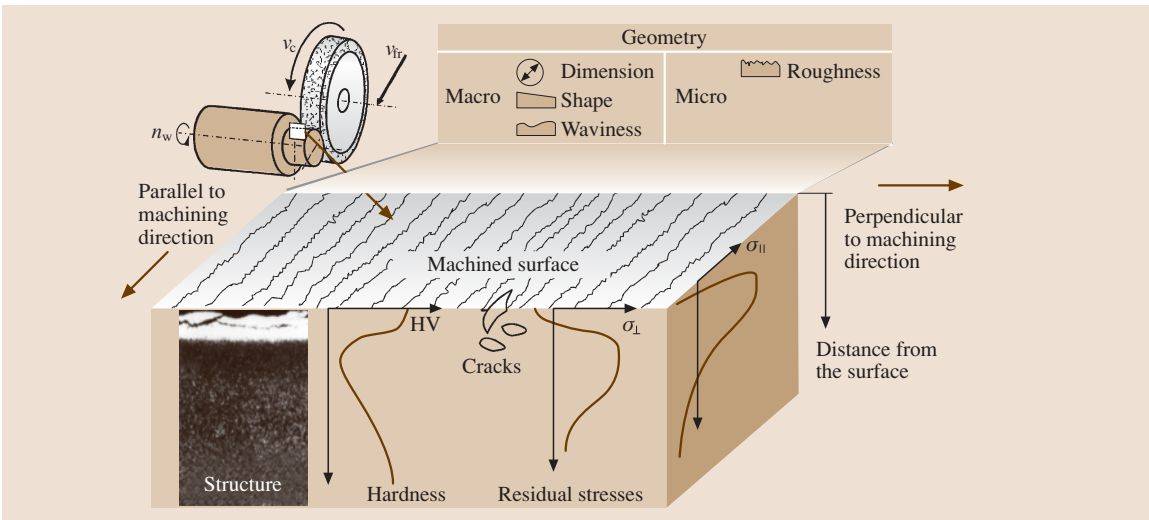

Fig. 7.176 Geometrical and physical quality characteristics after grinding

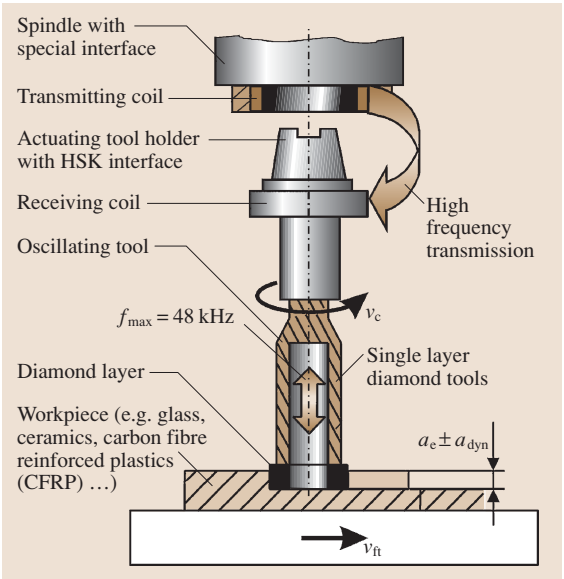

Fig. 7.177 Ultrasonically assisted grinding

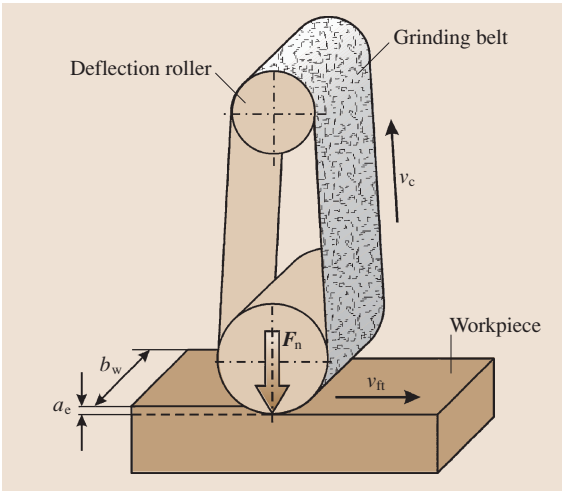

Fig. 7.178 Schematic representation of surface belt grinding

ing this energy for process integrated hardening while grinding [7.110].

Ultrasonic (US) assisted grinding has reached industrial maturity especially for brittle materials like glass or ceramics. While in the first applications the US-vibration was generated in a complex spindle system or from the workpiece clamping side, in latest developments the US-excitation is realized with wireless induction transmission in the tool-spindle interface, allowing the tools to be mounted to the actuating tool holder (Fig. 7.177) [7.111].

Belt Grinding

Belt grinding is grinding with bonded abrasives on a supporting flexible bed. Belt grinding can also be classified according to the surfaces machined, e.g. surface, cylindrical, profile or form belt grinding. Surface belt grinding predominates in industrial applications (Fig. 7.178). Belt grinding is normally performed at a constant perpendicular force F_n (pressing force). Thus, consistent surface qualities can be produced. The material removal rate is determined by the sharpness of the belt (of the active cutting edges). In belt grinding with constant working engagement a_e a constant material removal rate is achieved. Surface quality depends on the condition of the cutting edges. This process is especially suitable for removing large volumes of material with high efficiency [7.112].

The adjustment of the process variables during belt grinding derives from the changes of the cutting edges during working. In contrast to grinding wheels, grinding belts generally consist of a single layer of abrasives. Therefore, the cutting edge zone changes over the period of use, owing to progressive abrasive and bond wear.

Grinding belts consist of four elements: backing (paper, fabric), ground bonding and top bonding materials (phenol resins), and abrasive grains (corundum, zirconium-corundum, silicon carbide). Scattering of the grains on the first coat of bonding material is carried out in an electrostatic field. This ensures that the abrasive grains are aligned perpendicularly (Fig. 7.179). An even grain distribution in belt manufacture compared with conventional gravity scattering can be achieved [7.113].

For higher material removal rates multilayer grinding belts are available, where several abrasive grains are held in a bond and mounted to the backing.

The grinding belt is supported in the working zone by contact elements. A contact disc is used in peripheral grinding, while a contact shoe or beam is used in side grinding. Hard contact rolls made of aluminum or steel are particularly suitable for roughing with coarse grinding belts because they transmit the relatively high grinding forces. Soft, rubber-coated contact rolls are used in finishing with fine grinding belts [7.114]. They absorb the shocks occurring during the process. Conventional applications of belt grinding are grinding of individual sheets and sheet coils, deflashing and deburring, and grinding down of excess metal in welded

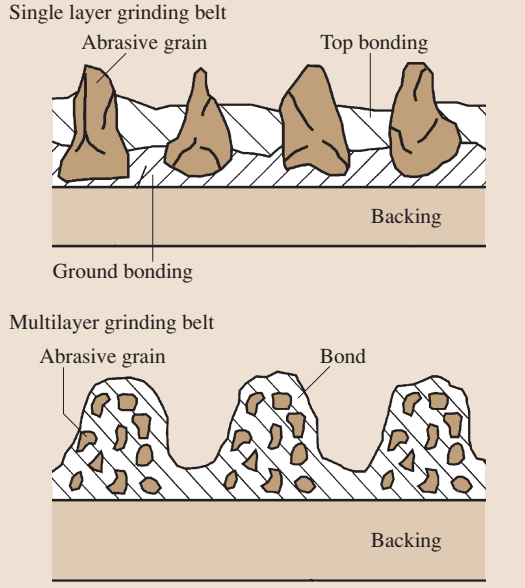

Fig. 7.179 Schematic setup of grinding belts

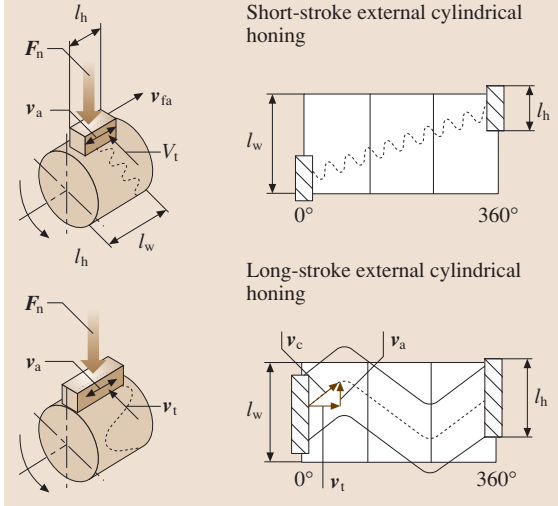

Fig. 7.180 Geometry and kinematics in short- and long-stroke superfinishing

joints. Heavy-duty belt grinding might even work as a substitute for turning and milling of components made of gray cast iron or aluminum alloys [7.112, 113].

Honing, Superfinishing

Honing is performed with a multiple-point cutting tool consisting of bonded abrasive grains using a cutting motion with two components of which at least one is oscillating. The most common honing processes are external cylindrical honing, internal cylindrical honing, and surface honing. The external honing variant is often called superfinishing. According to the oscillation amplitude, a further distinction can be made between two main groups: long-stroke honing and short-stroke honing (Fig. 7.180) [7.115].

Long-stroke honing employs large oscillation amplitudes at a low frequency; in short-stroke honing the oscillating motion is performed at low amplitudes and a correspondingly high frequency. The path curves in Fig. 7.180 depict the motion of a honing strip over a developed workpiece surface.

Owing to the superimposed motion during honing, the workpiece surface exhibits intersecting tracks of the cutting grains, the two tracks enclosing an overlap angle α (Fig. 7.181). The magnitude of the overlap angle α is determined by the selection of the ratio of the axial (v_a) and tangential (v_t) cutting speed components. For workpieces without longitudinal and transverse grooves, the angle α is generally 45°. The cutting speed v_c can be calculated by means of the aforementioned speed components according to $v_c = \left(v_a^2 + v_t^2\right)^{1/2}$. Usually the cutting speed does not exceed $v_c = 1.5\,\mathrm{m/s}$ [7.115, 116].

During the cutting motion the honing stones are pressed against the workpiece surface that is to be machined with a perpendicular honing force F_n, which may be generated by means of various feed systems (Fig. 7.182). In force-dependent feeding, a defined hydraulic pressure p_{oil} is set on the machine. The resulting

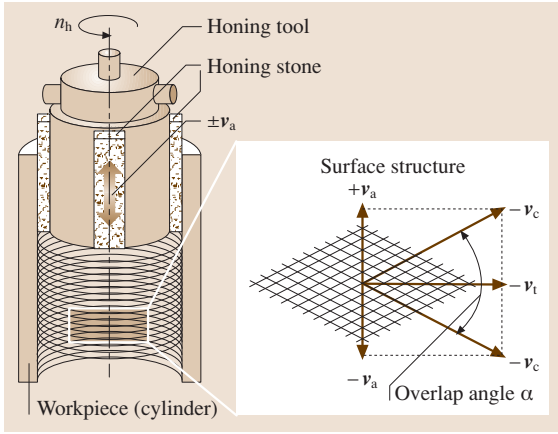

Fig. 7.181 Principle of internal long-stroke honing and resulting surface structure

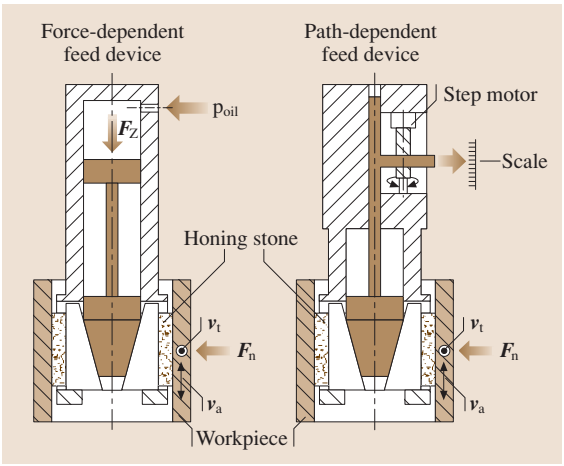

Fig. 7.182 Force- and path-dependent feed devices for honing

advancing force F_z is transmitted to the honing stones via an advancing pin and cones. In path-dependent feeding defined feed paths are generated e.g. with a stepping motor, which produces the perpendicular force F_n on the honing stones.

Important variables influencing the result of honing are the type of abrasive, grain size, type of bond, hardness and impregnation of the honing stones. The types of abrasive can be classified into conventional abrasive materials, such as corundum and silicon carbide and the superhard abrasive materials diamond and cubic boron nitride (CBN). The grain size influences the material removal rate and the surface quality. The achievable surface roughness values are $R_z = 1\,\mu m$ for long-stroke honing and $R_z = 0.1\,\mu m$ for short-stroke honing. Dimensional accuracies and accuracies of shape of the machined workpieces of 1–3 µm are achieved [7.117]. Unlike in grinding, the grains bonded in the honing stone are stressed on more than one axis owing to the oscillating motion. Honing tools are, therefore, self-sharpening.

Cutting fluids are used in honing as well as in grinding. Due to the low cutting speed, however, heating is minimal, so the cooling effect plays a minor role. But the surface contact between the honing stone and the workpiece requires instead a friction-reducing lubrication. For this purpose, pure oil, with additives if required, is generally used.

The applications of honing can also be categorized according to whether long-stroke or short-stroke honing is used. Long-stroke honing is generally used for bores, e.g. cylinders in internal combustion engines. Short-stroke honing is mainly used for machining small cylindrical components, e.g. running surfaces of inner and outer rings and rollers of rolling-contact bearings. Furthermore, the application of gear honing should be mentioned. With the coupled motion of a gear shaped abrasive tool and the workpiece counterpart a high surface quality for gears can be achieved, thus qualifying honing as an attractive gear finishing technique [7.118].

Other Processes: Inside Diameter Cut-Off Grinding, Lapping, and Abrasive Waterjet Cutting

Inside-Diameter Cut-Off Grinding. Inside-diameter (ID) cut-off grinding is a high-precision finish-machining process for hard-brittle materials. It is used to cut rod-shaped materials into thin slices (Fig. 7.183). Besides its applications to optical materials (glasses, glass ceramics), magnetic materials (samarium-cobalt, neodymium-iron-boron), and ceramics and crystals for solid-state-type lasers, this process is also used for semiconductor materials. Single crystal silicon rods are cut into thin slices called wafers.

Compared with conventional abrasive cutting processes, the loss of material in the cutting gap can be reduced by approximately 80% by means of a narrow width of cut. This is a decisive advantage, especially for expensive, high-grade materials.

To achieve the narrow widths of cut that are typical of this process, a comparatively unconventional tool is used for ID cut-off grinding. The basic body of the tool

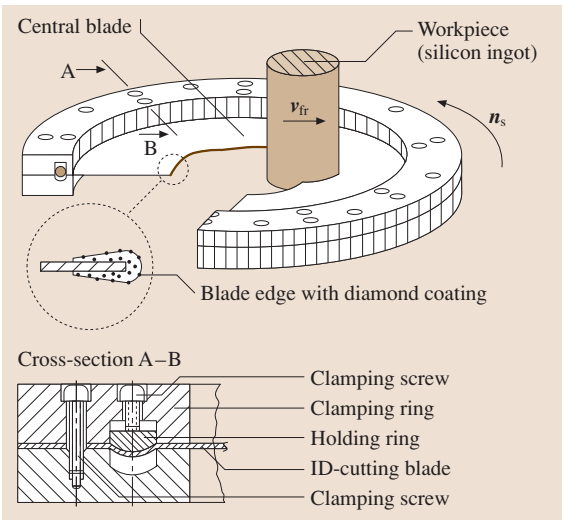

Fig. 7.183 Principle of ID cut-off grinding

consists of a cold-rolled ring of high-tensile stainless steel with a thickness of 100–170 µm.

The inside edge of the cutting blade is coated by electro deposition with a diamond layer in a nickel-base bond; this layer forms the droplet-shaped cutting edge. Grain sizes commonly range from 45 to 130 µm. The width of the cut extends between 0.25 and 0.7 mm. Natural diamond is generally used as cutting material. CBN may also be used for special applications. Workpieces with a diameter of up to 200 mm can be cut. Due to this diameter limitation this process has lost its pole position for wafer manufacturing because of the constantly rising diameters of silicon ingots for wafer production in the semiconductor industry (Fig. 7.185).

To achieve the stiffness at the cutting edge that is necessary for cutting, the cutting blade, which can be compared to an eardrum, is clamped at its outside edge with a special clamping device. This widens the ID cutting blade radially until the tangential stresses at the inside edge reach around 1800 N/mm^2. In cut-off grinding, the workpiece performs a radial feed motion relative to the rotating tool [7.119, 120].

Lapping. Lapping is defined in a German standard (DIN 8589) as metal cutting with loose grains of abrasive material distributed in a paste or a liquid, the lapping mixture, which is carried on a generally shape-imparting counterpart (lap), and the individual grains following cutting paths, which are random. Lapping processes are divided into surface lapping, cylindrical lapping, hole lapping, and ultrasonically assisted lapping (Fig. 7.184).

Surface lapping or plane parallel lapping is carried out on single-disc or twin-disc lapping machines. The lapping discs act as the holder for the lapping abrasive. They are frequently made of perlitic cast materials or hardened steel alloys. The workpieces are usually driven in specific carrier discs, for larger diameter lapping discs often use the planetary gear principle to achieve cycloid motion. A special variant of plane parallel lapping is based on the use of special slurry as liquid to carry the abrasives and to improve the material removal process by chemical activation. This process is called chemical-mechanical planarization (CMP) and is widely used in the semiconductor industry to machine wafers made of silicon or other suitable materials [7.121].

The abrasive consists of lapping powder and fluid in a ratio of 1 : 2 to 1 : 6. Particles of silicon carbide, corundum, boron carbide or diamond are used as lapping powder. The type of grain for a particular application is determined by the material to be machined. Grain sizes ranging between 5 and 40 µm are generally used. Besides high-viscosity oils or similar fluids, water with suitable additives has been more and more frequently used as a transport medium for the abrasive in recent years. The main purpose of lapping fluids is to cool the workpiece and ensure chip removal from the effective zone.

Lapping is a precision or ultra-precision machining process for the production of functional surfaces of optimum surface quality. Surface roughness values down to $R_t = 0.03$ µm, flatness, and plane parallelisms of 0.2 µm are achieved. Besides the semiconductor application other typical fields of lapping are the machining of precision cemented carbide tools, calliper gauges, or hydraulic rams.

A special category is ultrasonically (US) assisted lapping, which is particularly suitable for machining hard-brittle materials, e.g. fully sintered ceramic components [7.122, 123]. The process is carried out by moving a complex shaped tool called sonotrode downwards into the workpiece while hammering the loose abrasive particles, which are supplied via a liquid to the contact zone, into the workpiece surface for material removal. If rotational symmetric shapes are to be produced, nowadays US-grinding is substituting for this lapping process due to its higher efficiency (Fig. 7.177).

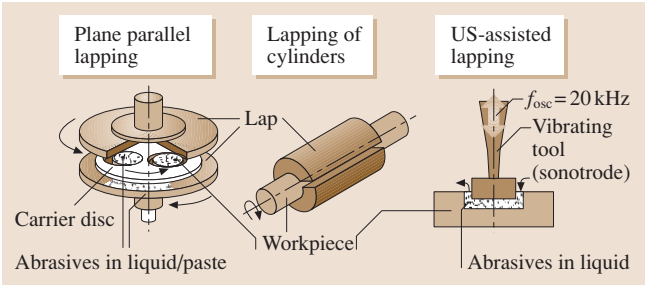

Fig. 7.184 Lapping processes

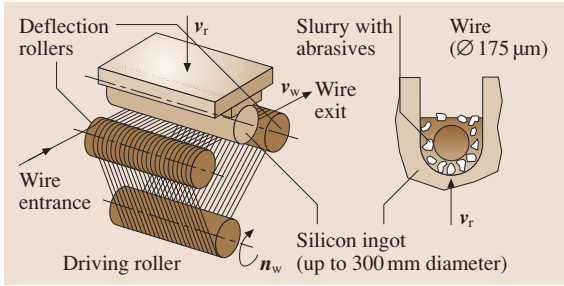

Fig. 7.185 Multiwire slicing

Due to the above-mentioned increase of silicon ingot diameters for wafer production a special variant of lapping has been developed called multiwire slicing by lapping (Fig. 7.185). In this process a silicon ingot is glued to a steel support and radially fed downwards to a multiwire field. Comparable to an egg-cutter, hundreds of wafers are separated at the same time, because on the specially developed high-strength wire a spray of silicon carbide abrasives in special slurry is applied. This process is capable of significantly increasing the productivity compared to ID cut-off grinding and currently works for diameters up to 300 mm. Parallel research is being done to develop an abrasive coated wire instead of loose lapping grains, thus reintroducing grinding for wafer manufacturing.

Abrasive Waterjet Machining. Abrasive waterjet (AWJ) machining is a material removal process with a high velocity slurry jet. The slurry is formed by the injection of abrasive particles into a waterjet by an orifice (Fig. 7.186) [7.124]. The abrasive waterjet head is controlled in two to five axes by a CNC system or by a robot arm. The process is mainly used for cutting a large variety of materials. The main advantages are the versatility regarding complex shapes and the ability to cut both ductile and brittle materials at very low process temperatures.

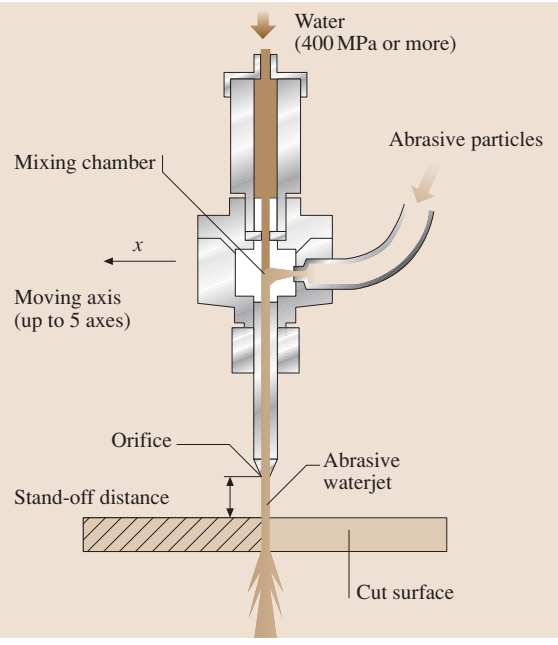

Fig. 7.186 Basic concept of abrasive waterjet cutting

Abrasive waterjet machining is usually performed at jet pressures up to 400 MPa. The applicability and the advantages of the cutting process beyond 400 MPa pressure is currently being investigated [7.125]. The success of this process at increased levels of pressure depends on the endurance of the system components subjected to high alternating stresses, the avoidance of solidification of water at ultra high pressures, and the good coherence of the jet.

The quality obtained in waterjet cut is higher than that achieved by conventional cutting processes, mainly in the edges. The dimensional and form quality will depend on the CNC system and the coherence of the jet. A cutting thickness of 200 mm and dimensional tolerances of about 0.1 mm can be achieved with this process. The main quality disturbances are related to the jet distortion or turbulence during cutting. Shape distortions occur when cutting corners, thick parts, or at high feed speeds.

The equipment for AWJ can be very simple and relatively inexpensive. A stationary waterjet is usually used in the aerospace industry to trim composites similar to a band saw. But abrasive waterjet cutting can also be performed in CNC machines and robots allowing the cutting of complex shapes. In any case, the waterjet has to be caught in a suitable catching system after cutting through the workpiece material to avoid danger to the operator or the environment. Furthermore noise protection measures are recommended.

7.3.3 Nonconventional Machining Processes

The nonconventional machining processes can be classified according to the type of energy employed: mechanical, thermoelectric, electrochemical, mechanical, and combinations. The way of material removal varies and so do the transfer media.

Mechanical energy is used in the abrasive-jet and waterjet applications, which have already been covered in Sect. 7.3.2.

Thermoelectric energy is used in electro-discharge machining (EDM) for making cavities mostly in difficult to machine materials. Metal removal is accomplished through the controlled vaporization of the workpiece material by suitably applied electric sparks. A very important variant of EDM applies thin wires to generate small gaps in the workpiece. This is called spark electro-discharge machining (SEDM), spark erosion machining (SEM), or wire-EDM.

The principle of electron beam machining (EBM) is the transformation of the kinetic energy of high speed electrons into thermal energy as they strike the workpiece. Laser beam machining is based on the transformation of light energy into thermal energy. Plasma arc machining (PAM) and ion beam machining (IBM) utilize ionized plasma for energy transfer. These beam machining processes are being used in hole-making and slicing operations and in welding metals and alloys.

Electrochemical energy is harnessed in electrochemical machining (ECM) and in combination with grinding in electrochemical grinding (ECG). Another application is the combination of ECM with electro-discharge machining (EDM), in the form of electrochemical-discharge machining (ECDM). The beam machining group also applies electrical energy in various forms.

Common in all nonconventional electrophysical-chemical machining is the application of high energy density in the range of 10^3–10^8 W/cm^2. High energy concentration is achieved by space and time localization of the emitted energy [7.126, 127].

Electro-Discharge Machining (EDM)

In the EDM process, material is removed by a series of discrete electrical discharges (sparks) in the machining gap between the electrode and the workpiece, as illustrated in Fig. 7.187. The dielectric fluid creates a path for the discharge as the fluid becomes ionized between the nearest opposing points. The initiation of discharge takes place to cause ionization and current starts to flow. As conduction continues, the size of the discharge column increases and so does the current. The discharge temperature is far beyond the melting point of the work materials, including exotic materials.

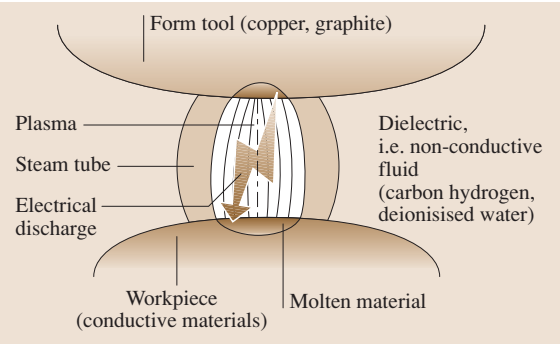

Fig. 7.187 Schematic diagram of electro-discharge machining (EDM)

However, the machinability of metals and alloys depends on their thermal-physical properties and the electric parameters of the process. Material removal is not affected by the mechanical properties of workpiece materials.

Electric-spark machining is characterized by use of electric discharge with an on-off time ratio, where the current amplitude to pulse duration is high. The tool-electrode is of direct polarity (cathode), applying powers between a few watts and several kilowatts. Application areas include cutting components of complex form by wire-electrode, broaching, and die sinking of precision components from refractory alloys, sintered carbides, and nonferrous metals with surface sizes up to 3–5 cm^2.

In electric-pulse machining the use of electric discharge with a small on-off time ratio with reduced current amplitude to pulses is common. The tool-electrode is of reverse polarity (anode). Application areas include the generation of complex surfaces with an area of up to hundreds thousand mm^2.

The dielectric fluid is an important variable in the EDM process. The methods of its application are shown in Fig. 7.188. It has three main functions: it works as an insulator between tool and workpiece, it acts as coolant, and as a flushing medium to remove chips [7.128]. It also affects electrode wear, material removal rate, and other EDM characteristics. The dielectric fluid normally used is hydrocarbon-based, but other fluids like tri-ethylene glycol and tetra-ethylene glycol are also used to improve the material removal rate. For wire erosion it is common to use deionized water in constant supply to the working zone.

Tool electrodes are made of graphite and copper, but other materials can also be used. The machined surface shows no direction of marks; on the contrary, the surface is formed from a number of craters and might show areas of molten material with accompanying surface integrity changes, as can be seen in Fig. 7.189 [7.129]. The application areas of EDM are shown in Fig. 7.190.

Electro-discharge machining provides machining accuracies of up to 0.005–0.02 mm in the case of through holes and up to 0.01–0.1 mm when machining cavities [7.130].

Surface roughness when machining through holes is in the region of $R_a = 0.4$–1 µm and $R_a = 1$–2.5 µm for machining cavities.

The material removal rate depends on the volume of material removed by individual sparks and by the discharge frequency. The volume of material is a function of the discharge energy, which increases with the cur-

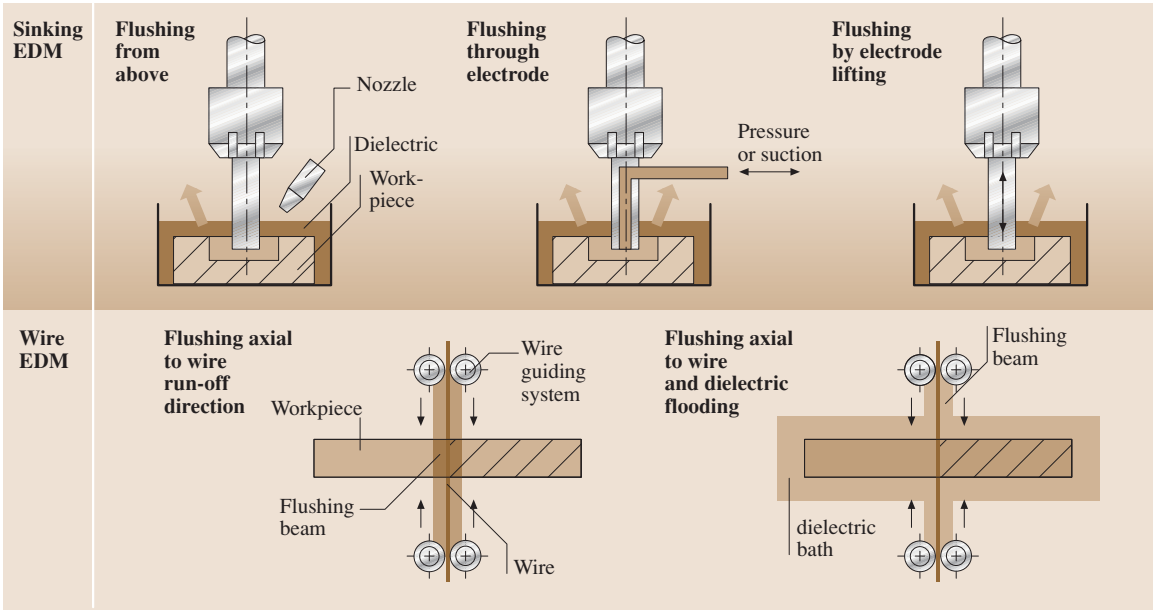

Fig. 7.188 Application of dielectric fluid in EDM (after [7.126])

rent. The typical removal rate when machining steels lies in the region of $10-12\times10^3$ mm^3/min.

Typical output parameters of wire electro-discharge machining (WEDM) are: dimensional accuracy 0.005–0.03 mm, surface roughness $R_a=0.4-2$ µm; the surface division rate for steels up to 300 mm^2/min, for carbides up to 120 mm^2/min.

The given parameters of electro-discharge machining allow these processes to be applied in tool manufacturing and in the production of components made from hard-to-machine materials with complex shapes.

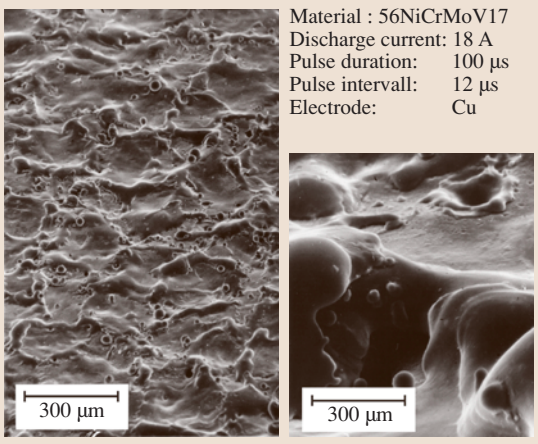

Fig. 7.189 Electro-discharge machined surface

Electrochemical Machining

The operating principles of electrochemical machining (ECM) have been known for a long time. Its two conductive poles are placed in an electrolyte bath and energized by direct current; metal may be removed from the positive pole (anode), the negative pole (cathode) is also metallic.

ECM requires a cathode tool with an appropriate mirror image of the cavity to be made; a workpiece and locating/holding fixture in close proximity to the tool, a suitable electrolyte supply and removal to/from the gap, DC electrical source with sufficient power to provide high current density between the tool and workpiece [7.131, 132]. The metal is removed rapidly from the workpiece, therefore provision has to be made to feed the tool to maintain the gap at a constant value.

Metal removal is governed by Faraday's and Ohm's law. The material removal is proportional to the current flow through the gap and the elapsed time, while the current is proportional to the applied voltage and inversely proportional to the gap's electrical resistance.

ECM is carried out as anodic dissolution of metal, and the product is removed from the working zone (gap) by an electrolyte flowing at speeds of about 5–50 m/s.

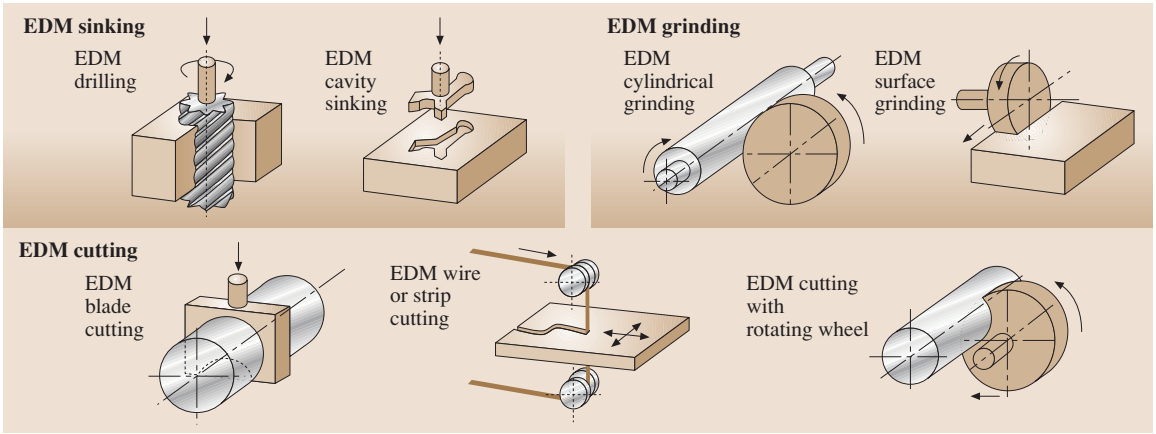

Fig. 7.190 Examples of electro-discharge machining

A DC generator supplies the current at a working voltage of 3–24 V governed by the material and technology requirements. A working gap between the two electrodes is maintained accurately by a process monitoring system between 0.02–0.5 mm. The tool-electrodes are typically made of stainless steel, brass and graphite. A typical ECM arrangement is schematically shown in Fig. 7.191.

Many process parameters affect the output parameters, including tolerances of the product. These can be electrical, chemical and mechanical parameters, which have to be monitored and controlled all the time.

The applications of ECM include turning, die-sinking, hole drilling/multiple-hole drilling, trepanning, broaching, milling, and deburring. In ECM sinking and broaching the shape of the tool-electrode is copied into the component. This is used to make cavities for dies, forging stamps, compression molds, casting forms, etc. The roughness of the machined surface is within the range of $R_a = 0.25$ up to $R_z = 20\,\mu m$. Feed rates of 0.03–0.5 mm/min can be selected.

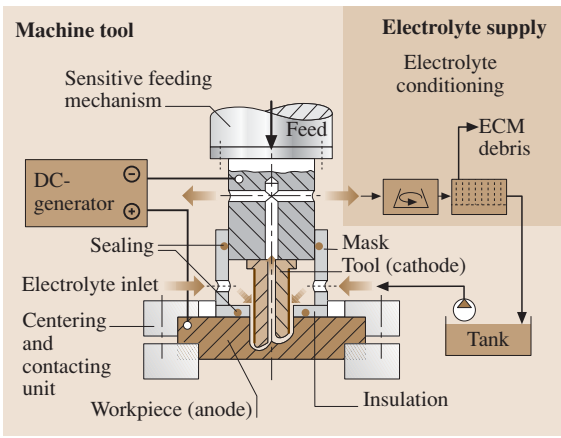

Fig. 7.191 Principle of electrochemical machining (ECM) (after [7.126])

Electrochemical milling, using rotary-cathodes, can be used for the production of profile, flat and round external surfaces by the cathode wheel at a removal rate of 150–200 mm^3/min in the case of stainless steels and 60–80 mm^3/min when machining carbides.

This process can be used to produce thread-cutting dies, various form tools, thread rolling dies with surface roughness of about $R_a = 0.63\,\mu m$ to $R_z = 20\,\mu m$. The process can also be used for machining magnetic materials (permanent magnets).

Electrochemical deburring is particularly suited for the deburring of holes, gears, and components of hydraulic equipment mainly in mass production.

Ultrasonic Machining

Ultrasonic machining (USM) utilizes a tool, which oscillates at high frequency beyond the audible limit (hence the name of the process), i. e. beyond 20 000 Hz. In the case of ultrasonic assisted lapping with loose abrasives, the tool has the same shape as the required cavity in the workpiece (see the section *Other Processes: Inside Diameter Cut-Off Grinding, Lapping, and Abrasive Waterjet Cutting*). The high speed alternating motion of the tool drives the abrasive grains across a small working gap against the workpiece. The impact energy is responsible for the material removal. Although this process is not restricted to brittle materials, and ductile failure works in machining tough materials as well, it is usually used to machine hard

and fragile materials, such as glass, ceramics, silicon, ferrite, ruby, sintered carbide, diamond and the like [7.133]. Besides the oscillation from the tool side, ultrasonic movement of the workpiece is also possible [7.134].

It is accepted that material removal results from the combined effects of hammering (impacting) abrasive particles in the work surface, the impact of free abrasive particles on the surface, cavitations, erosion, and the chemical action of the fluid employed.

The most important process input parameters controlling the material removal rate, surface roughness, and accuracy are the frequency and amplitude of oscillation, abrasive particle size, and by implication the impact force. During machining abrasive grains enter the machining zone as abrasive suspension.

Mechanical vibrations of the tool with ultrasonic frequency are achieved by a suitable electro-mechanical converter. Usually, the converter will consist of magneto-resistive elements with the ability to change their linear size in a variable magnetic field. In some cases, piezoelectric converters are employed in a variable electric field.

Tools for USM are made of structural steels, whilst carbides, CBN, silicon, and diamond are used as grits with grain sizes up to 3–10 μm [7.137].

The abrasive slurry moves into the machining zone either freely or under pressure and is removed by suction through the tool or workpiece, which substantially increases machining productivity. Mass concentration of grits in the abrasive slurry at free feed is in the region of 30–40% and 20–25% when it is supplied under pressure.

When machining sintered carbides, USM can be combined with electrochemical anodic dissolution. Processes of rough and finishing ultrasonic operations can be carried out on one machine tool.

USM can provide a removal speed of up to 5500 m^3/min when machining glass and of up to 500 m^3/min when machining carbides; the corresponding surface finish is $R_a = 0.32–0.16$ μm.

In recent ultrasonic developments the loose abrasive set-up is replaced by a tool with bonded abrasives (see the section *Grinding with Rotating Tools*). Regarding the kinematics it is an ultrasonic assisted grinding process, but in some cases it is referred to as ultrasonic milling. Besides milling and drilling also ultrasonic assisted turning has gained attention due to the improved wear behavior of the chosen tools [7.138, 139].

Beam Machining

Thermoelectric processes utilize concentrated thermal energy to remove material and electrical energy, in some ways, to generate thermal energy. The main characteristics of these processes are high temperatures and high thermal energy densities that can be achieved for material removal up to 10^9 W/cm^2. The main beam machining processes are: laser beam machining (LBM), electron beam machining (EBM), and plasma beam machining (PBM). Beam machining (BM) can be used for machining both electrically conductive and nonconductive materials.

Table 7.46 Characteristics and application of thermal sources (after [7.135, 136])

Thermal source	Limiting concentration of energy (W/cm^2)	Energy source	Application
Gas flame	8×10^2	Jet of the heated gas $T \approx 3500$ K	Cutting off, accompanying heating, maximum thickness up to 3 mm
Arc plasma	6×10^3	Gas and the metal steam ionized by electric discharge	Cutting off up to 3 mm, welding, heat treatment, welding
Electron beam	10^5	Electron beam in vacuum	Cutting off, welding (up to 20 mm/pass), heat treatment, welding
CW type laser beam	10^9	Beam of photons in a gas	Welding (up to 10 mm/pass), heat treatment, welding on, evaporation of layers
Pulsed laser beam	10^{10}	Beam of photons in a gas	Evaporation of layers, drilling of apertures, surfaces amorphous, shock hardening

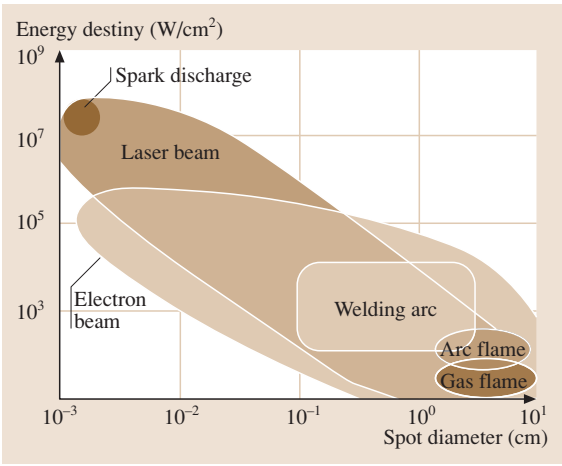

Fig. 7.192 Energy density of various thermal sources (after [7.135])

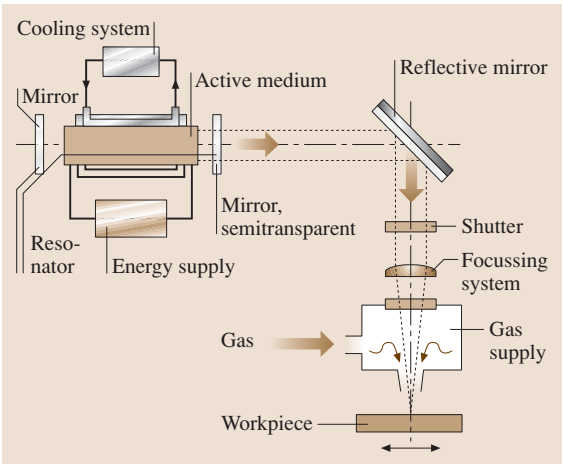

Fig. 7.193 Schematic diagram of laser beam cutting

The energy concentration of beam sources and that of comparative technologies are illustrated in Fig. 7.192. Of the beam-based technologies laser and electron beams provide the greatest intensity of energy in the region of 10^8–10^9 W/cm^2. The main characteristics of high density beam thermal sources are given in Table 7.46.

Laser Beam Machining. The technical term *laser* is the acronym of light amplification by stimulated emission of radiation. Laser cutting (LC) is based on use of the monochromatic electromagnetic radiation generated by the laser. The laser beam is formed by means of an optical system and is focussed on the machined surface, causing heating, fusion, evaporation, or explosive destruction of the workpiece material (Fig. 7.193).

In the radiation zone the form and diameter of a light spot changes over a wide range from several up to hundreds of micrometers. Depending on the temperature and energy concentration on the machined surface, various laser machining processes can be applied, e.g. drilling, cutting, marking, welding, heat treatment, and others. The application of laser beam (LB)-based manufacturing processes is summarized in Fig. 7.194. Meanwhile the application of laser technology is state-of-the-art in every area of manufacturing processes.

Laser cutting can be carried out in air, vacuum, or the required gas media. The type of LB-radiation is determined by duration, frequency of following and peak capacity, and also in a kind of continuous or quasi continuous radiation with the set average capacity modulated with a frequency of 5–50 kHz.

Laser cutting of metallic materials requires intensities of $> 10^6$ W/cm, which are achieved by focusing the laser beam with the aid of lenses or mirrors. The thermal material removal process, which is directed into the depths of the material, produces a kerf in the material when the feed motion is applied [7.140, 141].

The material is melted (laser fusion cutting), burnt (laser flame cutting), or vaporized (laser sublimation cutting) at the focal point of the laser beam, depending on the intensity and the length of interaction. It is expelled from the kerf by a stream of gas emitted from a nozzle coaxially to the optical axis (Fig. 7.193). The cutting gas also serves to protect the sensitive focusing optics from spattered material.

In laser flame cutting, oxygen or oxygen-rich gas is used as cutting gas, at higher cutting speeds. However, this leads to oxidation of the cut surfaces owing to the introduction of additional exothermic energy. In contrast with the other laser cutting processes mentioned above, inert gases (e.g. argon, nitrogen) are used as cutting gases, which results in a slower cutting speed. However, they produce an oxide-free cut.

The relative motion between the laser beam and the workpiece that is that produces a continuous kerf is achieved in various ways. For laser cutting of small, easily handled components, the latter are generally moved underneath the stationary laser beam. e.g. with the aid of an X–Y coordinate table. For laser machining of larger workpieces, the laser unit including the cutting tip is either moved across the stationary workpiece, or a movable system of mirrors is guided together with the cutting tip (*flying optics*) between the fixed laser unit

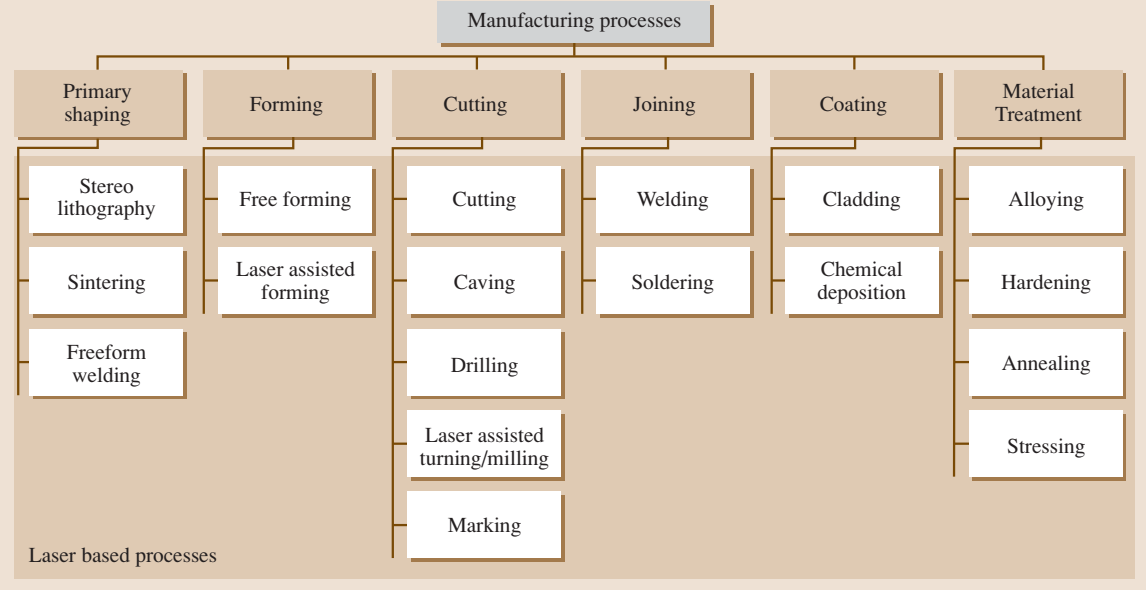

Fig. 7.194 The application of laser beam-based manufacturing processes

and the workpiece. For Nd:YAG lasers alone, flexible optical fibres may be used for guiding the beam.

The cutting speeds for other metallic and nonmetallic materials for a CO_2 laser with a power of 500 W are summarized in Table 7.47.

Table 7.47 Machining parameters for laser cutting of various materials (after [7.142])

Material	Thickness (mm)	Cutting gas/ pressure (MPa)	Cutting speed (m/min)
PMMA	4	Air/0.06	3.5
Rubber	3	N_2/0.3	1.8
Asbestos	4	Air/0.3	1.6
Plywood	3	N_2/0.15	5.5
Cement asbestos	4	Air/0.3	0.8
AlTi ceramic	8	N_2/0.5	0.07
Aluminum	1.5	O_2 /0.2	0.4
Titanium	3	Air/0.5	2
CrNi steel	2	O_2/0.45	1.9
Electrical sheet	0.35	O_2/0.6	7
Grey cast iron	3	N_2/1	0.9
Laser CO_2/500 W; focal length $f = 127$ mm			

High-powered lasers of the type mentioned above generally belong to laser (protection) class 4, which has the highest hazard level (except for laser machining systems with dosed working chambers, which are equipped with additional safety facilities such as interlock systems and radiation-absorbing protective windows). Allocation to this safety class means that even diffusely reflected laser radiation is a hazard to the skin and the human eye.

Technological laser systems mainly use the following types (active media) of laser radiation: excimer

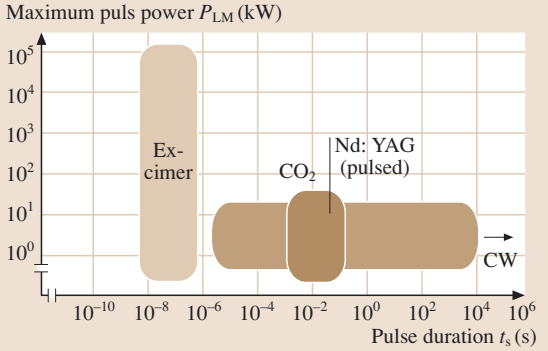

Fig. 7.195 Characteristics of different laser sources (source: LZH)

Table 7.48 Parameters and application area for various laser systems (after [7.136])

Laser type	CO_2	Nd:YAG	Excimer
Average power (W)	Up to 10^4	Up to 300 (pulse type) Up to1000 (continuous type)	< 0.3
Wave length (nm)	10 600	1064 532 (double frequency)	193, 248 308, 351
Pulses duration (s)	10^{-5}–10^{-2}	$(4–20)\times10^{-8}$	$(3–30)\times10^{-9}$
Pulses energy (mJ)	–	Up to 18	Up to 15 000
Pulses frequency (kHz)	Up to 20	Up to 50	Up to 1
Pumping source	Gas discharge	Lamps/diodes	Gas discharge
Machinable work-piece materials material	Glass, Al_2O_3-ceramics	Si_3N_4/AlN-ceramics, various metals	Polymers, plastics, ceramics, glass
Application	Cutting out, welding, heat treatment, drilling	Cutting out, welding, heat treatment, drilling, marking	Heat treatment, marking, surface modification

lasers (gas); CO_2 lasers (gas); Nd:YAG lasers (solid-state). The special characteristics of each laser system define its optimal field of application. The characteristics of the laser sources are shown in Fig. 7.195, and the main parameters are summarized in Table 7.48.

Basic elements of the equipment for laser machining are the generation source, beam guidance, forming and focusing system, and fixation and control of workpiece moving system (Fig. 7.196).

The laser equipment on the basis of solid-state lasers is generally used, basically, is used for precision machining in various materials (ceramics, polycrystalline glass, ferrite, ruby) and applications like e.g. apertures for input of a wire-electrode, apertures in thin foils and films, apertures in watches stone billets, diamond draw, atomizers, etc., or precision cutting out and marking.

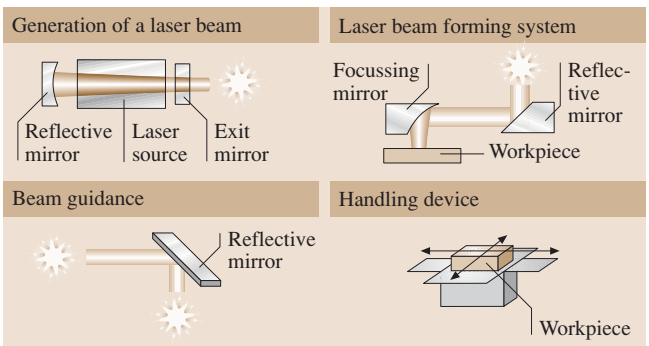

Fig. 7.196 Components of a laser manufacturing system

The fast development of laser sources and the large variety of beam forming systems open a wide field of applications as shown in Fig. 7.194. Especially in the fields of micromachining and medical applications laser systems have become an essential driver for innovation and improvement [7.82, 143].

Electron Beam Machining. Electron beam machining (EBM) is based on acceleration and focusing of electrons in a narrow bunch (beam), radiating from the cathode in deep vacuum with the help of a powerful electric field, to hit the machinable workpiece surface (anode). The physical essence of the EBM

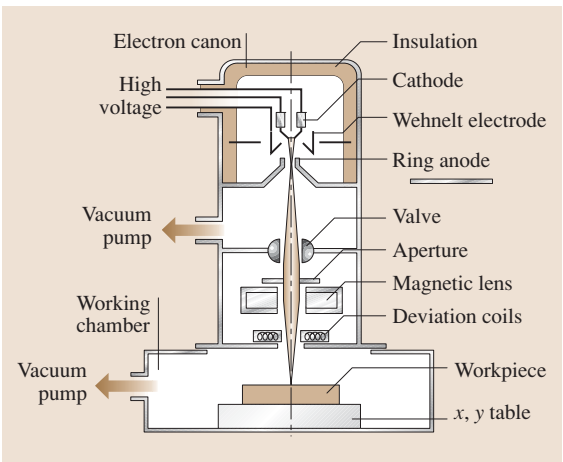

Fig. 7.197 Schematic set-up of electron beam machining

process is the transformation of electron kinetic energy into thermal energy. The electrons are emitted from a hot cathode and accelerated towards a ring shaped anode with a round opening (Fig. 7.197). The acceleration voltage is around 25–200 kV. The electrons reach the workpiece surface and release their high kinetic energy. The energy density of an electron beam is up to 10^5–10^7 W/cm^2, which is comparable to laser beams. Due to the fact that electrons, unlike photons, have a mass ($m_e = 9.108 \times 10^{-31}$ kg) and an electric charge ($e = 1.602 \times 10^{-19}$ A s), the energy transfer and effect on the workpiece surface is different compared to laser processes. To prevent electron collisions with gas molecules, the system is highly evacuated. The focusing of the electron beam is done with magnetic fields, which are generated by so-called magnetic lenses. The electrons can penetrate much more deeply into the workpiece material than laser beams. They transfer their energy via collisions with enveloping electrons.

EBM systems are more complex compared to regular laser systems. Due to the limitation of the working chamber this process is dedicated to special applications, where the benefits of high penetration depth, high impulse frequency, and fast beam deflection can be used [7.144]. Thus drilling is a perfect process to elaborate the potential of EBM, e.g. small bores (diameter down to few μm) can be made in thin foils at a rate of up to 10 000 bores/s without moving the target.

Typical application fields are combustion-chambers of aircraft turbines (difficult to machine cobalt-based material, several thousand holes) or spinning heads for glass fiber production (6000 holes of 0.8 mm diameter in 5 mm thick material [7.145]). A disadvantage of the technology is related to the fact that X-rays are generated above an acceleration voltage of 80 kV, which makes a severe shielding of the system necessary.

Plasma Beam Machining. Plasma beam machining is based on the use of low temperature open plasma, which is applied to increase operational properties of machined components such as wear resistance, corrosion stability, thermal stability, etc. Such an amelioration is carried out in order to attain the formation of functional coatings from corresponding materials, generated by a plasma jet, plasma welding, and plasma depositing. Furthermore plasma is used in some combined plasma-mechanical processes, in particular in plasma-mechanical machining.

Plasma coating is characterized by a great concentration of the thermal stream and high speed of the plasma jet. For coating fine grained powders are used (40–100 μm). The thickness of the deposited layer is around 0.3–0.5 mm and higher; deposition productivity is 2–4 kg/h.

Plasma cutting is characterized by local removal of metal along a cut line by a plasma jet using quality plasma forming gases like argon, nitrogen, hydrogen, air, etc.. It is applied for cut off stainless steels with thicknesses up to 60–80 mm and low-carbon and low-alloying steels with thicknesses up to 30–500 mm. After plasma cutting the surface roughness may reach $R_z = 80$–160 μm.

Combined Methods of Machining

For further development of manufacturing technologies a combination of energy sources is possible. With a complex joint use of mechanical, thermal, chemical, or electrical energy an enhanced material removal, better surface quality or improved tool life time can be achieved. Examples for these process combinations are e.g. electrochemical grinding, electro-discharge grinding, ultrasonic-electrochemical, electro-discharge-chemical, anodic-mechanical, plasma-mechanical, and laser-mechanical processes.

Electrochemical Grinding. Electrochemical grinding (ECG) is carried out by overlapping material removal by microabrasive grains (diamond, CBN) with anodic (electrochemical) dissolution. Anodic dissolution of metallic workpiece materials reduces the microchip thickness and the area of mechanical contact between workpiece and the grinding wheel [7.146]. Furthermore ECG reduces the material resistance against mechanical penetration by means of reduction of the strength of the superficial microlayer.

ECG processes work at a voltage of up to $U_p = 5$–10 V (at machining with independent electrode $U_p = 24$ V) and a current density of up to 15–150 A/cm^2. Nitrate/nitrite solutions are often used as working media (dielectric fluid). They contain various passivation additives (soda, glycerin, triethylamine, etc.) for reduction of the corrosion activity.

ECG processing is applied on surface ground components of hard, magnetic, heat resisting steels and alloys; surface and cylindrical grinding of thin-walled, nonrigid components; profile grinding; grinding of viscous materials, etc.

Electro-Discharge Grinding. During electro-discharge grinding (EDG) metal removal is carried out by microcutting of bonded abrasive grains while the grinding wheel working surface is continuously influenced by electroerosion. Electric discharges provide an opening of the grinding wheel topography, allowing new abrasive grains to come into contact, and the removal of adhering chips from the wheel surface to prevent loading. Also just cut chip segments might be directly evaporated in the zone of contact. Discharges occur between the workpiece and the wheel, or between the tool and a specially adapted additional electrode [7.147, 148]. EDG processes can be actively controlled and their intensity can be adjusted to provide substantial increase and stabilization in the lifetime and cutting ability of the grinding wheel.

For EDG processes either standard cutting fluid or 3% water soda solution is used as working medium. Current-conducting metal bonded abrasive wheels (or wheels with diamond or CBN grains) are connected to the positive pole and the workpiece is connected to the negative pole of a pulse voltage source. EDG is applied in tool grinding, surface grinding, and cylindrical internal and external grinding machine tools.

Laser-Assisted Machining. Laser-assisted machining (LAM) has found rising acceptance due to its potential to significantly increase machining efficiency; in particular, in processes of punching and cutting complex shaped workpieces. Laser radiation is employed for two reasons. Firstly, the laser source is used for heating (thus annealing or hardness reduction) of the workpiece material surface layer directly in front of the cutting tool. By this tool lifetime is extended and the productivity is drastically increased. It even opens the possibility of applying cutting technologies to materials that were not machinable in this way before, like laser-assisted turning of ceramics [7.149]. Secondly the laser can be used for final surface formation (for example, a groove after milling by an end mill). Applied in this combination LAM processes increase the accuracy and quality of the machined parts.

7.4 Assembly, Disassembly, Joining Techniques

Considering manufacture of tomorrow, production process and technology of joining will continue to hold its dominating position worldwide in the production of added value. Figures 7.198 and 7.199 clearly show the increasing economic importance that must be attributed to joining in those industrial branches where it already has been intensively utilized so far – an importance as is hardly attributed to any other metal working manufacturing procedure. A large number of bonding methods having evolved within the last one hundred years have gained in importance by developing from a conventional into a high-performance welding procedure. Highly effective joining technologies have been adapted to the specific characteristics of material and structural parts and developed into microjoining or hybrid joining techniques.

Fig. 7.198 Value added by joining industry (2003) [7.150], with permission

Today, joining technology in general covers about eighty different modern joining techniques which are in use worldwide, even though with varying intensity.

Therefore it cannot be aim of these chapters to provide the international readership, engineers, specialists or students with process engineering descriptions of all joining procedures known. The author and his coauthors agree with the fundamental idea of this book to present even a profound description of joining technology, though with intended restriction to selected state-of-the-art technologies (Fig. 7.200).

Thus it seems to be quite reasonable, within the frame of this technology handbook, to point out trends in the chapters presented, and to show the interested reader how an innovative product optimized in its

properties can be produced dependent on innovative materials, modern principles of design and manufacturing techniques (Fig. 7.201).

Pointing out trends in joining technology offers, on the one hand, the possibility to introduce current state-of-the-art technologies and to describe them in a competent way; on the other hand, the reader may draw conclusions from these high-technologies about the conventional joining processes. With that, authoritative standard works and bibliographical references listed in the appendices to each chapter will provide assistance.

Considering the production processes of tomorrow, the entire range of joining-technological processes as described here will certainly develop into centres of initiation and growth for a rapid and smooth manufacture, and will play an outstanding role in all phases of the so-called production life cycle, i. e. from design and development of a product through all phases of its manufacture and maintenance to recycling (Fig. 7.202).

Joining technology today is not only based on a substantial range of conventional process technologies but has also derived high-technological procedures from these and is, besides, ever more developing towards microjoining technology or even a nanotechnology.

History in the past and present reveals that joining technology is and has always been continuously expanding into new fields of practice, as a view over 2000 years back to Roman times (soldering) shows. Thus, at present, modern joining technology is increasingly engaged in supporting further development of modern organ- and vessel surgery.

7.4.1 Trends in Joining – Value Added by Welding

During the development of new technical products and the further development of existing technical products, greater attention is being paid to optimized material utilisation which also takes account of local stresses. Even individual components are being composed from different materials to an increasing extent. Examples are tailored blanks made of different steel sheets with various thicknesses and surface qualities or components which are coated locally against corrosion or wear. Furthermore, combinations of steel with light metals or plastics are being used ever more frequently in lightweight construction and the significance of nickel-base alloys is continuing to grow in the construction of power stations and aircraft engines.

Fig. 7.199 Value added by joining industry in different sectors (2003) [7.150], with permission

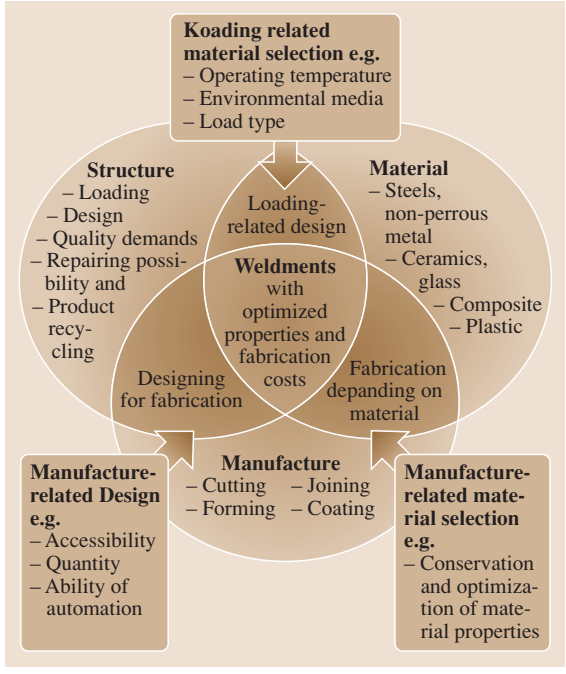

Fig. 7.200 Joining technological correlation between structure, material and fabrication

To an increasing extent, joining-technology processes will be necessary for this purpose and, in the future, will be core elements for quick, problem-free and reliable production – in this respect, they will be integrated into the chain of the manufacturing processes. Thus, joining technology remains economically significant; it is making a fundamental contribution to

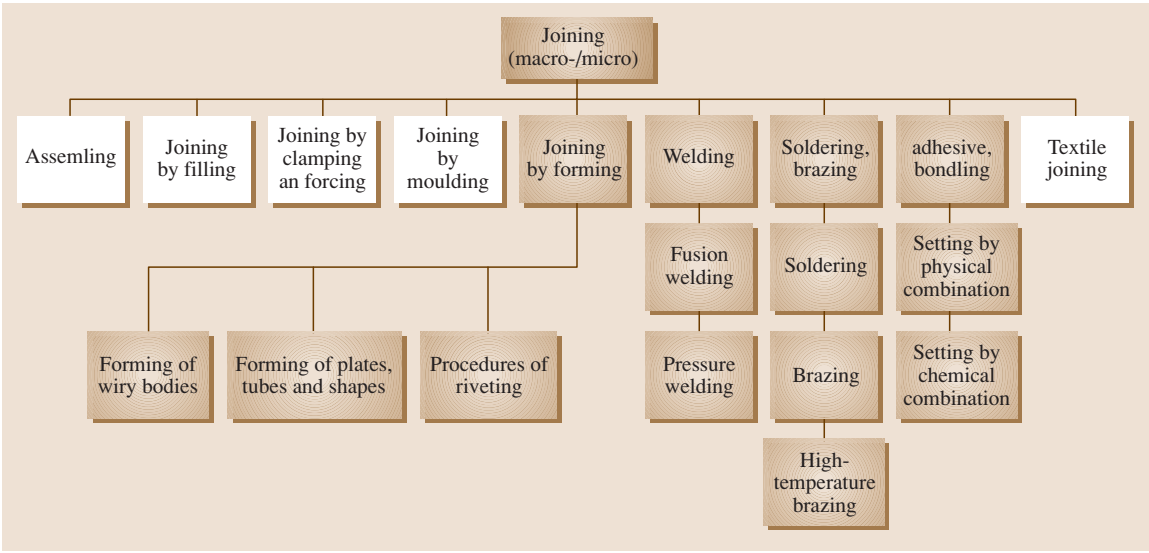

Fig. 7.201 Trends of joining procedures (DIN 8593)

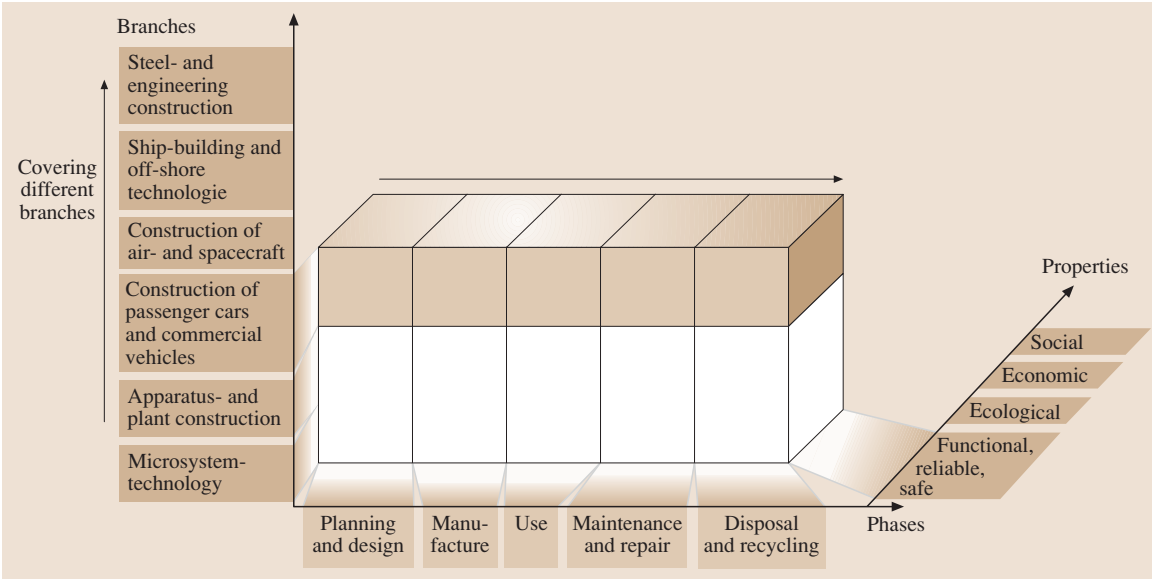

Fig. 7.202 Joining in product life cycle (source: DVS)

the value added by the producing sector and has good prospects of growth. Joining technology will play an exceptionally important role in all the phases of a product life – these phases encompass the design, development, fabrication, utilisation, maintenance and repair of a product as well as its recycling and disposal. Not only mechanisation and automation but also the use of industrial robots for joining will increase [7.151]. In this case, consistently interdisciplinary approaches in research, development, fabrication and application will be adopted in order to incorporate requirements resulting from the product, production and material development.

For economic reasons, the simulation of processes and properties is becoming the key factor also for the application and further development of joining pro-

cesses and materials. Those processes and materials which evade reliable simulation will no longer be used in the future. Simulated joining processes permit the virtual testing and optimisation of the joining processes even in advance of the production, permit the planning and implementation of quality-assurance concepts before the joining process and help during commissioning, operation and repair. At an early stage, they also provide information for the necessary training of personnel for the fabrication, maintenance and repair. The objective must be to permit a universal concept for the simulation of the entire process chain on the basis of the elements consisting of process simulation, structural simulation and material simulation [7.152].

The reliable calculation of the resistance, durability and strength of joined products when they are subjected to all the stresses to be expected is still of elementary significance for their utilization. Particularly with regard to cyclic stresses and the fatigue strength of joint structures, stringent requirements continue to be placed on design and calculation (Fig. 7.203).

This also results from the fact that joining technologies and joint geometries are being refined continuously. Another factor is that, in certain fields (e.g., in the transport sector), materials with a low volume weight and a higher strength are being used increasingly in order to meet the demands of lightweight construction. The further development of computing technology permits strength analyses also on the basis of local stresses. The aim is to reliably record fabrication influences on the strength of joined products. This encompasses an assessment of the effects of the joining technologies used and of the after-treatment processes used as well as the recording of the weld quality. It is necessary to determine the differences between the characteristics established on small specimens and the properties of products joined in reality. To this end, the existing database for fatigue strength must be analysed while paying attention to various aspects. It is indispensable to record residual stresses in a differentiated way and to take multiaxiality into consideration. Operational-strength analyses and fracture-mechanical assessments of joints are the state of the art. In many cases, requirements are defined by sets of rules and guidelines and must be developed further. The vision being pursued is that a combination of simulation, calculation and experiment results in material-dependent characterization which takes account of the real structure of the joint and of the actual properties. The objective is to exactly predict the behaviour of joined products when they are subjected to stresses. With regard to the strength, joints will no longer be regarded as weak spots.

Basically, it may be assumed that the definition of weldability until now (as a component property with the concepts of the welding possibility of the fabrication, the suitability of the material and the welding reliability of the design) must be refined by a definition of the joinability – with the subdivisions of the joining possibility, the joining suitability and the joining reliability [7.153] (Fig. 7.204). This terminology takes into consideration the fact that, in addition to welding-technology processes, other joining-technology processes such as brazing, adhesive bonding, mechanical joining and also coating are being used to an increasing degree.

In a continuous process, developments from information and communication technology will be introduced further into joining technology. Interface management will permit the communication between various information systems at various levels (Fig. 7.205).

Greater importance has been attached to repair and maintenance concepts especially for joined products in road-vehicle construction. With almost 45 million vehicles in Germany and around five million accident repairs and 30% seriously damaged body structures every year, economically viable repair concepts are

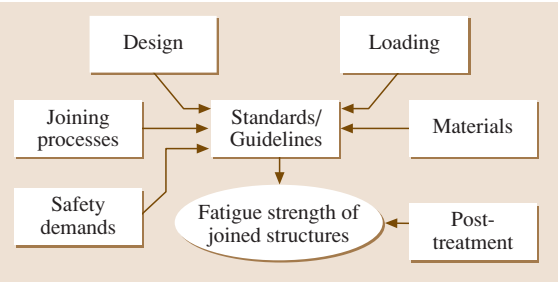

Fig. 7.203 Construction of joined metallic structures

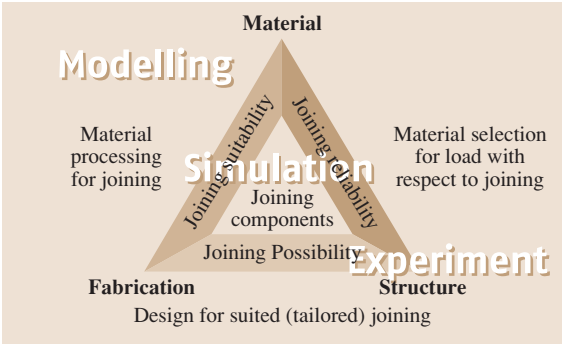

Fig. 7.204 Correlation between structure, material and fabrication

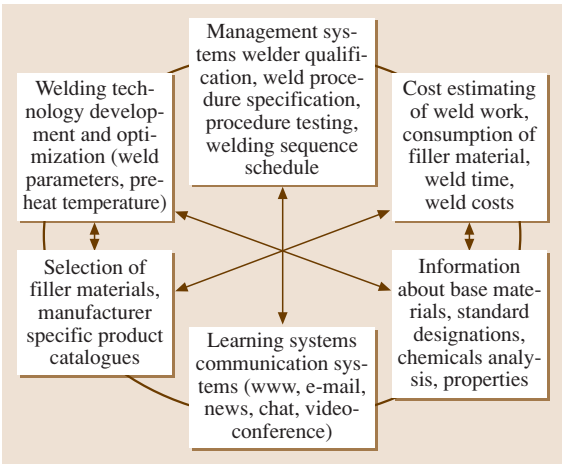

Fig. 7.205 Information- and communication systems – collaboration – interfaces

becoming more significant. Repair concepts must be an integrated part of the product development and must take account of the increasing utilization of high-strength steels, light-metal alloys, plastics and tailored blanks as well as of the applications of the laser-welding processes, adhesive bonding and mechanical joining. This is important because the joining processes applied in the production may have a direct influence on the possible repair costs of vehicles. Moreover, the costs of third-party and own-vehicle insurance are dependent not only on the accident frequencies but also on the repair costs. Joining processes which lead to rapid fabrication but generate high costs in the cases of repair may therefore be counterproductive. Modular construction methods which are suitable for repair are being applied especially in the case of vehicle construction. Concepts for qualified training in new repair techniques have been developed [7.154].

The people's justified wish for the protection of their environment is leading to particular expectations with regard to technology – this applies to joining technology as well. As examples, the requirements resulting from this can be described with the following headwords: Economical handling of primary and secondary energy, conservation of raw materials, avoidance or elimination or storage of residual materials, selection and utilization of reusable materials as well as recycling processes for joined components. In addition, measures for health and safety in joining technology remain urgent [7.155].

With a comprehensive concept incorporating the whole product life cycle, joining technology must react to these requirements specified here as examples. Such a concept is described in the following text which is preceded by a few trends from research and application in joining technology. For the future, a competition between the joining processes is emerging in the applications. Personnel qualification and competence management are becoming determining factors for the competitiveness of the companies in joining technology. As an example, this is shown on the basis of statements about the value added by welding technology in various welding-intensive sectors in Germany. The fundamental statements are summarized at the end and are connected with an outlook.

Trends in the Joining Processes

The statements in this section are essentially based on the results of the cooperative technical-scientific work in the DVS, findings from enterprises and research institutes are included.

One main focal point of the joining-technology research is to be found in the further development and optimization of joining processes, including automation. Consideration is given to the processes of welding, soldering and brazing, adhesive bonding and microjoining. In this case, welding accounts for the majority and is followed by the research in the areas of adhesive bonding, microjoining and soldering and brazing. It is significant here that the joining process of adhesive bonding has already become established as the second research field in joining. But also the future importance of the mechanical joining processes should not be underestimated. They are dealt with briefly below. Initiated by the trend towards lightweight construction and by other technological trends (e.g., the joining of coated sheets and the increasing modularization of the fabrication), there is resulting competition between the joining processes with regard to applications. Here, the thermal joining processes are competing not only with each other but also with low-heat and *cold* joining processes.

A more detailed analysis relating to the welding processes shows, that gas-shielded arc welding as the stock process in many companies continues to be an essentially determining factor in the research work. However, the beam-welding processes (laser beam welding and electron beam welding) already make up a substantial part of the present research work – with an upward tendency. In contrast, research work on resistance welding shows a slight downward tendency.

The necessity of using hybrid welding processes to a greater degree in practice is also shown in the research. This is reflected in the expectation of using these to a greater degree in practice. In this respect,

it is primarily the combination of laser welding with gas-shielded metal-arc welding which is regarded as a hybrid process. However, combinations of laser welding with gas-shielded tungsten-arc welding and with plasma welding are also being used. Basically, those welding processes in which different welding processes are coupled via a common molten pool and a common process zone thus exists are designated as hybrid welding processes. For the sake of completeness, attention is drawn to combinations of the following processes: welding and adhesive bonding as well as mechanical joining and adhesive bonding. These hybrid joining processes will possibly be important for the development in joining technology.

A relatively high proportion of research in the field of microjoining technology corresponds to the trend towards the miniaturization of products. Research trends with regard to the microjoining technologies show applications for example in high-temperature microelectronics and in optoelectronics. But also research focused on quality assessment dealing with simulation, calculation and reliability is a must. Microjoining processes under investigation are leser beam welding, soldering in electronics, bonding and adhesive bonding.

Not only the processes but also the materials influence heavily the research work in joining. Steel makes up to a significant amount of research, but light-metal alloys (aluminum and magnesium) will become ever more significant in the research and application. The already indicated rapid developments in lightweight construction are documented in the research contents. These are also associated with the increasing importance of *multimaterial design*, i. e. with the selective combination of materials with different properties, dimensions and surface conditions. As summarized on Fig. 7.206, highest-strength steels, light metals and mixed joints will be main focal points of the research in the future. This statement is confirmed not only by an extensive industry poll but also by applications in the companies.

Increasing significance is being attached to research projects in the fields of calculation, design and simulation – not only in the field of microjoining as mentioned above, but also in structural joining. There will also be more research in the area of health and safety. Points of research here are to be made not only to processes but also to the recording and assessment of welding fumes and to early-diagnostics methods in occupational medicine.

In this respect, it has also been proven that even greater consideration than until now should be given to research projects with an evident reference to the quality of the joined products (Fig. 7.207). Here, not only nondestructive testing but also sensor equipment and process diagnosis are emerging as main focal points – with the aim of controlling joining processes according to quality characteristics to an even greater extent than until now.

Coming back to the joining processes, it is possible, in simplified terms, to make the following trend statements about individual joining processes.

Gas-shielded arc welding retains a dominant position and the latest research supports the applications and further developments of these processes. However, an estimation for the future suggests that gas-shielded arc welding will not grow as quickly as in the past years.

The processes of resistance welding will hold a dominant position due to their process performance and productivity – anyhow they will lose applications, in particular because of the increased application of mechanical joining technology but also because of adhesive bonding. It remains to be seen, whether developments like hybrid processes (e.g., a combination

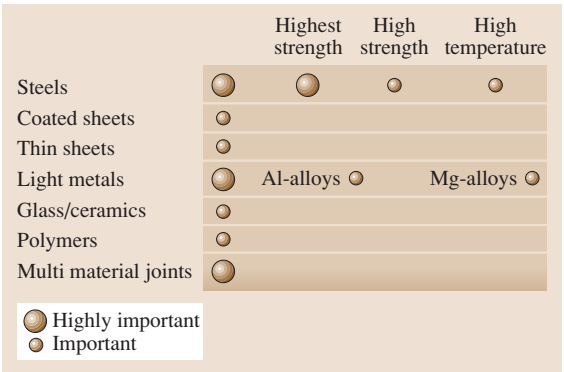

Fig. 7.206 Future research activities – materials

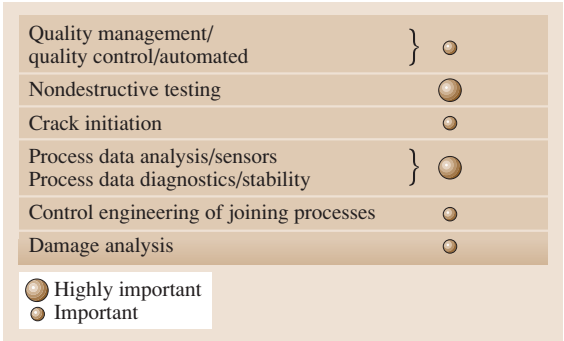

Fig. 7.207 Research in quality

of resistance spot welding and adhesive bonding) will prove its success.

The beam-welding processes (especially the laser beam welding processes) will become far more significant as a result of the rapid transfer of the findings from the research to the application. In this case, the growth of electron-beam welding will possibly slow down.

These statements are supported by the already specified study into the research needs of installation manufacturers and system suppliers [7.155]: the welding process with the highest growth in the next ten years from the viewpoint of the users will be laser beam welding – however, its growth will be accompanied by adhesive bonding, mechanical joining and soldering and brazing (Fig. 7.208).

For individual welding processes, a few examples of development potentials and research approaches are to be summarized below:

In the case of gas-shielded arc welding, the electronization of the power-source technology as well as the integration of fundamental operating functions into the welding torch will make further advances. Moreover, new process variants are being developed. Low-heat joining processes will be of particular importance for the future. Approaches are also being shown towards the development of an optimum installation concept for the user not only with easy-to-operate machines but also on multifunctional machines.

With regard to resistance welding, the servo welding guns are being refined and the operator interfaces on the welding controllers are being optimized. The goal is to perfect the sensor technology for on-line quality testing in the case of resistance welding as well.

For electron beam welding, improvements may be expected in the process observation and in the process recording as well as developments for the beam deflections. Appliance developments are optimizing vacuum electron beam welding by shortening the off-times. Non-vacuum electron beam welding is also the state of the art today.

For laser welding, the utilization of new beam sources is being tested and an improvement in the on-line process control is being striven for in the case of this process as well. The objective is to simplify the handling jigs by using flexible beam manipulators. Methods of beam deflection are leading to new applications in the form of the remote welding of large-surface, three-dimensional components. The utilization of welding filler materials is also being tested. Hand-guided laser systems are in use.

The monitoring and on-line regulation of the welding process as well as the on-line documentation of the weld quality are seen as technical challenges for all the welding processes. In all cases, top priority is being attached to the operator-friendly implementation of technical solutions in the appliances and systems.

Because of the diversity of the application possibilities in each individual case, these trend statements must remain in these general terms. In addition to the stable further developments in the specified processes, new welding processes are also being applied. Friction

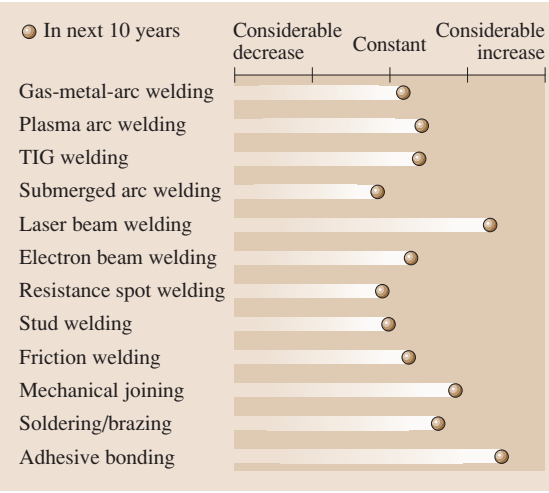

Fig. 7.208 Development of joining procedures from the companies point of view

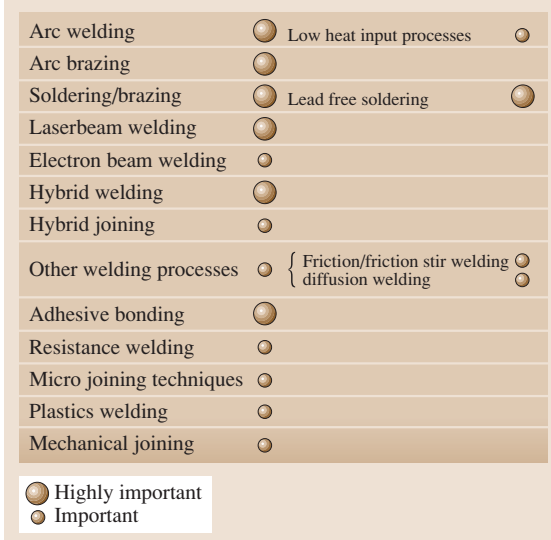

Fig. 7.209 Research/joining processes

stir welding in which it has been possible to exploit interesting economic applications after a relatively short development time is regarded as an example of this. Further examples are friction spot joining and magnetic-pulse welding. Figure 7.209 makes a rough assessment of the research fields of joining processes.

Before the explanation of the effects of the statements made here about the joining processes in some welding-intensive sectors, the value added generated by welding technology in Germany should be considered.

Value Added by Welding Technology in Germany

Studies conducted in 2001 [7.150] and in 2005 [7.156] show the economic importance of joining and welding.

- The production value of the companies providing goods and services for joining in Germany amounts to approximately Euro 3.6 billion. These goods and services include welding machines, appliances required for welding, welding filler materials, adjuvants, gases, protective clothing, testing machines and also the further training of the welding-technology personnel.
- The companies working for this production value employ 37 000 people (converted to full-time staff) and generate a value added amounting to around Euro 1.6 billion.

Investigations conducted by the DVS have indicated that the German market for ancillary supplies for joining technology may be estimated to be about one third of the European market and this in turn one third of the global market. For 2003, it is thus possible to estimate a value of approximately Euro 15 billion per year for the value added generated by ancillary supplies for welding technology all over the world.

However, the specified figures do not serve to define the value added by the companies which use joining technology in their fabrication in order to manufacture their products. It is far more difficult to estimate the economic benefit for this sector because welding is just a part of the value added in these companies and only few statistical values are available. A calculation is carried out here on the basis of a macroeconomic model. In this case, the study comes to the following results (Fig. 7.198): The macroeconomic value added by the production and application of welding technology in the investment-goods industry in Germany amounts to around Euro 27 billion (i. e. 4.8% of the value added by the producing sector in Germany). In this respect, around 640 000 employees are directly or indirectly connected with welding technology.

Results show that joining technology can hold its own even in a difficult economic environment and is proving to be a cross-sectional technology which, because of the close cooperation with various sectors, is relatively resistant to economic cycles and can open up new sales markets. A comparison of data from 2005 with the data from 2001 shows an increase in the value added of 18% with a simultaneous increase in the numbers of employees of 5% in welding technology. This is indicative of higher productivity.

This results from the strategies pursued by the companies in joining technology and by the companies applying it with the three following main focal points:

- Concentration on core competences
- Adaptation of the production processes
- Increase in the labour productivity

In Germany, a number of sectors are regarded as welding-intensive, including vehicle construction (road vehicles, rail vehicles, ships and aircraft) as well as metal construction and mechanical engineering. On average 5% of the total value added by these sectors is generated by welding technology (Fig. 7.199). A few joining-technology trends for these sectors are considered below.

Trends in Welding-Intensive Sectors in Germany

The following statements are essentially based on the results of the cooperative technical-scientific work in the DVS and make no claim to being complete.

Joining Technology in Road-Vehicle Construction. In order to reduce weight, tailored blanks are being used to an increasing extent in bodymaking. The combination of sheets with different materials, material thicknesses and/or surface conditions (as a rule, welded together using the laser beam) serves to achieve better material utilization with regard to the stress-bearing capacity. The tailored blanks allow the increasing use of high-strength ductile steels. The bodies are assembled not only by means of resistance spot welding and adhesive bonding but also by means of mechanical joining and gas-shielded arc welding. In this respect, the latter process is utilized in regions subjected to high and dynamic stresses. Another application is for the attachment of studs in order to fasten built-in and at-

tached parts according to the various methods of stud welding.

The joining processes are selected according to the criteria which are customary in other sectors as well. These are the joinability (regarded as a component property) and the economic viability. In this respect, it must be borne in mind, precisely in large-scale series fabrication, that the cycle times of the fabrication lines are very short. This necessitates the utilization of high-productivity welding processes.

In the last few years, the efforts to reduce the weight of vehicles of all kinds with the aim of reducing the fuel consumption during operation, the development of new materials and the developments of the joining processes have led to fundamentally new strategies for the construction of road vehicles. In addition to steel, light metals and plastics are being used to an increasing extent wherever this contributes to weight reductions without affecting the properties of the end product. This has resulted in pure aluminum bodies or in bodies made of a material mix. For such bodies with a structure consisting of different materials (multimaterial design), the selection of the correct joining technology constitutes a particular challenge.

Not only mechanical joining (bolting, clinching and riveting) but also laser welding and MIG welding are used for aluminum bodies. Resistance spot welding is now applied to a limited extent only. Thermal but low-heat joining processes which, for example, get around the difficulties relating to the metallurgical compatibility when different materials are welded are being developed for these applications as well. It remains to be seen how this *competition* between the thermal, low-heat and *cold* joining processes develops (Fig. 7.210).

Adhesive-bonding technology is becoming ever more significant for the assembly of bodies not only made of steel but also made of aluminum or material combinations because linear structural adhesive-bonded seams produce better stiffness behaviour than the punctiform resistance weld spots and seal the joint at the same time (Fig. 7.211). The disadvantage of this solution is that, as in the case of various welding processes, the sheet must overlap in the joining region and adhesive-bonded seams only obtain their strength at the end of the fabrication process during the firing of the paintwork. Other additional joints (manufactured, for example, by means of spot welding or clinching) must then ensure the necessary cohesion of the body during the fabrication.

The search for economically viable solutions is continuing: preference is given to the use of butt welds in bodymaking as well. Today, this is feasible and economically possible with laser welding since the fabrication of the raw parts is constantly improving its compliance with those tolerances of the single parts which are necessary for this purpose. The achievements with regard to the further development of high-power diode lasers for welding precisely in the thin-sheet range are giving cause for great hopes on the cost side as well. Where this is not successful, hybrid processes (e.g., the combination of gas-shielded arc welding and laser welding or laser brazing or gas-shielded brazing) are being used as alternatives.

Joining Technology in Rail-Vehicle Construction. As in motor-vehicle construction, lightweight construction is a main focal point in rail-vehicle construction as

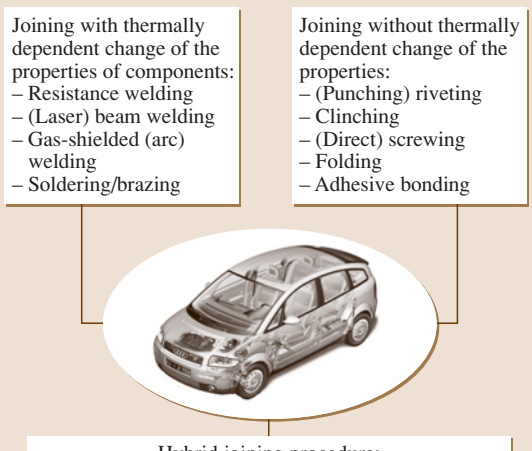

Fig. 7.210 Vehicle construction as *welding sector*

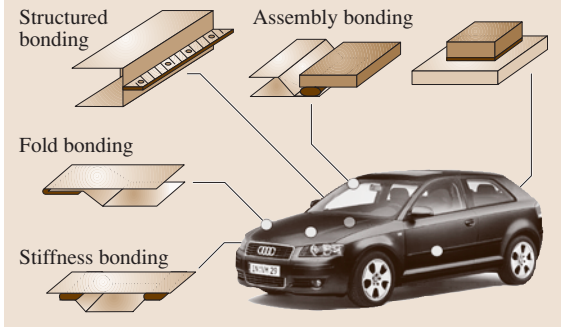

Fig. 7.211 Bonding systems

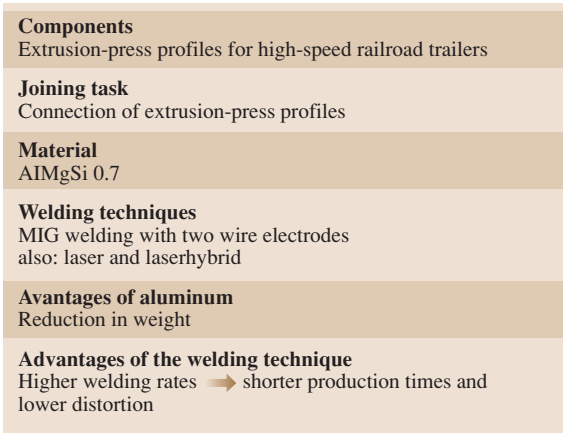

Fig. 7.212 Joining of aluminum materials through welding

well. The utilization of aluminum and its alloys for the construction of passenger carriages for the trains is gaining increasing acceptance. The joining technologies are, in part, the same as in motor-vehicle construction: gas-shielded metal-arc welding (also as twin-wire gas-shielded metal-arc welding, as shown on Fig. 7.212), laser welding and mechanical joining. Furthermore, rail-vehicle construction is developing into an application field for adhesive-bonding technology. However, since the components to be joined are thicker than in the case of the road vehicles, friction stir welding can be used as a young joining process, in particular for the very long longitudinal welds when extruded sections are welded together, for example, for the manufacture of the carriage roofs. However, the trend towards the utilization of aluminum is certainly reversible. Also high-strength steels and possibly even once again high-alloy steels will be used but the bogies will continue to be manufactured from steel with the aid of arc welding.

Joining Technology in Metal Construction. In both building construction and civil engineering, metal structures (as a rule, made of steel) are welded using arc processes. The degree of mechanization during welding is stipulated depending on the repetition frequency of the individual parts or of the weld lengths. If these deliberations lead to the application of manual electrode welding, TIG welding or partially mechanized gas-shielded metal-arc welding, the high wage costs and ancillary wage costs in Germany play a fundamental role in the consideration of the economic viability and frequently lead to the relocation of this production to low-wage countries.

The increased utilization of high-strength steels in structural steel engineering and the connected more stringent requirements on the precise compliance with the welding parameters are leading to greater mechanization and also to the utilization of laser welding in this sector.

Hand-guided welding processes are used regularly in Germany as well merely in special cases when the expense of transporting the parts is not in a reasonable ratio to the welding expense and for assembly welds.

Joining Technology in Installation and Mechanical Engineering. Statements similar to those in metal construction are also generally applicable to installation and mechanical engineering. Here as well, the manual processes with the different materials are replaced by mechanized and automated processes. In the future, the arc-welding processes used will be extended by laser welding and, in the case of greater material thicknesses, possibly by electron beam welding; this will also happen in the manufacture of large-diameter pipes. Current users are following developments in friction stir welding with great interest, possibly for the welding of steels as well.

Not only in the chemical industry but also in energy generation, process temperatures are rising constantly, thus leading to ever more stringent requirements on corrosion resistance. As a result, other materials such as nickel and cobalt alloys must be used instead of steels. The associated subsequent developments with regard to welding filler materials and welding processes must take place concomitantly with the development of materials for semifinished products.

Joining Technology in Shipbuilding. The changeover of welding processes in shipyards to laser-welding processes or to a combination of gas-shielded metal-arc and laser welding as a hybrid process with and without filler material is currently taking place in German shipbuilding. Although the costs of welding are not reduced very much (if at all) in this case, the benefits of the new process are to be found in the lower distortion caused by the drastically reduced weld volume and in the savings on expenses related to unnecessary straightening work. As an example, Fig. 7.213 shows laser-welded sandwich panels for shipbuilding.

Joining Technology in Aircraft Construction. Until now, riveting has been the basic joining technology in aircraft construction. For the first time, laser welding

is being applied in the wing area and in the fuselage. However, stiffeners are not the only thing that should be welded and not riveted. Developments for butt welding in the skin area have been initiated. Furthermore, adhesive-bonding technology is becoming increasingly significant in aircraft construction.

Joining Technology in the Product Life Cycle

As was already described, in various industries, the competitive situation of joining technology will, in the future, necessitate even stricter orientation to the product and to the product life cycle. The product life cycle begins with the idea for a product, with a customer order, or with a recognized market need. This leads to product development. The product life cycle ends with recycling or waste disposal. Between the beginning and the end of the cycle, the product is tested, manufactured, used, maintained, and, if necessary, repaired. In all these phases, joining technology must be taken into consideration from the very start. For automobile manufacturing, such strategies have already been described in detail. In the future, such strategies will, however, also have to be transferred to other areas of application of joining technology as well as to other sectors.

In this respect, it is necessary to pursue approaches not only relating to individual phases of the product service life but also, in particular, extending across different phases. Using the example of the automation capacity of the recycling of joined components, Fig. 7.214 shows an example of a phase-oriented approach.

Additional examples of such approaches that are related solely to one phase in each case are as follows:

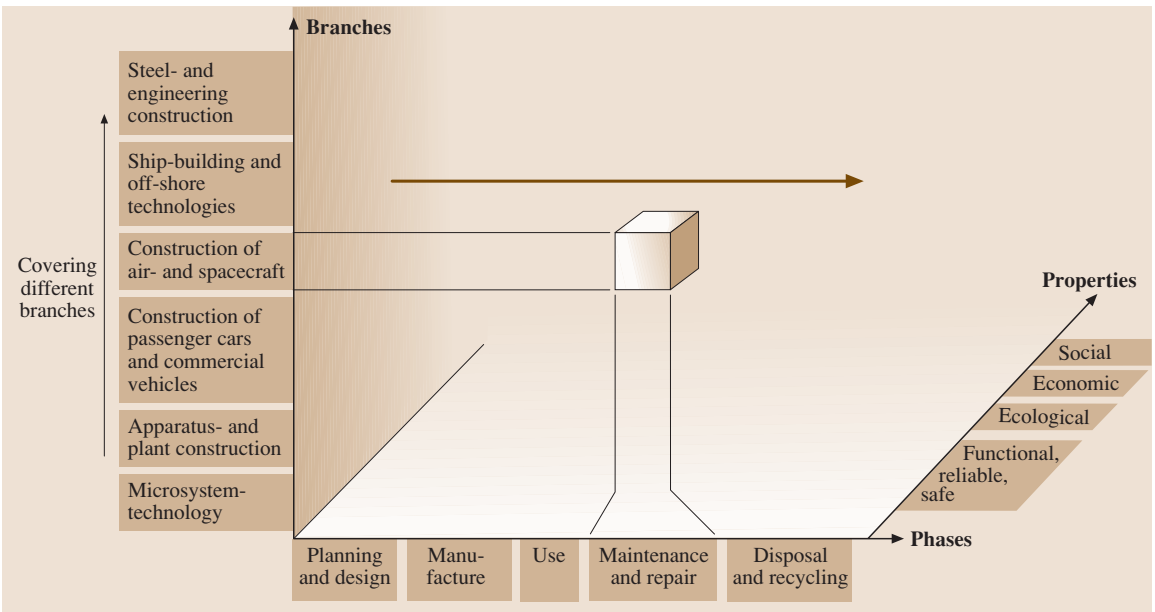

Fig. 7.214 Joining in product life cycle

- Designing in a way that allows for joining
- Real-time quality systems to control production by means of joining technology
- Long-term behavior of joints
- Economically viable processes for the repair and maintenance of joined components
- Economically viable processes for the dismantling of products
- Recycling concepts for multimaterial components

The interconnections in joining technology with respect to the design, composition, and manufacture of a product have already been elaborated in detail (cf. Fig. 7.214). Despite this level of knowledge about joining technology, there is still a need for further action and research. This is due to the fact that, until now, not all the aspects and influences that may arise during a product life cycle have been considered in good time and in an appropriate way. There is no all-embracing concept of joining technology that takes into account all the phases of the product life cycle and their interactions with each other (Fig. 7.215).

Approaches extending across different phases of the product life cycle are, for example:

- Designing in a way that is suitable for maintenance and repair
- Designing in a way that is suitable for recycling
- Cases of damage and repercussions on design and production

The universal simulation of joining processes and properties in all the phases of the product life cycle is an interesting example of such consideration extending across different phases of the product life cycle (Fig. 7.202).

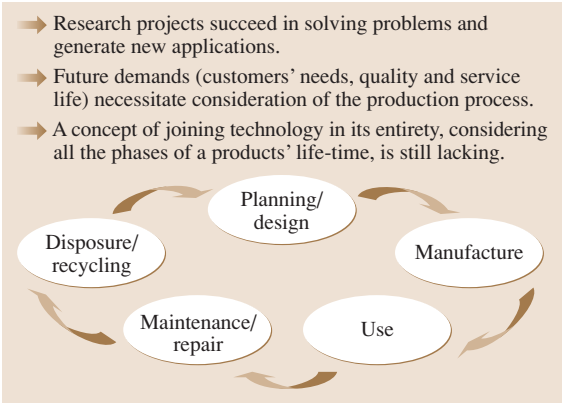

Fig. 7.215 Joining in product life cycle – initial situation

The consistent orientation of joining technology to the product life cycle may generate further value added and therefore has great economic significance for companies engaged joining technology. For the future of joining technology, it is thus necessary to strive for consider all the process chains from technical and economic viewpoints. In this respect, the integration of joining technology into automated production processes is playing an increasingly important role. The isolated consideration of individual joining processes or manufacturing steps must be given up in favor of the consideration of the manufacturing chain as a whole with the processes to be integrated and their interactions. The future will be characterized by the simplification of installation operations, improvements in sensor equipment, flexible and intelligent clamping and handling techniques, and integrated quality assurance – of course, supported by the universal use of simulation tools.

Summary and Outlook

For the technically and economically optimum utilization of joining processes, in the future, it will be essential to consider joining technology over the entire product life cycle. Interdisciplinary approaches and actions are imperative. In this respect, attention should focus on the system connections between materials, manufacturing, the joining technology, and the product. Lightweight construction will be a technological driving force behind joining technology in the future as well. Material developments with regard to the steels, aluminum alloys, and magnesium alloys will set new requirements on joining technology, and the multimaterial concept will gain acceptance. As a result, not only will increasing significance be attached to adhesive bonding and mechanical joining processes, but the thermal joining processes will also make enormous development advances in these application fields and will safeguard and extend applications.

The following trend statement may be made for the welding processes: gas-shielded arc welding retains a dominant position and the latest research supports the applications and further developments of these processes. The processes of resistance welding will become less significant despite considerable innovation efforts, and beam-welding processes (especially laser-welding processes) will become much more important due to the rapid transfer of the findings from research to applications. Combinations of welding processes (basically consisting of arc and laser welding) will belong to the state of the art in the future. New welding processes

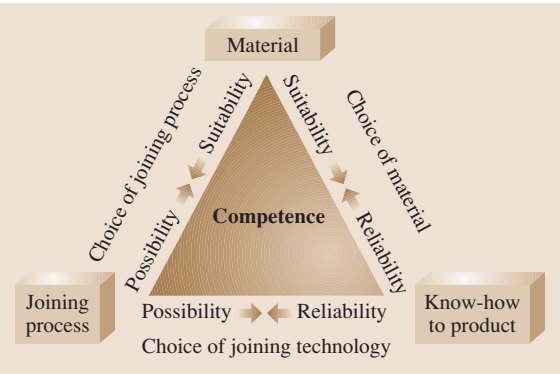

Fig. 7.216 Competence management in joining

such as friction stir welding will open up new applications.

The increasing complexity of joining technology is necessitating competence management in companies. Here, competence is defined as the joining together and use of relevant knowledge in materials engineering and in fabrication and joining technology for a very specific purpose. In this respect, the competence of a company is more than the sum of the competence of the individuals, but only when it is managed correctly. With reference to the joinability relationships already specified in Fig. 7.204, it is possible to develop competence management for joining (Fig. 7.216). The objective must be to assess and implement the experience available in a given company, the existing facilities, and proven processes in a proper and cost-effective way over the entire product life cycle. With attention focused on these conditions, joining technology will continue to account for a large proportion of the value added in the producing sector with prospects for further growth.

Joining technology will gain acceptance even in difficult economic conditions. The consistent further development of joining technology entails investment in appliances, processes, and infrastructure – however, particularly in people and in their knowledge and abilities.

7.4.2 Trends in Laser Beam Machining

By improving the laser beam source, new applications for laser beam welding could be found. With an increase in the maximum power output and improvements in the quality respectively the focusability of the beam, it has now become possible to perform joining on plate material as it is used in rail-vehicle-, plant- and apparatus-, or shipbuilding with the help of laser beam technology. Along with the enlarged scope of its usage, laser beam welding, as practiced in manufacturing engineering, its operation technology, and process-specific control engineering have all undergone innovation. But especially improvements in the laser systems have made the practice of laser beam welding simpler, safer, faster, and more reliable.

Laser Beam Welding

Basic Principles. Laser beam welding is a fusion welding process. Through the laser beam, the laser produces the energy necessary for welding. It is led to the focusing lens system by mirrors or optical fibers. The lens system then focuses the laser beam on the joint. Depending on the intensity generated there, different processes of beam–material interaction will take place. When the intensity is low, most of the radiation will be reflected by the workpiece, and only a very small part will be absorbed by the metal in a thin layer ($< 1\ \mu m$) at the surface and transformed into heat. The energy input into the workpiece is achieved by heat conduction. With increasing intensity, the workpiece is locally heated by the laser radiation that is absorbed. When the melting temperature is reached, a molten puddle forms as the time of influence is increased. If the parameters are chosen so as to maintain a stationary state, the process is described as thermal conduction welding (Fig. 7.217a).

If, however, the intensity is further increased so that more energy is absorbed than can be dissipated by heat conduction, then the enormous energy density of the laser beam in the focus will cause the metal to vaporize. The pressure of the metal vapor that flows off

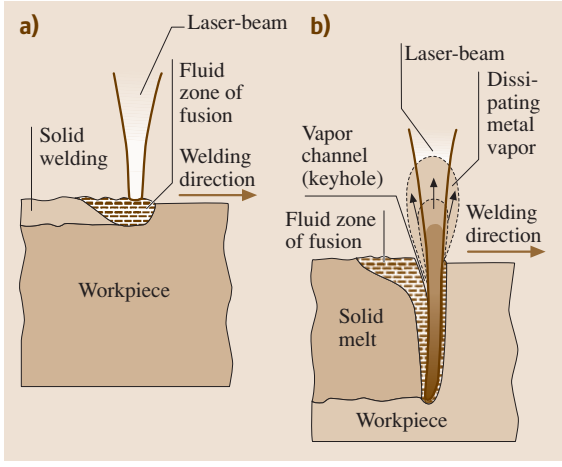

Fig. 7.217a,b Principle of laser beam welding: **(a)** Heat conduction welding, **(b)** deep welding

creates a steam passage in the melt, the so-called *keyhole*. Typically, the diameter of such a capillary steam tube shows the magnitude of the beam diameter (0.1 to 1 mm). Characteristic threshold intensities for capillary formation lie in the range of 10^6 W/cm^2.

In laser beam penetration welding, the system of capillary steam tube and surrounding molten bath is led along the assembly line. The molten bath flows around the capillary on both sides, comes together behind it, and, when solidifying, forms a joint (Fig. 7.217b) [7.157].

Trends in Systems Engineering. The motivation behind the development of lasers for industrial material processing has always been the demand for higher performance together with higher quality of beam. With the use of the traditional lamp-pumped Nd:YAG solid-state laser, increased performance of the laser is always connected to a decrease in beam quality, due to the thermal lens formed. By using laser diodes instead of pulsed-light sources, the thermal lens can be reduced; however, the principal decrease in beam quality will remain even if the laser performance is increased. The situation is different with a disc laser. This laser eliminates the thermal lens in the crystal so that a high performance together with a good quality of the beam can be obtained. With this, important new preliminaries for new laser applications are provided by achieving smaller focus diameter, longer distances between the optical machining system and the workpiece, and, last but not least, a higher focus depth of the focused laser beam [7.158].

In welding and cutting, the improved beam quality of the disc laser can directly result in a reduction of the focus diameter, which then causes the power density of the laser beam on the workpiece to increase to the square. The machining threshold moves toward lower performance, and the laser welding penetration effect begins sooner. The range of welding parameters is enlarged, and thus process reliability is increased. By the laser welding penetration effect that comes into play already at lower performances the weld seam width can be kept narrow. From this will result a low heat input and, thus, less distortion of the structural parts. Thus, an efficient and precise welding of thin sheets becomes possible. In addition, considerable penetration depth and welding speed are achieved [7.159].

Also when welding with scanner optical systems, the beam quality may be used to much advantage. Scanner optical systems with their galvo-mirrors deflect the laser beam within a working area. The focus diameter and working distance depend directly on the beam quality of the laser used. With the rod systems currently used and with their beam quality of 16 mm mrad, only working areas of approx. 150 mm side length could be accommodated when welding within a typical sheet thickness range of 1–2 mm. When working with a disc laser, an area of up to 300 mm side length can be covered without difficulty with the smaller scanner systems. This so-called remote welding procedure makes redundant the otherwise necessary system of axles with which the focusing optical system or the structural component is moved, but it is also of interest when combined with robots [7.160].

In the kilowatt range of performance, predominantly CO_2 lasers, longitudinally diode-pumped Yb:YAG lasers, transversally initiated Nd:YAG rod lasers, and Yb:YAG disc lasers are currently used. CO_2 lasers differ from other beams by almost diffraction-limited beams even at a performance of several kilowatts (typically $M^2 < 2$). With a wavelength of $\lambda = 10.6\,\mu$m, however, the beam parameter product of a CO_2 laser cannot be smaller than 3.4 mm mrad ($M^2 = 1$). Currently, in the kilowatt range, solid-state lasers do not yet produce diffraction-limited beams, but with 2.8 mm mrad ($M^2 = 8$) at 1 kW medium performance (rod laser) and 7 mm rad ($M^2 = 21$) at 4 kW (disc laser) they already offer excellent focusability with their short wavelength, which is ten times shorter than that of other lasers. In addition, diode-pumped solid-state lasers reach a high efficiency of greater than 20% (electrical-optical without cooling). Recently, fiber lasers have also appeared on the market that, by incoherent collimation of several fibers, offer a capacity of several kilowatts as, e.g., 1 kW power output with a beam parameter efficiency of 6 mm mrad ($M^2 = 18$) or 4 kW with 20 mm mrad ($M^2 = 59$) [7.161, 162].

The unique advantages of fiber lasers are their unsurpassed efficiency, excellent beam quality, low volume and weight, and outstanding robustness. These advantages can be attributed to their fiber-optical microstructure. Recent investigations have shown that their high performance can be achieved with several evanescent wave guides without impairing the beam quality. With such developments, fiber lasers are also capable of producing beams in the kilowatt range that offer an excellent focusability. The form of the modes can be determined by an appropriate design of the wave guides (distribution of the refraction index) [7.161].

It must be pointed out here that CO_2 lasers are available today not only with a 10.6 μm wavelength but also up to a performance of 6 kW, with a 9.3 μm wavelength.

The reduced wavelength leads to a 10% increase in focusability and improves the launching ratio [7.163].

Innovative Process Modifications. Recently, process quality in laser beam welding – a highly dynamic process – has been the topic of numerous experimental as well as theoretical investigations.

To increase the process stability in the welding of aluminum, a purposeful arrangement of two focused laser beams, the so-called TWINFOCUS technique, suggests itself. By welding with one or several lasers with two focused laser beams at one joint, a cavity geometry immune to deficiencies and imperfections can be achieved that at the same time guarantees an unimpeded streaming out of the metal vapor and with it pinhole-free seams. A multibeam technique can be carried out by splitting the beam as well as by combining individual beams. With CO_2 lasers, splitting of the beam is achieved either by a deflecting mirror with tilted surfaces or by a parabolic mirror with two dishes. With Nd:YAG lasers, splitting can be achieved either by using a double fiber and two independent beam sources or by placing a beam splitter into the beam path [7.166].

A double-focus technique in laser welding, i. e., the use of two spatially separated foci producing a common pool, is a new method which has advanced from laboratory tests to manufacturing practice (Figs. 7.218 and 7.219). By artificial dilatation of the steam passage a distinct increase in process stability in laser welding of aluminum has become possible so that weld pores and weld puddle eruptions can be almost completely avoided. However, dilatation of the steam passage will at the same time lead to a decrease in process efficiency [7.167].

Using laser beam sources with the highest beam quality it is possible to build up a focus matrix that allows the advantages of the double-focus technique, i. e., good quality of the weld seam, to be achieved with high process efficiency [7.164].

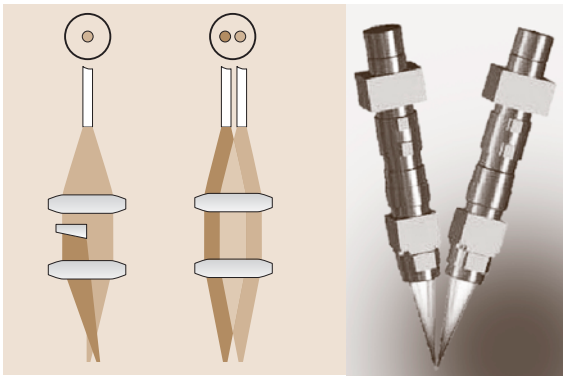

Fig. 7.218 Generation of double focus (after [7.164])

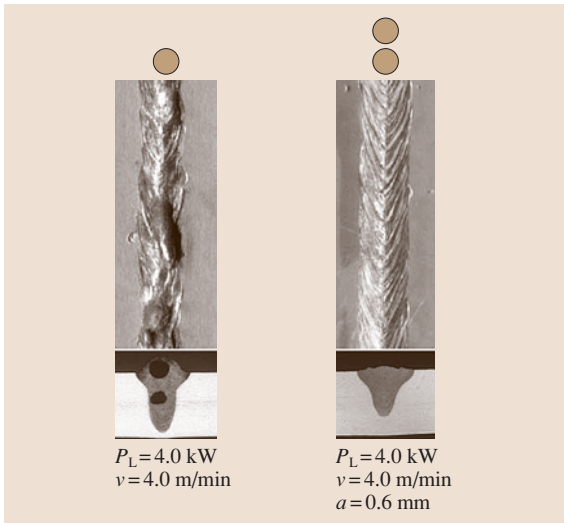

Fig. 7.219 Increase in quality by using double-focus technique

Another method for increasing process stability is magnetically supported laser beam welding, based on the application of an external magnetic field during welding. With this variant type of process, the flow behavior in the weld pool of molten metal can be changed by utilizing magneto-fluid-dynamic mechanisms in such a way that it will be stabilized and a higher welding speed will be arrived at. Considered in detail, the following results are verified: humping can be subdued, the final run quality is improved, spattering during weld-

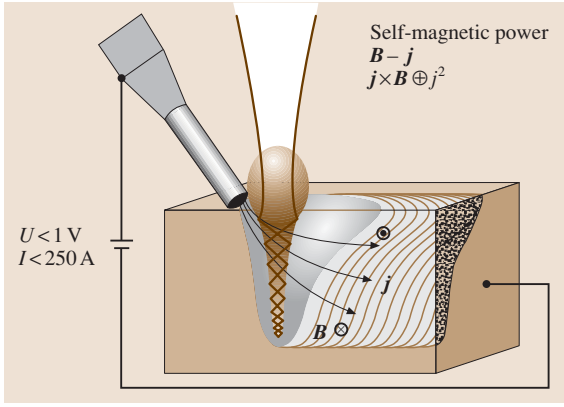

Fig. 7.220 Diagram of generation and utilization of self-magnetic power (after [7.165])

ing is reduced, fluctuations of the plasma flame are suppressed, and, last but not least, process stability is increased [7.168].

Every life wire is surrounded by its self-induced magnetic field, which is why energies are generated in it that act perpendicularly to the direction of both the electric current density j and the magnetic field B; their amounts are proportional to the square of electric current density. This principle is used in the following application (Fig. 7.220). An external current source provides direct current, which is applied either by a tungsten electrode moving just ahead of the molten pool or by a filler wire. The resulting self-magnetic power will influence the flow within the weld pool respectively the results of the welding operation. Both of the last mentioned methods (external magnetic field and external current) can be used together for influencing the process [7.165].

Traditionally, pulsed Nd:YAG lasers are typically used in the fields of boring and drilling, fine-edge blanking, and spot and microwelding. Due to their pulsed-energy release, pulsed solid-state lasers are extremely well suited for spot-welding operations. In seam welding, however, pulsed lasers are also frequently used in such areas that, due to their geometrical conditions, offer a challenge in the manipulation of a heat source, are demanding with respect to their metallurgy, or are problematic in their launching behavior. Beam penetration of pulsed solid-state lasers typically amounts to values from several tenths of 1 mm to about 4 mm. Mere deep welding with a high aspect ratio is usually not found with pulsed solid-state lasers [7.169].

Another forward-looking technology that expands the range of applications of pulsed Nd:YAG lasers is the so-called SHADOW method. With this method, joints several millimeters or centimeters in length cm are welded with only a single laser pulse by high feed speeds which are attained using fast rotating axles or scanners. Typical pulse lengths are around 10 to 50 ms for welded seams with possible lengths of up to 80 mm. The efficiency of the SHADOW method results from the special manner in which energy is input into a material. While for conventional seam welding with a pulsed Nd:YAG laser a high proportion of heat conduction is characteristic, the SHADOW method typically has a welding speed higher than the heat conduction in the material being welded [7.170].

For labeling, scanners and laser beams have for a long time offered a perfect combination, though rather for smaller-scale projects. Deflection of the laser beam via two extremely fast rotatable mirrors might now also revolutionize welding (Fig. 7.221). A decisive advantage of this principle is that positioning times are reduced to practically zero, which drastically diminishes processing time. The decisive advantage of laser welding with a scanner compared to traditional laser welding consists in a considerably faster positioning of the laser beam. When welding structural parts with several welds in a conventional way, there will often be longer traverses with corresponding nonproductive times, whereas these times move toward zero when using a scanner. The high positioning speed and flexibility of welding with a scanner offers additional advantages: heat distortion can be reduced as welding operations distributed over the workpiece can be executed without delay.

By combining the advantages of scanner-based processes and robot-guided machining, parts can be processed extremely flexibly and over longer distances (Fig. 7.222). Of special importance are optical sensors that are able to recognize the position of the weld and automatically control the process. The lasers used must meet extreme demands as to the beam quality, and, considering the very long focal distances, they must reach sufficiently small focus diameters. Robot-guided scanner welding is mainly used in automobile manufacturing.

Currently, the actual operating and production time with laser beam welding is often short, compared to nonproductive times, which mainly result from operating the laser heads. With remote welding, however, a very fast sequential welding of spot or short welds

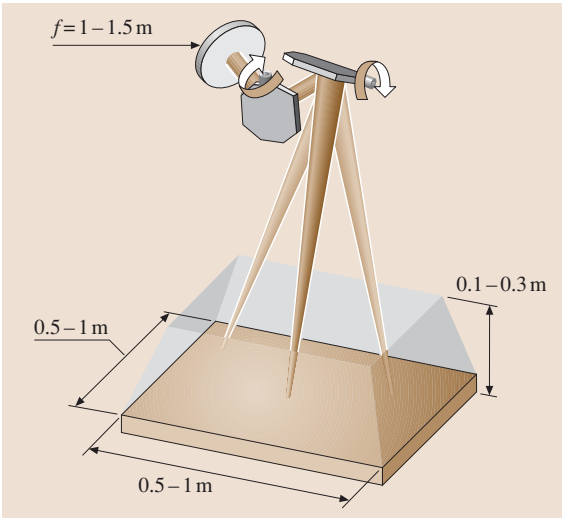

Fig. 7.221 Principle of scanner welding (source: Trumpf)

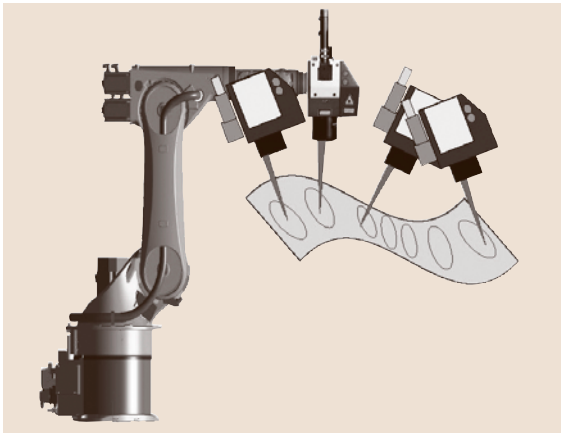

Fig. 7.222 Scanner welding with robot

can be accomplished with positioning speeds of roughly 700 m/min. This is advantageous, above all, in welding structural parts with numerous short welds distributed over the workpiece, and it allows an actual laser operating time of above 90%.

The remote method might mean a quantum leap for production. The process promises the substitution of techniques used so far as well as new types of products. In car body manufacturing, remote welding reduces investment costs by 30% and the cycle time by 60% compared to spot welding. Correspondingly, a study on the remote method for the year 2015 predicts its proportion of 8–10%, referred to the mass of joining methods.

Trends in Quality Monitoring. As the process of laser beam welding is only restrictedly fault-tolerant, it follows that the required quality of the weld might not be attained. Extremely high quality demands as required, e.g., in welding car bodies make an online assessment of processing quality absolutely necessary.

Typical signals from emissions that closely correlate with processing quality come from the heated respectively molten material (thermionic emissions in the IR wavelength range), from hot metal vapor as plasma radiation (UV wavelength range), or as metal halide lamp (visible wavelength spectrum). Upon reaching the evaporating point of the material (quantitative threshold intensity typically several 10^6 W/cm) the so-called deep-welding effect occurs. Here, the flowing-off metal vapor reaches an equilibrium of forces with surface tension and hydrostatic respectively hydrodynamic pressures so that a vapor cavity is formed in which, due to multiple reflections at the cavity walls, laser radiation will be absorbed. The unabsorbed radiation will be reflected backwards out of the cavity. Here, information may be acquired on the quality of the weld deep from the inner part of the material. Methods for controlling the laser welding process are mainly based on the above-mentioned process emissions [7.171].

The most reliable statement on quality can be made by combining different measurement methods. In this respect, plasma diagnostics, monitoring of the molten pool, and, by the increasing use of the Nd:YAG solid-state laser in industrial production, the laser power reflected from the workpiece are primarily used as measured parameters for online process control [7.157, 172].

Laser Beam Cutting

In this process, the focused laser beam hits the workpiece where it locally fuses the material and also partly or completely vaporizes it. By the impulse of a gas jet emerging from a nozzle the material is removed and leaves the kerf due to the relative movement of beam and workpiece (Fig. 7.223). The gas jet is, at the same time, meant to protect the focusing optical system against vapor and weld spatter.

Of all the techniques of laser processing of materials, laser beam cutting is the most widely used. This process became widely used as a result of its high flexibility, the great variety of manufacturing processes, and the excellent quality of the cut were of crucial importance. With this technique almost any material can be cut, the suitability for laser beam cutting depending on the absorption behavior of the surface, the ignition, melting, and evaporation temperatures of the material, and its thermal conductivity.

In laser cutting, three versions of the process are to be distinguished:

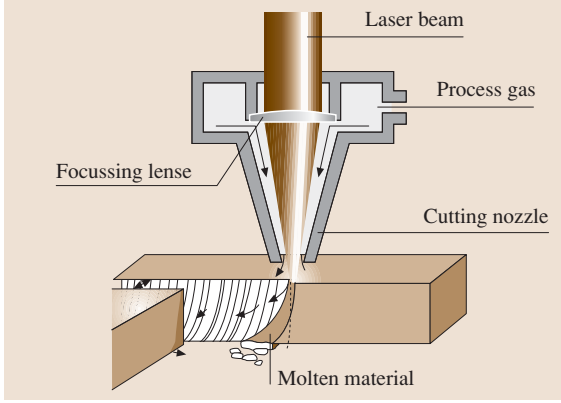

Fig. 7.223 Principle of laser beam cutting

- Oxygen laser cutting
- Fusion laser cutting
- Evaporative laser cutting

Oxygen Laser Cutting. The laser beam heats the material to ignition temperature. The oxygen injected into the kerf burns the material and expels the slag formed. The combustion process generates additional energy. With the quality of the cut being continuously high, a distinct connection between the purity of the oxygen and the maximum possible cutting speed can be proven.

Fusion Laser Cutting. In this version of the procedure, the material gets fused in the crossover point by laser radiation. The melt is expelled from the kerf by an inert gas. High-pressure fusion laser cutting is proving to be increasingly successful in oxide-free cutting of stainless steels. It is also successfully used in cutting mild steels and aluminum. As a rule, nitrogen is used as the cutting gas. The cutting gas pressure at the cutting nozzle can be 20 bar and above.

Evaporative Laser Cutting. In evaporative laser cutting, the material to be cut is evaporated at the crossover point of the laser beam. An inert gas, e.g., nitrogen or argon, expels the byproducts from the kerf. This cutting process is used with materials that have no liquid phase or melt, as is the case with paper, wood, several synthetic materials or plastics, textiles, and ceramics.

At present, CO_2 lasers with performances of up to 5 kW and Nd:YAG lasers with performances of up to 2 kW are in use for laser cutting. Special CO_2 cutting lasers with performances of up to 5000 W allow process-reliable machining of mild steel plates with a thickness of up to 25 mm. With high-speed thin-sheet cutting, cutting speeds of up to 40 mm/min are achieved. New drive mechanics allows positioning speeds of up to 300 m/min [7.173].

So far, CO_2 lasers have proven suitable tools for fast 2-D laser cutting of thin sheets due to their good focusability and high laser beam performances. By increasing the beam quality of solid-state lasers through the use of diode-pumped Nd:YAG lasers, with new resonator programs, launching into ever smaller fibers becomes possible with which, in the meantime, suitable focusing for high-speed cutting has become practicable.

So, for example, launching of laser beam performances of up to 4 kW in fibers of 300 µm diameter is feasible. The aim of the current development of solid-state lasers in the multikilowatt range is an increase in beam quality to about 5 mm mrad. At this level, the beam could be launched into an optical wave guide of 100–200 µm core diameter, and a laser would be available for machining that could be very finely focused as is possible with the best CO_2 lasers already in use [7.174].

Laser cutting has, until now, been dominated by flat-sheet cutting. This is mainly due to four factors: the dynamics and precision of five-axle laser cutting systems have been too poor, and cutting speeds have been much lower than with cutting flat sheets. Programming of five-axle cutting systems is very time consuming and inaccurate. The price of the system is higher than that of two-axle cutting systems. Finally, the market for parts cut in three dimensions is much smaller than that for flat-sheet cutting [7.175].

The use of laser cutting systems becomes especially critical when cutting thick plates. A 4 kW CO_2 cutting laser can, e.g., facilitate processing of mild steel plates up to 25 mm thick, using oxygen as the cutting gas. In conventional laser cutting, an increase in the range of cuttable plate thickness can only be reached by further increasing the laser beam performance available. However, with the newly developed LASOX technique (laser-assisted oxygen cutting) it is, given a considerably lower laser beam performance, possible to cut plates more than 50 mm thick with a laser beam performance of 2 kW. This is achieved by modifying process conditions at the front of the kerf. The laser beam is defocused and will heat the workpiece surface only to ignition temperature without melting it. The diameter of the laser beam on the plate surface is larger than the diameter of the cutting oxygen jet. Under these conditions, the cutting process is similar to oxy-gas flame cutting rather than to the conventional laser cutting [7.176, 177].

The increasing availability of high-power lasers above 6 kW of good mode quality, TEM 01 or better, for fusion laser cutting opens up new possibilities for entrepreneurial reorientation. According to laboratory tests, a cut thickness of more than 30 mm is feasible with a laser beam performance of 9 or 12 kW. At present, the perspective limit is considered to be a material thickness of 45 mm [7.178].

In fusion laser cutting in the plate range, the incomplete expulsion of the melt from the joint presents considerable difficulties. By applying liquids instead of gases this problem may be eliminated. In comparison to gas jets, water jets produce a higher impulse response. In this way the material is more effectively removed from the kerf [7.179].

Already for a considerable time, laser users have been observing a connection between cutting quality and the quality of the steels to be cut. For this reason, special steels have been developed that meet the demands of the respective standards for sheet metals as well as optimal cutting results [7.180].

An innovative microjet procedure (LMJ) is based on a fine laminar jet of water 40–100 μm in diameter into which the pulsed laser energy is introduced. During the pulse time the material will melt and at the same time be removed by the water jet. During the pulse interval, the kerf is cooled by the water jet. Thus, heat input into the workpiece is distinctly reduced. The process is especially suitable for use with temperature-sensitive materials such as, e.g., silicon wafers or ceramic materials where the brittleness of the material or its extreme hardness make machining with other methods more difficult [7.182, 183].

Laser Beam Drilling

Drilling with a laser beam was among the first industrial applications of material processing by laser. Already in the 1960s, sapphire and ruby bearings for clockworks were laser-drilled in large numbers in the Swiss clock- and watch-making industry [7.184]. The early 1970s saw the introduction of the industrial use of laser beams for drilling metal.

Laser drilling is a thermal abrading process. The power density necessary for abrading is reached by focusing the laser radiation onto the workpiece with the help of a lens system. In general, drilling is based on the material getting melted within the area treated by the laser beam and being vaporized. Whether the material is abraded in the form of melt or vapor or in both phases depends on the material's properties and intensity of radiation. After the launching phase, the evaporation front moves into the workpiece [7.185, 186]. A gas jet directed coaxially at the laser beam supports the expulsion of the melt out of the created hole and simultaneously protects the focusing lens system against spattering metal. As for the process technology, the following methods are used in drilling: single-pulse, percussion, trepanning, and twist drilling (Fig. 7.224).

In *single-pulse drilling*, the workpiece is drilled through by a single laser pulse. This procedure is used for drillings with small diameter in thin sheets with an aspect ratio of $< 1 : 15$.

In *percussion drilling*, several laser pulses are directed at the same place on the material. This is necessary when a deeper hole is drilled than can be done with single-pulse drilling. Thus, holes several millimeters deep can be made. With this method, high-quality drill holes with an aspect ratio of up to $1 : 200$ can be achieved. Percussion drilling also offers the advantage of a better repeatability of drill hole geometry compared to single-pulse drilling.

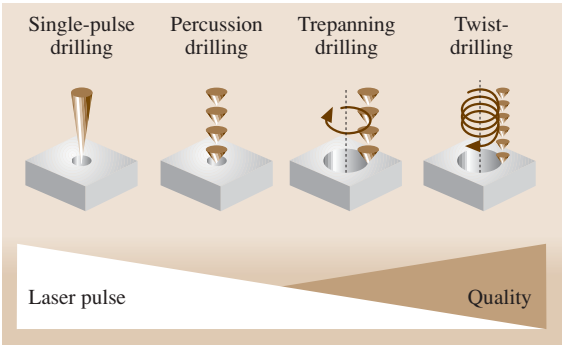

Fig. 7.224 Process technologies in laser beam drilling (after [7.181])

Trepanning drilling, also known as the *circular cutting method*, is used for producing larger holes. With this method, the dimension and precision of the drill hole diameter is determined by the relative motion between the workpiece and the laser beam. This technology roughly corresponds to laser cutting.

An additional increase in precision by further decomposing the drilling process in ever more individual steps becomes possible by the so-called *twist drilling*, developed from trepanning drilling. Various scientific investigations have proven that a drill-hole quality that has never been achieved in ceramics and steel is possible with this method [7.181].

The centerpiece of the trepanning optical system consists of three specially designed beam splitters for aimed deflection of the laser beam. During the process, all three beam splitters rotate around the fiber optical axis. This allows one to adjust a desired phase shift proportional to the radius of the helix on the material. Integrating the trepanning optical system into the polarization adjustment will further improve quality. Drag lines will be avoided, the outlet cross-sectional area will be circular, and process efficiency will increase due to higher absorption [7.187].

With all four processes mentioned above, drilled holes can be made perpendicular as well as angled to the workpiece surface. Blind holes can only be drilled into the material with single-pulse and percussion drilling [7.188, 189].

For drilling, mainly pulsed lasers are used. Many different investigations have shown in recent years that,

with shorter pulses, processing quality can be improved with respect to repeatability. This is essentially due to modifying the mechanism of removal with different pulse lengths [7.181, 190].

When drilling with solid-state lasers in the nanosecond range, holes with a melting film thickness of less than 1 µm can already be produced with suitable process technology. Further diminishing of pulse lengths into the range of picoseconds and femtoseconds is often propagated as a possibility for completely avoiding the formation of melt. Theoretical investigations have shown, however, that with metals a reduction of pulse length is sensible only down to about 10 ps (Fig. 7.225). An explanation for this is to be seen in the specific heating behavior of the crystal lattice on the ultrashort time scale [7.191]. This result, gained through an understanding of the process, should be taken into consideration by development engineers of beam sources.

Laser drilling is successfully used in many domains of engineering and industry. Typical examples of use in the motor manufacturing industry are, e.g., the production of blind hole grooves, structuring of surfaces with oil pockets for minimizing friction, and production of holes in diesel injection nozzles and in metallic filter discs. For example, with this procedure 100 holes/s can be produced in a metallic filter screen with a wall thickness of 0.95 mm [7.192, 193]. If there are special demands for precision holes with respect to cylindricity or surface finish, holes made by a laser beam can be refinished with conventional drilling methods. For these purposes, spark-erosive and mechanical drilling methods are used first. In these cases, at first a somewhat smaller pilot hole is made by a laser beam and is finished to size using a conventional drilling method [7.194].

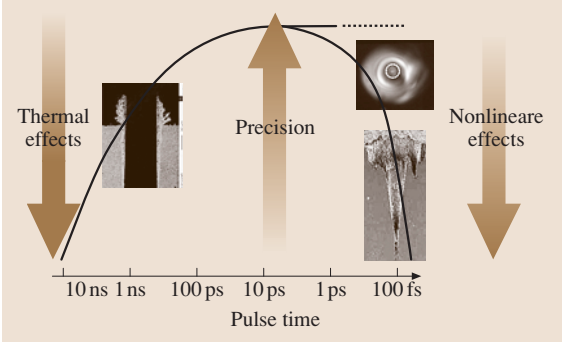

Fig. 7.225 Precision dependent from pulse length in drilling metals (after [7.191])

7.4.3 Electron Beam

Introduction

The principle of electron beam (EB) technology is based on high-voltage-accelerated electrons that can be used as a tool for material treatment, especially welding. Nowadays, EB welding is firmly established in many areas of manufacturing and is generally accepted for its reliability and efficiency. Joining tasks can be used in a variety of tasks ranging from foil welding with thin plate thicknesses of just a few tenths of a millimenter up to thick-plate welding with achievable weld depths of more than 150 mm in steel materials and more than 300 mm in aluminum materials. Moreover, almost all electrically conductive materials are weldable, and many of those materials may also be joined in material combinations. The high power density in a range of up to 10^7 W/cm^2, which is typical of EB welding, and a connected depth-to-width ratio of weld (up to 50 : 1) allows for a large variety of possible applications of this joining process. As the electron beam is electromagnetically deflectable and quasimassless, progress in the field of control technique and increased processor performances has even extended the multitude of applications, and there are more in the offing.

Apart from the EB variations where welding is carried out with high or low vacuum in a vacuum chamber, there is also the possibility of applying the EB in the atmosphere (nonvacuum) as a joining tool.

Basics of the Process

Electron Beam Generation and Guiding.

Generation of the Electron Beam. In modern electron welding machines, triode systems for the beam generation are generally applied. These systems are composed of anode, cathode, and controlelectrode (Wehnelt cylinder). The electrons that are necessary for beam generation are emitted from the cathode by thermionic emission. The cathode is made of a material in which the work function that has to be performed by the electron in order to leave the material is comparatively low. The cathode material must show a high electron emission rate and also be high-temperature resistant. The material should, moreover, also guarantee a relatively long cathode life. Appropriate materials are tungsten and tantalum. Mostly direct heated cathodes are used, which are flowed by current and heated thus by Joule resistance heating. By the application of an electric high-voltage field, the electrons are supplied with kinetic energy in order to emit them from the electron cloud and to subsequently accelerate them. Depending

on the height of the applied voltage, the electrons may be accelerated up to two thirds of the speed of light. For the generation of the electric field, between cathode and anode (the anode is arranged across from the cathode), the acceleration voltage is activated [7.195]. By the application of a control voltage between the cathode and a control electrode a barrier field is generated in this triode system that forces the emitted electrons back to the cathode. Thus the beam current is controlled by alterations of the control voltage as by the decrease of the control voltage more electrons pass the barrier field toward the anode. Due to its particular shape, which can be compared to a concave mirror used as in light optics, the controlelectrode affects the electrostatic focusing of the electron beam. After having passed the anode, the electrons have achieved their final speed, and the EB is focused and deflected by means of electromagnetic focusing lenses. The focusing effect leads to the constriction of the EB, the so-called crossover.

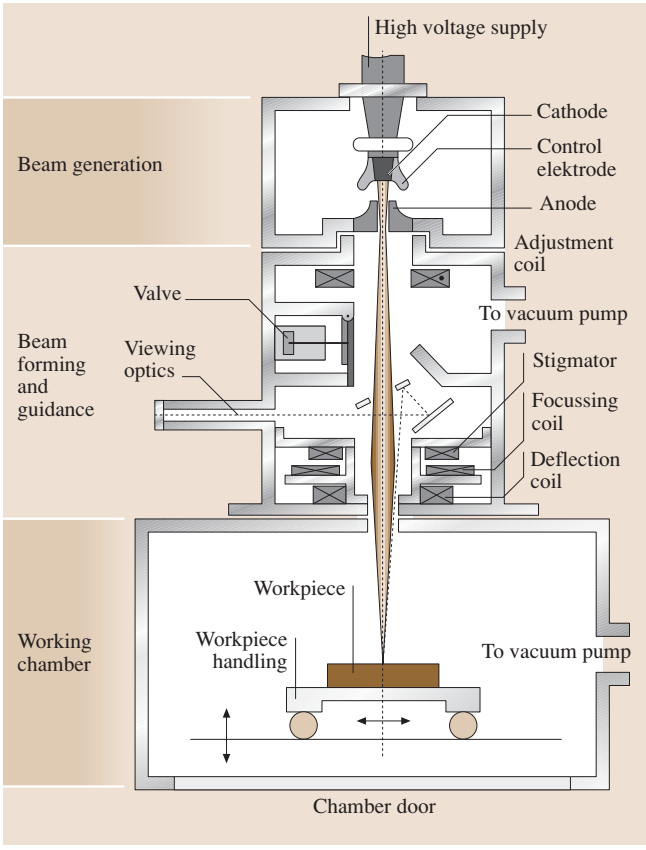

Fig. 7.226 Diagrammatic representation of an electron beam welding machine

Beam Manipulation. The EB that diverges slightly after having passed the pierced anode is focused to a spot diameter of 0.1 and 1.0 mm by the following beam manipulation system in order to reach the necessary power density of 10^6–10^7 W/cm2. First, the beam is guided through the alignment coil onto the optical axis of the focusing objectives. One or several electromagnetic lenses bundle the beam onto the workpiece inside the vacuum chamber. Deflection coils that are positioned at various parts of the EB generator assist in the deflection or oscillating motions of the EB. A diagrammic representation of an EB welding machine is depicted in Fig. 7.226.

Deep-penetration Effect. When the electrons strike the surface of the workpiece, their kinetic energy is converted into thermal energy. Although the electron mass is very low, approx. 9.1×10^{-28} g, they have a high electric voltage potential that, at an accelerating voltage of 150 kV, allows electron acceleration up to a speed of $\approx 2 \times 10^8$ m/s. Not all beam electrons penetrate into the workpiece and release thus their energy to the material. A part of the striking electrons is emitted in the form of backscattered electrons, thermal radiation, secondary electrons, and X-ray radiation (Fig. 7.227).

As the electrons, owing to their low mass, that penetrate into the material achieve only very shallow penetration depths (up to 150 µm), a special effect is needed to obtain large weld depths, the so-called deep-penetration effect. The material is melted and vaporized in the center of the beam. This happens so fast that the heat dissipation into the cold material shows practically no significant effect. The resulting vapor is superheated

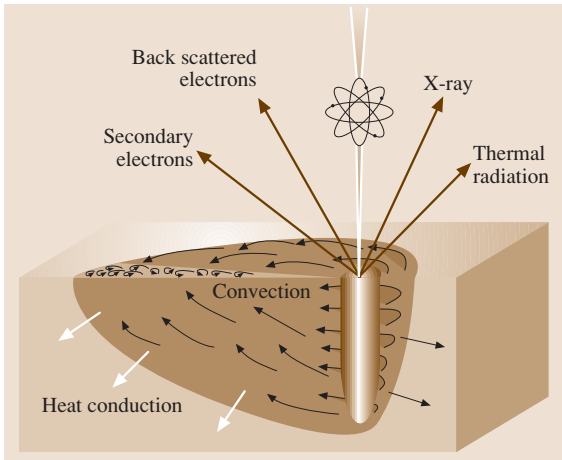

Fig. 7.227 Energy transformation into the workpiece

and extends at temperatures above ≈ 2700 K. The vapor pressure is sufficiently high to press the molten metal upwards and to the sides. A cavity develops where the electron contacts the yet unvaporized metal and heats this further. This leads to a vapor cavity that at its core consists of superheated vapor and is surrounded by a shell of fluid metal. This effect is maintained as long as the pressure from the developing vapor cavity and the surface tension of the molten pool are in equilibrium. The diameter of the vapor cavity corresponds approximately with the EB diameter. With a sufficiently high energy supply, the developing cavity penetrates through the entire workpiece [7.196]. The relative motion between workpiece and EB causes the material that has been molten at the front of the EB to flow around the cavity and to solidify at the backside.

Machine Components. An EB welding machine is composed of a multitude of individual components. The basic component of the machine is the EB generator where the EB is generated in a high vacuum, influenced by electromagnetic deflection coils, and then focused onto the workpiece into the vacuum chamber. As the electron beam in free atmosphere diverges strongly by the collision with air molecules and thus loses power density, welding is generally carried out in fine or high vacuum inside a vacuum chamber. For the vacuum generation in the beam generator and in the working chamber, different vacuum pumps are used. While in the beam generator a high vacuum ($p < 10^{-5}$ mbar) for insulation and for oxidation circumvention of the cathode is indispensable, the possible working pressures in the vacuum chamber varies between high vacuum ($p < 10^{-4}$ mbar) and atmospheric pressure.

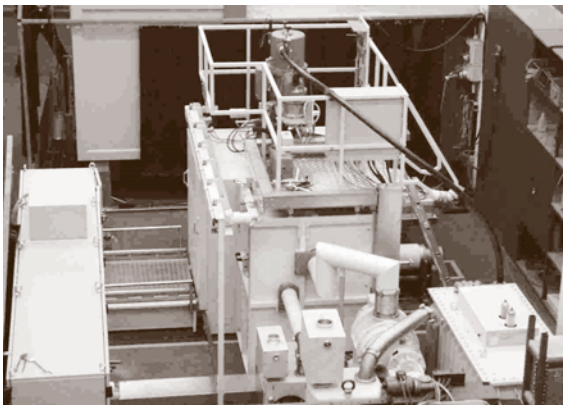

Fig. 7.228 Electron beam welding machine and peripherals

A shutoff valve, positioned between the EB generator and the working chamber, allows for the maintenance of the beam generator vacuum even when the working chamber is flooded. Besides the already mentioned modules, the high-voltage supply, the controls for the high-voltage supply, the vacuum pumps, the NC of the work table, and the operator areas are also necessary. The equipment is controlled via the operator console where all relevant process parameters are set and monitored. In modern equipment, parameter selection and control may be assumed externally by a computer and corresponding software. For the determination of optimum welding parameters for process control and also for the adjustment of the EB on the workpiece, viewing optic systems are necessary. One can use either simple light-optical viewing optics with a telescope or a camera system and monitor that partially represent the magnified section or an electron-optical system. In these systems the EB scans the workpiece surface at a very low power without melting it. The backscattered secondary electrons show, as in SEM, an image of the workpiece surface.

A disadvantageous effect, along with the increasing acceleration voltage, has, however, an exponentially increased X-ray radiation and also an increased sensitivity to flashover voltages. In industrial production a distinction is made between high-voltage machines with acceleration voltages of between 120 and 180 kV and low-voltage machines with acceleration voltages of max. 60 kV. Beam powers of up to 200 kW are used.

Potentials of Fast Beam Control. As the EB is an almost massless welding tool that is deflectable, noncontacting, and almost inertia free, it is possible to oscillate the beam with extremely high frequency. With this technique the EB skips between several positions with a frequency so high that the metallurgical influence on the structure is carried out at different points

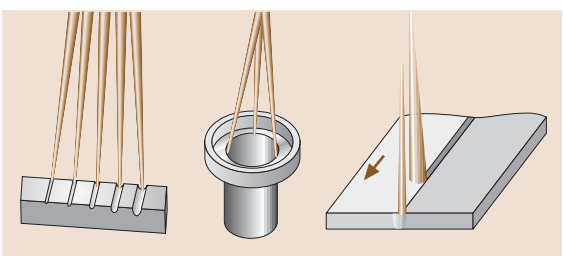

Fig. 7.229 Multibeam technique

simultaneously – due to the thermal inertia of the structure. It is possible nowadays to control the beam in such way that a simultaneous processing of the material due to Fig. 7.229 can be handled.

Production Machine Concepts

Apart from the further development of beam generators, the adaptation of the equipment to various demands is of considerable importance for the industrial application of EB welding. Using adapted vacuum chambers the evacuation times may, for many applications, be reduced in such a way that the necessary welding downtimes are not the decisive criterion against the use of EB technology. Different working chamber systems are now available to equip EB welding machines.

Chamber Machines. The most flexible variant is the universal working chamber where the workpiece is moved in two or three directions.

As an alternative to an NC coordinate table, revolving devices with horizontal or vertical axes of rotation are also applied. Typical chamber sizes reach from 0.1 to 20 m^3; machines with a chamber volume of up to 3500 m^3 are, however, also in use.

This vacuum chamber concept, however, entails comparatively high downtimes as the working steps *clamping the tool*, *entering the recipient*, *evacuation*, *welding*, *airing*, and *workpiece release* must be carried out one after the other.

Double Chamber and Lock Chamber Machines. Double chamber machines have two working chambers that are placed side by side. Either the beam generator is moved between those two chambers or the beam is deflected to one chamber at a time. Thus welding may be carried out in one chamber while the other chamber is loaded or discharged as well as evacuated. Figure 7.230, left, shows one of the variations of a double-chamber machine.

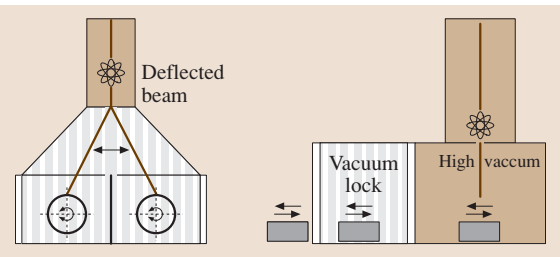

Fig. 7.230 Double chamber and lock chamber machine

Lock welding machines represent another equipment concept, Fig. 7.230, right. A high vacuum is permanently maintained in the chamber where the welding is carried out. Manipulation devices pass the workpieces through one or two prechambers. The machines have a position for loading and discharging, a lock for airing and deaerating, and a welding lock.

Cycle System Machines and Conveyor Machines. Cycle system machines are the right choice for welding similar or equal parts with equal weld geometries and axial welds. Underneath the chamber (generally small-volume), which accordingly demands only short evacuation times, a rotating jig with vertical, horizontal, or swivelling axes is fixed and is equipped with one or several loading stations. Thus loading and discharging as well as welding may be carried out at the same time. At new cycle system machines there is a low vacuum in the area where the jig rotates all the time. This leads to shorter evacutaion times from free atmosphere to low vacuum at the loading position and from low vacuum to high vacuum at the welding positions.

Especially for the manufacture of saw bands, a type of equipment that is the most productive but, on the other hand, the most inflexible, has prevailed on the market – the conveyor machines. These machines have the same operating principles as the lock welding machines where the workpiece is continuously transported over centering lips through pressure locks into the working chamber and from there again through a pressure lock. The inevitable leakage must be compensated by the vacuum technique.

Nonvacuum Electron Beam Welding

Already in the early stages of EB technology development, the method to guide the beam from the vacuum environment of the beam generator to the atmosphere was researched in Germany. This was the basis of the nonvacuum electron beam welding (NV-EBW) process. The substantial weld depths that characterize vacuum EB welding are not achievable with the NV-EBW method – those weld depths characterize the vacuum EB and are a result of its power density. The strong points of NV-EBW lie mainly in high-speed production. The achievable welding speeds reach up to 60 m/min when welding aluminum sheets and up to 25 m/min when welding steel plates. For a better energy coupling to the workpiece, to this day beam generators with an accelerating voltage of 175 kV are used [7.197, 198].

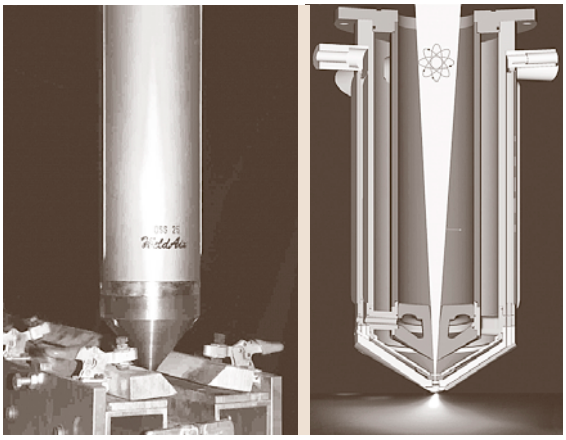

Fig. 7.231 Photo and principle of the ISF-non-vacuum nozzle system

Technology of NV-EBW. A solution to the vacuum-related restrictions is, following the modern state of the technique, achieved by guiding the vacuum-generated electron beam after it exits the beam generator to the atmosphere over a multistage orifice assembly and nozzle system. The pressure chambers that with a correspondingly higher pressure (10^{-2} and 10^{0} mbar) are connected after the beam generator chamber (vacuum 10^{-4} mbar) are evacuated separately and are separated, in vacuum terms, from each other by pressure nozzles. The EB is focused on the exit nozzle, which shows an inner diameter of 1–2 mm, Fig. 7.231. After its exit to the atmosphere the EB collides with air molecules and expands [7.196, 199].

The scattering of the EB is reduced by the increase in the accelerating voltage and by the application of helium as a working gas. For the effective utilization of the helium gas flow, a coaxial gas jet is applied at the beam exit outlet. The effect of the electron scattering at the gas molecules is additionally attenuated by the strong heating of the gas in the electron path. The gas density is reduced by that and the scattering also decreases [7.196–199].

After their exit from the orifice assembly, the electrons of the focused beam impinge on the material surface at a high speed and transmit their kinetic energy to the material lattice. As in vacuum EB welding the X-ray radiation must be shielded with sufficient radiation protection. In addition, the ionization of the air causes the generation of ozone, which must be neutralized. A radiation-proof working chamber may be designed with different materials and in optional dimensions. Limits to the component size are, therefore, not much higher in NV-EBW than in Nd:YAG laser welding.

Applications of NV-EBW. A high-power and out-of-vacuum EB is the ideal tool for welding conventionally manufactured sheets and sheet metal parts. The upper bead of the weld is similar to that of an arc weld and is thus not comparable to the typically narrow deep geometry of vacuum electron beam-welded joints. The method is characterized by a high energy efficiency, and its high available beam power yields a high power density even when the beam is expanded and allows high welding speeds (Fig. 7.232).

A classical application field of NV-EBW is the welding of components where several plates that form a flange weld are joined (Fig. 7.233). NV-EBW is perfectly suitable for this application. The broad beam fuses several plate edges simultaneously, which leads to a gas-tight and even joint. The flange weld and the lap joint are particularly suited for components where, after a very rough weld preparation, the desired result is a gas- and liquid-tight weld.

The materials that have been tested up to now with the NV-EBW method were uncoated and coated steels, light metals such as aluminum and magnesium and nonferrous metals such as brass or copper. Material combinations such as, e.g., the combination of steel and copper may also be realized with results comparable to vacuum EBW, without, however, achieving the higher weld depths of vacuum EBW. Supplementary, application tests on the use of filler wire in NV-EBW have been carried out.

Quality Assurance

Beam Measurement. For full exploitation of the advantages of the EB as a tool for welding, knowledge about all beam properties is necessary. The processes that occur in EB welding are very complex and are characterized by a multitude of different parameters such as, e.g., accelerating voltage, beam current, focus position, or power density distribution. For the determination of the various beam parameters and for the facilitation of the parameter transfer between different EB units a number of beam-diagnostic systems that apply different measurement principles are currently being developed [7.200–202]. The DIABEAM [7.203–205] has been developed at the ISF Welding Institute, RWTH-Aachen University. This system may be employed in almost all existing EB units and allows signal acquisition of the electron beam, up to a power of 100 kW. The DIABEAM measurement system was developed for easy determination of the focus position with slit measuring or a rotating wire, eliminating the need for complex and cost-intensive welding tests. The measurement and the three-dimensional display of the power density distribution across the beam diameter can be made by means of the apertured diaphragm. The other purpose of beam diagnostic is the prevention of negative influence, which may be caused by cathode adjustment, cathode distortion, variation of the vacuum level, etc., on the welding result by in-time identification of variations of beam characteristics. As a result of the three measuring processes (hole, slot, and rotating wire), the DIABEAM beam diagnosis system is suitable for a broad range of applications, especially for analyzing and assuring beam quality.

Sensor Systems. Scanning can, alternatively, be carried out via a slit or apertured diaphragm or via a rotating tungsten wire. The point of slit measurement with slit widths of 20 µm is the comparatively fast and simple determination of a signal that is in proportion to the beam intensity and, also, the determination of the beam diameter. The principle of slit-measurement with the appropriate voltage signal over the beam cross section is depicted in Fig. 7.234a.

With the slit measuring process, the core and edge areas of the beam can be compared by means of five different selectable diameters. Measurement of the beam diameter under varying working distances enables the caustic curve of the beam to be determined and displayed (Fig. 7.234b). In this way, the beam aperture can be determined precisely, thereby considerably simplifying the welder's selection of electrical and geometric parameters.

The application of a double-slit sensor enables online measurement of the deflection speed, which in-

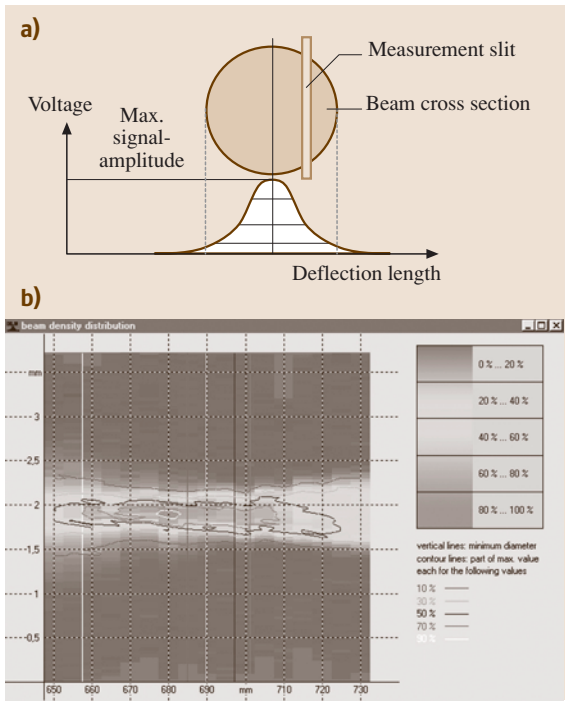

Fig. 7.234 **(a)** Principle of slit measurements, **(b)** results of a series of slit measurements

creases the precision of the measurement. Here, the beam is, at the start of the measurement, deflected from its neutral position transversely over both slit sensors. No deflection into the lengthwise direction of the slits occurs. By the measured difference in time of the signals at the first and second slit the deflection speed is determined.

Figure 7.235 shows the two different types of sensors. The left side shows a double-slit hole sensor, the right side a rotating sensor.

Another possibility for beam diagnostics is the application of the rotating wire sensor. The reason for the development of this new measuring variation in addition to the two methods described above lies in the question of whether and to what degree metal ions influence the power density distribution. In the case of a measurement with this sensor principle, a rotating tungsten wire with a diameter from 0.1 5 mm and a speed of up to 1000 s^{-1} moves through the beam. The deflection of the beam in this case is not necessary. The tungsten wire is coupled to a solid copper plate in order to increase heat dissipation. The current that is derived from the wire is measured in the form of a voltage signal. The measuring principle is comparable to the slit-measurement principle under the prerequisite that the diameter of the tungsten wire is smaller than the diameter of the beam.

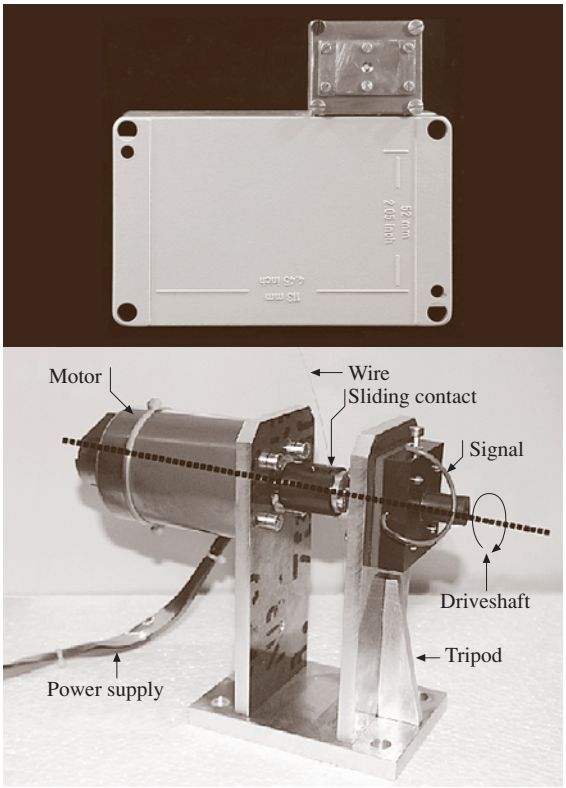

Fig. 7.235 Double-slit hole sensor and rotating sensor

Applications

Resulting from the large range of materials that are weldable with the EB (such as, e.g., tungsten, titanium, tantalum, copper, high-temperature steels, aluminum, gold) and material thicknesses, this method has a broad field of application possibilities, ranging from the specified microwelding of sheets with thicknesses of less than 1/10 mm, where low and extremely precise heat input is important, and thick-plate applications.

In heavy-plate welding, the process-specific advantages of the aforementioned deep-penetration effect and thus the joining of large cross-sections in one working step with high welding speed, low heat input, and small weld width begin to show. With modern welding equipment, wall thicknesses of more than 300 mm (aluminum alloys) and of more than 150 mm (low- and high-alloy steel materials with length-to-width ratios of approx. 50 : 1) are joined fast and precisely in one pass and without filler metal. In what follows, some application examples from different industrial sectors are given.

Below are some examples of industrial sectors with appropriate applications where the EB has become an established tool for material processing:

- Reactor construction and chemical apparatus engineering: welding of high-alloy materials, welding of materials with high affinity for oxygen, production of fuel elements and of circumferential welds of thick-walled pressure vessels and pipes
- Pipeline industry
- Turbine manufacturing: production of guide blades and distributors
- Aircraft construction: welding of structural/load-bearing parts made of titanium and aluminum alloys and of landing gears made of high-strength steels
- Automobile industry: welding of driving gears, pistons, valves, axle frames, and steering columns
- Electronics industry
- Tool manufacturing, e.g., manufacture of bimetal saw bands
- Surface treatment
- Material remelting
- Electron beam drilling with up to 3000 drills/s [7.206]

The numerous specific advantages of EB welding justify its increased application in industrial practice.

These advantagges include, for example, minimum workpiece heating by high power density, small beam diameters, and high welding speeds. The low heat input also allows for the welding of readily machined parts. The economic profitability of EB welding is not only a result of the high welding speeds and thus the short cycle times but also the high quality. The clean vacuum process without the influence of oxygen and the constant process parameters make the weld seams easy to reproduce.

These advantages are opposed by a series of process-related disadvantages. As the workpieces that are to be welded must be electrically conductive and as there is the risk of hardening and cracking due to the high cooling rates, the weldable range of materials is restricted. In addition, because the beam deflection is carried out via magnetic fields and the whole process needs to be shielded because of the development of X-ray radiation during welding, the investment costs are high.

7.4.4 Hybrid Welding

Emerging from the need to bridge larger gaps than was possible with the sole application of the laser and of welding faster than with a laser with filler wire addition, the hybrid welding methods have – also supported by major advances in laser technology in recent decades – been developed from its niche position to a method with a broad application spectrum.

Already in the 1970s, laser beam welding applications were widely used for their excellent process properties, which are due to the very high welding speed and low energy input. Due to production-related limitations, as, for example, rough part tolerances and large gaps, laser beam welding had not been used in many industrial sectors.

As a result of these problems and also because of the need to take advantage of laser beam welding, the idea of combining the laser with other welding methods arose by the end of the 1970s [7.207].

If a laser beam and arc are used in one production step for welding purposes, a distinction must be made between the combination and the coupling of the processes (Fig. 7.236). In the case of a combination, both joining tools act in different process zones and do not interact, except indirectly, such as preheating or tempering and similar effects. The two processes are combined when a given plate or root face thickness is welded with a tack weld or as a root pass by means of a laser beam and a subsequent SA or GMA welding [7.208].

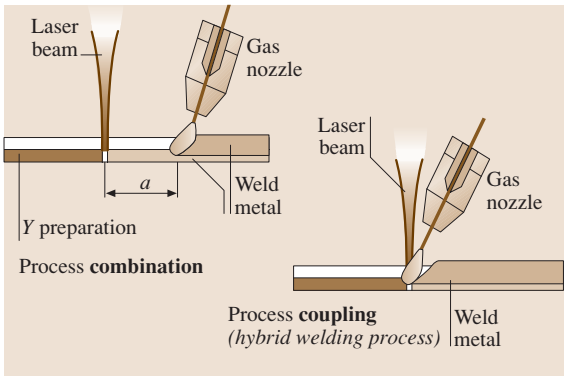

Fig. 7.236 Process variations of the combination of laser beam and arc

If both energy carriers are coupled in one common process zone, this is called a *hybrid process* or hybrid welding process. The coupling of both methods results in process-specific advantages called synergistic effects.

The laser beam and the arc interact in the process zone. They are coupled via the molten metal and in the majority of cases via the common process plasma [7.209].

In hybrid welding, the arc process effect of lowering the molten pool surface may result in an increase in weld penetration depth through the adaptation of the focus position [7.210, 211]. The weld penetration depth is mainly determined by the laser beam's power, power distribution, and shaping. The weld width is primarily determined by the arc, particularly the arc voltage. At a constant laser beam power, under special conditions an increase in the welding speed was achieved, a speed that was twice as high as the speeds obtained in pure laser beam welding [7.208, 212]. In contrast to the laser beam welding process, the energy efficiency of the whole process is increased through the application of an arc power source that works more efficiently than the laser.

Types of Hybrid Welding

The designation of the hybrid welding processes depends on the different process combinations and is stipulated in a guideline of the Deutscher Verband für Schweißen und verwandte Verfahren e.V. (DVS) (Table 7.34 [7.209]).

Laser Beam-GMA-Hybrid Welding Processes. In laser beam-GMA-hybrid welding, the addition of filler material is carried out via the arc process. The applica-

tion of GMA technology has the advantage that the filler wire can be molten with relatively inexpensive energy while the high-quality laser beam energy is maintained in an almost undiminished form for the transport of material into the depth. The positioning of the wire with respect to the laser beam is also relatively unproblematic in comparison with cold filler wire as the arc is positive effected through the common plasma and is pulled towards the keyhole (Fig. 7.237).

The arc is either pulsed via commercial GMA welding power sources [7.213] or triggered by direct current arc, in most cases a spray arc. The shielding of the welding point is, as in CO_2 laser beam welding, realized through pure helium [7.210] or helium/argon gas mixtures. Already low argon content in the shielding gas exerts a positive influence on the material transition and arc stability [7.212]. The applicable gas mixture is a compromise between high plasma shielding and arc stability. The admixture of low oxygen quantities for better drop formation and detachment is possible and also effective [7.214]. Welding filler materials are mainly of the same material as the base material and commercial solid wires that are also used for GMA welding of the base materials [7.215].

For thick-plate welding primarily CO_2 laser beam sources are used for their higher available powers. For welding of plate thicknesses > 10 mm, nowadays CO_2 lasers are applied as this thickness corresponds with the maximum penetration depth of modern Nd:YAG solid-state laser beam sources of up to 6 kW [7.216]. It is expected that, due to new developments, solid-state lasers will catch up to the CO_2 lasers wit respect to the available laser power in the next few years and thereby match their weld penetration depth.

Besides the square butt preparation, also V-type joint shapes and single V-butt joints with broad root face (Y) can be used; these are partly the result of cutting without any additional edge preparation. The energy of the laser beam is, in contrast with laser beam welding with cold filler wire, not needed for melting the filler material; this is – on the contrary – fed to the process already in a molten state, thus a reduction of the welding speed is not necessary [7.217]. The filler material allows for a defined, metallurgical influence on the welded structure [7.218, 219].

While in laser beam welding primarily parallel welds with a high aspect ratio are produced (Fig. 7.238a), a GMA weld leads to a low aspect ratio and reinforcement (Fig. 7.238b). The merging of the laser and the GMA weld leads to typical hybrid weld seam geometry. In particular the upper part of hybrid welds is widened (Fig. 7.238c), resulting in a triangular or *mushroom* and/or *bell-shaped* weld shape [7.217].

The GMA torch can be arranged in different ways relative to the laser beam. It is partly in the welding direction in front of the laser (backward-pointing GMA torch) [7.210, 220] or behind the laser beam (forward-pointing GMA torch) [7.221–224]. The *forward-pointing* arrangement is mainly used in hybrid welding of aluminum alloys in order to create an arc attachment point where the oxide layer has been removed by the laser beam, which again results in the significant increase in the process stability [7.225].

Laser Beam–Plasma–Hybrid Welding Processes. Through a suitable combination of the two heat sources of an electric arc and laser beam, a controlled influence is exerted on the heat input in the weld region.

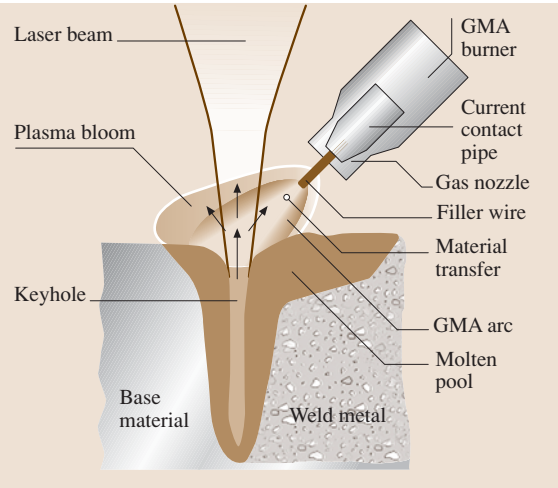

Fig. 7.237 Laser beam-GMA-hybrid welding process

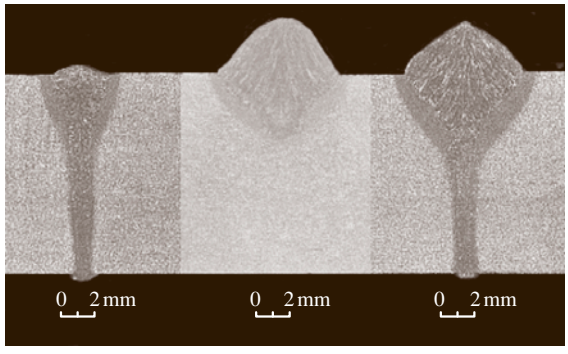

Fig. 7.238a–c Weld shapes: **(a)** laser, **(b)** GMA, **(c)** laser-hybrid

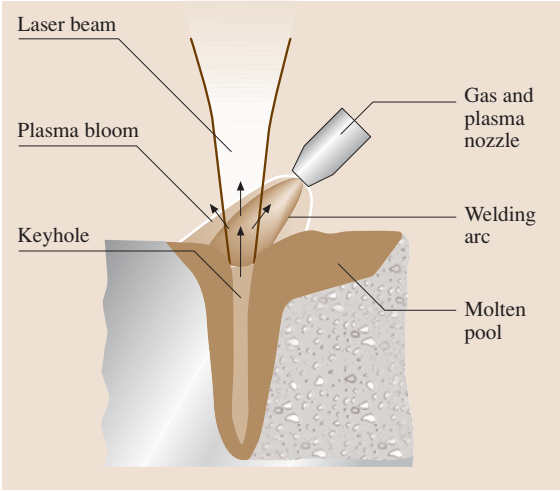

Fig. 7.239 Laser beam-plasma-hybrid welding process

Figure 7.239 shows the basic principle of such a process with a forward-pointing plasma torch. In contrast to pure laser beam welding, a plasma torch is arranged sideways or coaxially to the laser beam. When there is a need for filler wire, a cold wire can be added. Due to the plasma arc, the positioning of the wire is in comparison with a laser process with cold wire very easy.

The plasma arc brings about an additional heat input that can be independently adjusted by the laser beam. The electric arc essentially has three functions in this respect:

- It supports the beam welding process through an additional energy input and thus increases the operative capability and, as appropriate, the efficiency of the overall process.
- The concentric arrangement of an annular plasma arc around a laser beam brings about a defined heat treatment, in which respect the arc acts during the forward and backward run. The heat treatment provides the ability to reduce the cooling rate and thereby decreases the susceptibility to hardening and the development of residual stress states. It is, consequently, possible to adapt the microstructural condition to the application at hand.
- It produces a plane weld surface with a smooth and continuous weld interface.

Enhancing the operative capability of the beam welding processes through combination with plasma, arc technology opens up other new fields of application for welding, thereby presenting economic and manufacturing-related advantages that lead to savings in terms of fabrication time and costs and thus improve competitiveness [7.226].

The design-related benefits of this coaxial process variant – on the one hand, the small space requirement and, on the other hand, the nondirectionality of the process – are offset by the use of welding filler metal.

Laser Beam-TIG-Hybrid Welding Process. In laser beam-TIG-hybrid welding, the laser beam is, together with the TIG process, linked into the produced vapor cavity Fig. 7.240. One positive aspect of the use of a CO_2 laser is the developing plasma, which is generated by the laser process. The plasma is used as an ignition aid for the arc process and its effect is a considerable stabilization of the arc process in the hybrid welding process, especially in welding with low powers. [7.209].

Laser beam-TIG-hybrid welding is mainly applied in thin-sheet welding. The arc affinity for melting primarily the protruding edges makes the method most suitable for the joining of tailored blanks and for fillet welds on lap joints [7.209].

Applications

In 2000, laser beam-GMA-hybrid welding was the first hybrid method ever applied in industrial scale manufacture. Since that time, the Meyer Werft company, in Papenburg, Germany, has been using its hybrid unit with a 12 kW CO_2 laser (Fig. 7.241) for ship panel production.

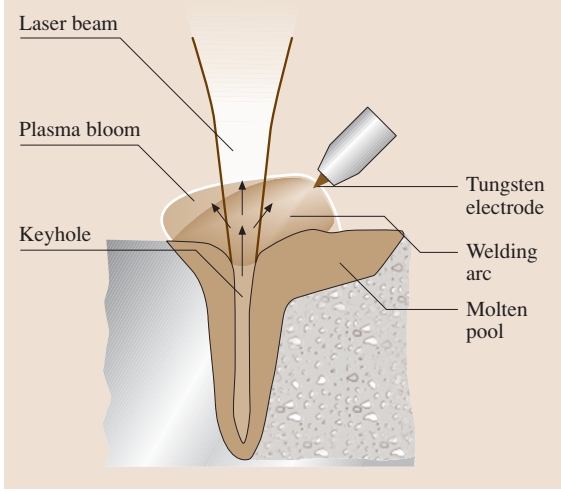

Fig. 7.240 Laser beam-TIG-hybrid welding process

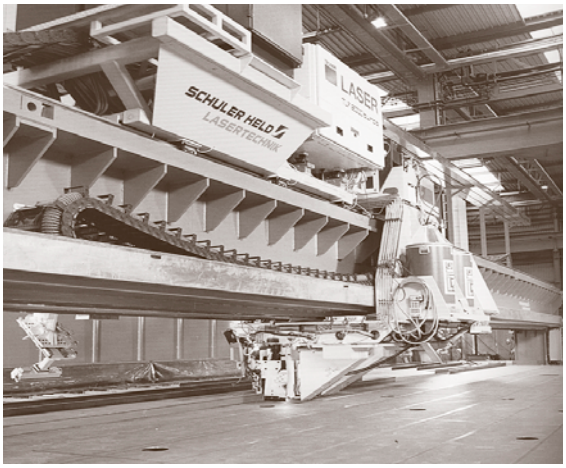

Fig. 7.241 Panel production with the hybrid welding method in the Meyer-Werft

The main advantages of the hybrid technology which led to its introduction in shipbuilding [7.227] are as follows.

- *High process speed* In contrast to conventional methods (SA for butt welds and MAG for fillet welds), it is possible to triple the welding speed. Also, even thicker panels can be welded in one part without reversing. In contrast with laser beam welding with filler wire, the welding speed can be duplicated. An additional advantage is the reduced throughput time and resultant less fixed material in the panel production.
- *Low thermal distortion* Due to the reduced energy input per unit length, the transverse shrinkage is, compared with conventional methods, reduced to a third. This leads to a significantly reduced amount of rework.
- *Good gap-bridging ability* Depending on edge preparation and plate thickness, air gaps between 0 and 1.5 mm can be welded. In contrast with the substantially lower values in laser beam welding, these tolerances can be realized with a justifiable expenditure, even with large parts in shipbuilding.
- *Excellent weld properties* Problems, such as, for example, high hardness and hot crack formation, as occur occasionally in laser beam welding have not been observed in hybrid welding, not even with large weld lengths.
- *Good process stability* Destructive and nondestructive tests showed that the correct balancing of the processes mainly results in consistently good weld quality. The results of the fatigue tests are shown in Fig. 7.242.

Laser hybrid welding has also become established in the automobile industry. The aluminum door frame of the Volkswagen Phaeton, for example, is manufactured by means of the hybrid weld process. This technique is also used for the Audi A8 space frame.

A further example of the efficient use of this hybrid technology is the joining of dissimilar material thicknesses, e.g., in the fabrication of tailored blanks. Figure 7.243 depicts the transverse microsection of a tailored blank. An example of the application of hybrid welded tailored blanks is the automotive floor panel with a thicker sheet in the tunnel zone. The low deposition volume of laser beam welds often leads to metal transfers with small radii. Apart from the notch-

TIG	CO_2-laser beam-TIG-hybrid welding process	Nd:YAG-laser beam-TIG-hybrid welding process

effect problem, such edges prevent the adhesion of applied coatings or paint films [7.228]. Use of the hybrid technology resolves such problems thanks to low-notch transitions produced by additionally fused material. Higher process speeds can also improve the productivity.

Summary and Perspectives

The advantages of the laser beam arc hybrid welding processes can be summarized as follows:

- High process speed
- Low thermal distortion
- Good gap-bridging ability
- Excellent weld properties
- Good process stability

Despite all the mentioned advantages of the laser beam arc hybrid welding methods, the fact still remains that, as a result of using two coupled welding methods, the number of setting variables also increases. For a reliable and stable hybrid welding process, the exact setting of the parameters is mandatory.

Laser hybrid applications in manufacturing, e.g., panel production in Meyer Werft ships or the manufacture of space-frame elements in the automobile industry, show the high potential of this method. Through the development of innovative laser systems, for example, the fiber laser and the disc laser, which excel with their compact design and high efficiency, new possibilities for the laser beam arc hybrid welding methods present themselves. The increasing power and beam quality of the solid-state laser will give rise to new possibilities, especially for welding light metals.

The increasingly compact design of the laser beam sources allows, for example, for mobile application in pipe production or application in the aircraft and aerospace industries.

7.4.5 Joining by Forming

Nonthermal joining technologies are used in almost every area of industry. Besides adhesive bonding and joining by pressing-on or expansion fit (e.g., threaded fasteners, clamping, pressing, wedging, cramping) joining by forming technologies is also significant and fundamental for multimaterial design in the sheet-metal-processing industry (Fig. 7.244).

Joining by forming processing, or mechanical joining as it is called in several publications, is enjoying a renaissance in its applications and its further development. As early as 2500 years ago in Greece pieces of cast bronze were joined permanently by rivets. Since that time especially arms, jewellery, and items of practical use have been joined or decorated by full or hollow rivets or with hemming or crimping processes. By the start of the Industrial Age riveting and crimping were being used in the production of steam boilers, e.g., at the site of railway construction and later in mechanical engineering and especially riveting for bridge-building as well. Since the 1930s, due to the costs involved, riveting was replaced by welding, particularly in bridge building.

In contrast to this development mechanical joining is now increasingly being used due to its many advantages. Modern high strength materials that acquire their mechanical properties by special heat treatments cannot be welded as traditional steel any longer and new joining methods without thermal influencing must be used to prevent weakening and high residual stresses of joined parts. Furthermore, many advantages (Table 7.50) justify the use of mechanical joining technologies.

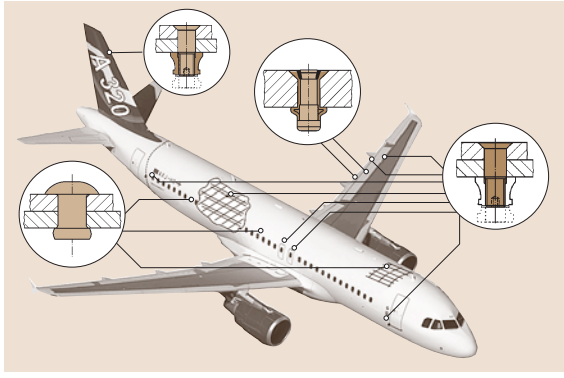

Fig. 7.244 Typical applications of joining by forming technologies at aircraft construction (after [7.229])

Table 7.50 Advantages and disadvantages of mechanical joining technology

Advantages	Disadvantages
● No thermal structural transformation of work pieces and therefore neither distortion nor residual stresses nor embrittlement ● Big variety of metallic and non-metallic materials and material combination can be joined as well as different material thicknesses ● Simple quality control mechanism ● High economic efficiency (small investment costs of machinery, rarely pre- and post-treatment of work pieces necessary) ● Materials with surface coatings can be joined without additional expenditure ● Very good environmental behaviour (neither emission nor pollution) ● High process reliability.	● Only lap joints possible, with redirect of power flow and higher weight of work pieces and therefore higher costs ● Lower tolerable static strain compared to e.g., welded joints ● Geometrical unevenness due to nature of processes (local protrusions of joining area) ● Usually more difficult correction and repair of improper joints ● Poor standardization and calculation methods

The broadest range of applications of joining by forming technologies is in the automotive industry just as well as in the field of heating, ventilation and air conditioning and the ship-building and container-building industries. Because of many new and specialized applications, additional or modified variants of mechanical joining technologies are emerging.

Overview

Terms. The technical term *mechanical joining* is generally used for technologies and processes for manufacturing permanent connections between two or more workpieces by transforming at least one of the workpieces or an additional fastener. Fasteners are additional parts needed for producing a connection with form or force closure between two or more workpieces, such as blind rivets. Some connections can only be produced by the use of fasteners, e.g., rivet connections; others do not need any additional parts, e.g., clinch connections.

The two ends of fasteners can be distinguished into a set-head and a closing-head. The set head remains after the joining process on that side from where the fastener is set into the workpiece, while the closing head – which is the opposite end of the fastener – permanently closes the connection.

Joining by forming of tubes, sheet metals, or sectional metals requires overlapping areas of workpieces. Different layouts of possible lap joints are shown in Fig. 7.245. Afterwards, all of these connection types will be called a lap joint. Butt joints cannot be joined by mechanical joining technologies.

Classification. So far no international standard for classification of joining by forming technologies exists. In German DIN standard several mechanical joining technologies are standardized at DIN 8593-5 [7.230] are classified by type and size of joined workpieces. Technologies are divided into joining of wires and tubes, sheet metals, or sectional metals. The joining technologies riveting and hydroform joining, which are classified by themselves, have an exeptional position, although they do not specifically differ from all other mechanical joining technologies of this standard.

An overview and classification of joining by forming technologies of sheet and sectional metals are shown in Fig. 7.246. Technologies shown in this classification are divided into joining with or without fasteners and also divided into during-the-process transformed parts, workpieces, and/or fasteners.

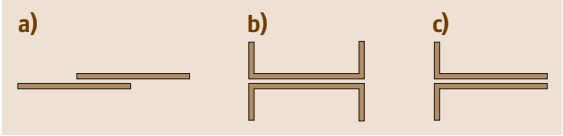

Fig. 7.245a–c Type of possible joints of mechanical joining technologies **(a)** lap joint; **(b)** parallel joint of U-sections; **(c)** parallel joint of flange connection

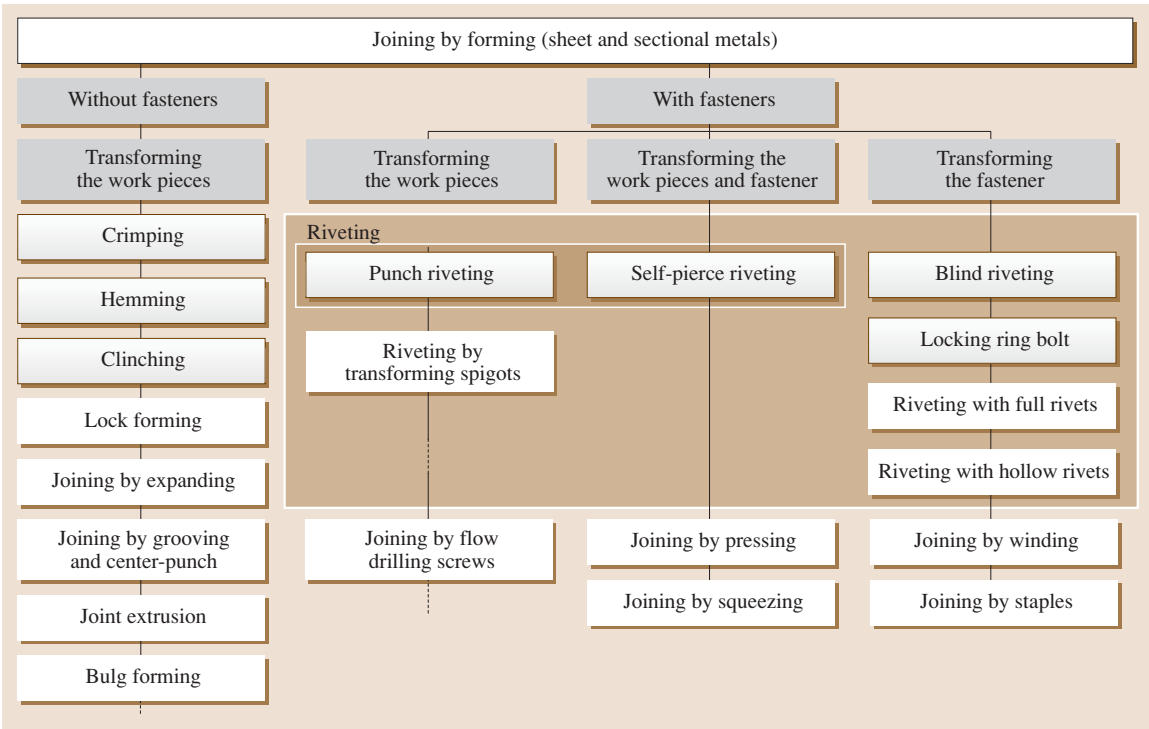

Fig. 7.246 Classification of joining by forming technologies (after [7.231])

Great significance for both applications and development is given to joining by forming technologies hemming and crimping, clinching, and riveting. For this reason these trends of mechanical joining technologies will be described in detail later on.

Selection of Significant Mechanical Joining Technologies

Hemming and Crimping. With hemming and crimping, overlapped edges of workpieces will be conjointly transformed to achieve a permanent form and force closure between the parts to be joined. Crimping used to be only a transforming process, more precisely a tension-pressure forming process, to turn up edges of curved sheet metals. Partial regions of convex or concave edges of workpieces are stretched or upset. For joining by crimping, the edges of containers, barrels, or tube ends will be transformed gradually to achieve a form and force closure between two or more parts (Fig. 7.247). In contrast to crimping, hemming describes a process where sheet metal edges are transformed in the same way to produce form- and force-closed connections (Fig. 7.248).

Various types of crimping and hemming technologies exist that require different kinds of tools and operation steps. Selection of a certain type has to be

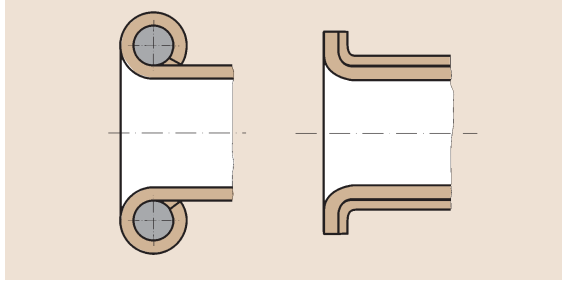

Fig. 7.247 Crimping joints

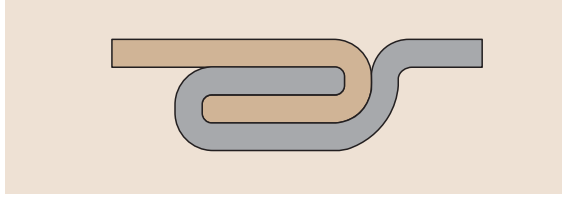

Fig. 7.248 Hemming joint

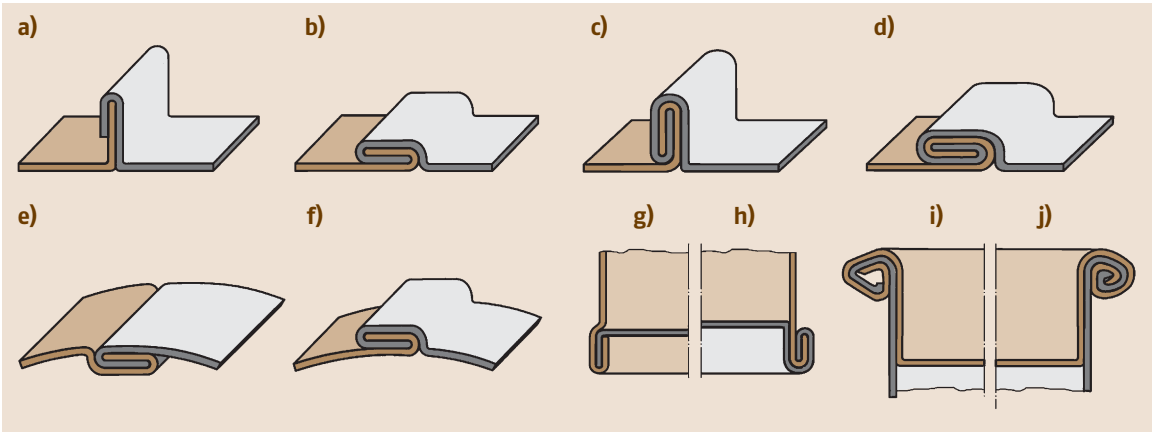

Fig. 7.249a–j Examples of different hemming and crimping joints (after [7.232]): **(a)** Stand-up hemming joint, **(b)** lying hemming joint, **(c)** stand-up double hemming joint, **(d)** lying double hemming joint, **(e)** inside hemming joint, **(f)** outside hemming joint, **(g)** single bottom crimping joint, **(h)** double bottom crimping joint, **(i)** trapezium crimping joint, **(j)** taper crimping joint

based on the kind of strain, accessibility of joining area, and other boundary conditions. Examples of different hemming joints are shown in Fig. 7.249.

Since there are no necessary surface preparations for hemming and crimping, parts only need to be aligned and fixed before. The manufacturing process can be divided into three steps:

1. Adjusting
2. Hemming or crimping
3. Redressing

With the first operation adjusting (1) the edge of all overlapping workpieces is bent up to a necessary minimum, though these hemming tools can grab the edge sufficiently. In this step, the size of the flange and hemming joint will be already fixed. The actual hemming or crimping (2) encompasses one or more gradual bending steps (Fig. 7.250). After closing the hemming or crimping seam, another redressing step (3) can plastically upset the joint and raises tightness and stress.

Hemming and crimping require a sufficient plastic formability of at least one workpiece to be joined, which can be joined with another nondeformable workpiece by form or force closure. In particular, materials with good cold formability are suitable for this joining method. One special field of application is the joining of different materials. Typical materials and material combinations are shown in Table 7.51.

Sheet thicknesses of workpieces joined by hemming are lower than 2 mm because of high forming degrees. Material thicknesses of tubes and barrels with crimping joints should be 6 mm at most depending on the level of mechanization. Te mechanical properties of hemming or crimping joints are determined by base material properties. Te connections of different materials are exposed to corrosion.

Clinching. Clinching is joining of lapped workpieces without any fasteners. A local limited area of material is pressed together by a punch into a die. A protrusion is formed by the materials yielding and creating a mechanical interlocking. The workpiece on the side where the punch presses into the material is called the punch-side piece and the opposite, which forms the protrusion, is called the die-side piece. Joining of more than two parts in one step is possible. In addition to form and force closure, under certain conditions a metallic continuity

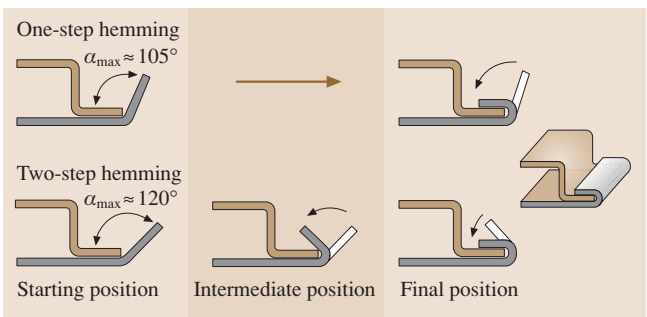

Fig. 7.250 Manufacturing steps of a hemming joint (one-step and two-step process)

Table 7.51 Materials and applications for hemming and crimping (after [7.233])

Materials and combinations	Applications
Copper	Metal fittings at roofs
Aluminum (e.g., EN AW-AlMg3, EN AW-AlMg4.5Mn)	Air conditioning and ventilation systems Sun roof and car doors
Steel (e.g., DC01, DC04)	Automotive applications
Bronze (also with other metals like silver, gold etc.)	Jewellery and art
Aluminum combined with steel	Automotive applications

(Fig. 7.251) can be found, which raises the connection strength.

Manufacturing of this kind of connection without any fastener is the major reason for its high economical efficiency, because of the saved costs of additional parts and the automatic feeding system of fasteners.

Clinching requires a double-sided accessibility. There is no need to remove coatings, like foils or paints, but for additional creation of metallic continuity clean surfaces free of dirt, oil, oxides, and coatings are needed. This could be reached, e.g., by cleaning with acid or especially for aluminum by deoxidizing or caustic etching.

The clinch tool consists of a punch and a die. The die can be only one massive part with a cavity and a ring groove (Fig. 7.252b) or have moving die blades (Fig. 7.252a) that are clamped together by springs. These die blades enable expansion of the diameter and allow an outward flow of metal to create a form- and force-closed permanent interlocking. A retainer fixes the workpieces before the punch is pressed into them and prevents distortion of the parts while joining is in progress.

Punch-and-die geometry influences the shaping of the interior and exterior geometry of clinch connections. Clinch technology can be divided into cutting and noncutting processes. Noncutting clinch processes produce no deliminations inside the connection. Material will be only transformed to reach form and force closure. For cutting clinch processes, punches with cutting edges are used that partially cut material and enable punch-side material to flow behind die-side material to produce an interlocking. A typical kind of cutting clinch connection is the square clinch because of its rectangular shape of protrusion. Besides dividing clinch systems according to their cutting ratio, they could also be classified according to their joining kinematics. Single-step and multistep clinch processes are known. Owing to many advantages (Fig. 7.253) mostly noncutting round clinch

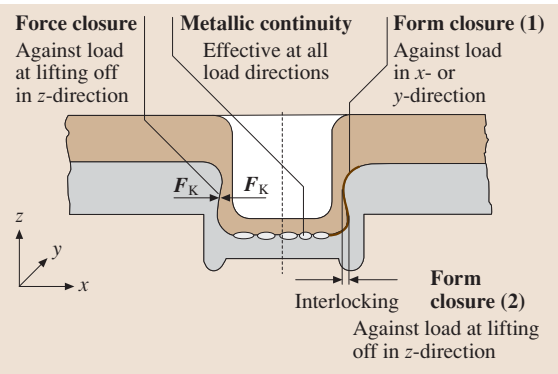

Fig. 7.251 Characteristic of clinch connections, e.g. round joint (non-cutting, single step process) (after [7.234])

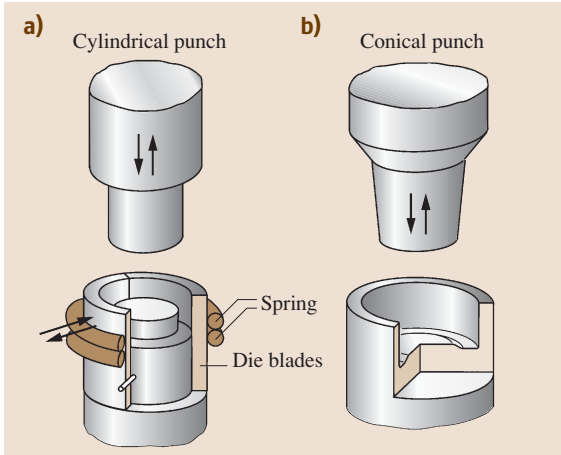

Fig. 7.252a,b Examples of clinch tool sets (after [7.235])

Non-cutting clinch connections	Cutting clinch connections
 Round joint	 Square joint (a) and special shape (b)
Advantages • Omni-directional load possible • Symmetrical look of connection	Advantages • Lower joining forces required compared to non-cutting clinch systems • Higher torsional stiffness of single connections
Disadvantages • Higher joining forces required • High strain hardening of material inside of connection	Disadvantages • Connection is not water-tight or airtight • Crevice corrosion is possible • Asymmetric load capability • No symmetric look of connection

Fig. 7.253 Comparison of non-cutting and cutting clinch systems

processes manufactured in a single action are used in European industry.

The principal working steps to produce clinch connections are almost identical for different kinds of clinch systems (Fig. 7.254). First, the parts to be joined are positioned between the punch and the die. Second, a retainer fixes the parts before the punch is pressed into

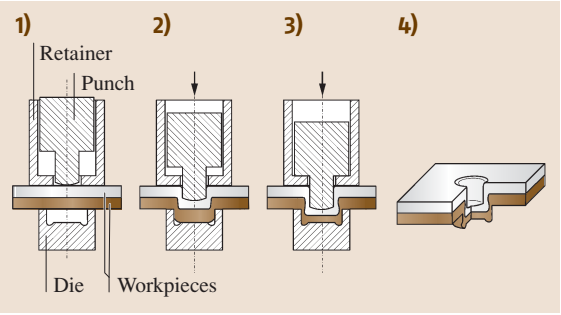

Fig. 7.254 Process steps of clinching (non-cutting, round joint)

them and creates a form and force closure by partial transformation. Using single-step processes, the punch will be drawn back after the preset bottom thickness of the clinch connection is achieved. For multistep processes one or more additional steps are required to produce an interlocking inside the connection.

Major applications of clinching are in the automotive industry, air conditioning and ventilation systems, as well as in the household appliance industry, e.g., washing machines, dishwashers, and refrigerators. This joining technology is used especially for lightweight constructions involving high-tensile steel and aluminum.

With clinch connections similar materials and material combinations can be joined. The suitability of materials depends mainly on deformability. The size of deformability can be measured by elongation on break, the yield ratio, and the tensile strength of the base materials. Conditions for good and restricted suitability for clinching are shown in Table 7.52. Restricted materials for clinching have to be proofed in particular cases.

Well-suited materials for clinching are naturally hardened and age-hardenable aluminum alloys, steel alloys for cold working, mild steel, cold-rolled dual-phase steel, high-tensile steel, ferritic and austenitic stainless steel, as well as copper and bronze alloys. Materials with an overall sheet thickness of up to 6 mm can be joined by clinching.

Table 7.52 Mechanical properties of well-suitable and restricted suitable materials for clinching (after [7.233])

	Well-suitable	Restricted suitable[a]
Elongation at break	$A_{80} \geq 12\%$	$12\% > A_{80} \geq 8\%$
Yield ratio	$\frac{R_{p0.2}}{R_m} \leq 0.7$	$\frac{R_{p0.2}}{R_m} > 0.7$
Tensile strength	$R_m \leq 500\,\text{MPa}$	$500\,\text{MPa} < R_m \leq 700\,\text{MPa}$

[a] Have to be proven separately

Because of form and force closure clinch connections should be preferentially loaded with shear stress. Head and peel tests of clinch connections show much lower possible loads. Torsional stress should be generally avoided for single spot connections, such as clinch connections.

Thermal, chemical, and electrical properties of clinch connections depend on properties of the base materials used. A combination of different materials raises the risk of electrochemical corrosion.

Riveting

Blind Riveting. In the early 19th century new manufacturing technologies and fields of applications required the development of joining technologies with only one-sided accessibility but comparable mechanical properties as full rivets used so far. Joining by accessibility of only one side is called *blind*, and so this newly developed kind of fastener was also called *blind rivet*, which later became very significant for aircraft and vessel construction. Besides the economic advantages of faster manufacturing rates, blind riveting differs from riveting with full rivets by a high noise reduction and less damage to the workpiece surface.

The development of different types of blind rivets took place gradually and many different kinds were invented. After trepanning full rivets, which still needed two-sided accessibility, by the early 20th century, for the first time blind rivets consisting of two parts were being produced in England. In Germany, not before the 1930s, blind rivets were developed that used a small explosive charge within a cavity to create a closing head after ignition by a thermal influence on the set head. With this the closing head of the explosive rivet was expanded and closed the connection (Fig. 7.256a).

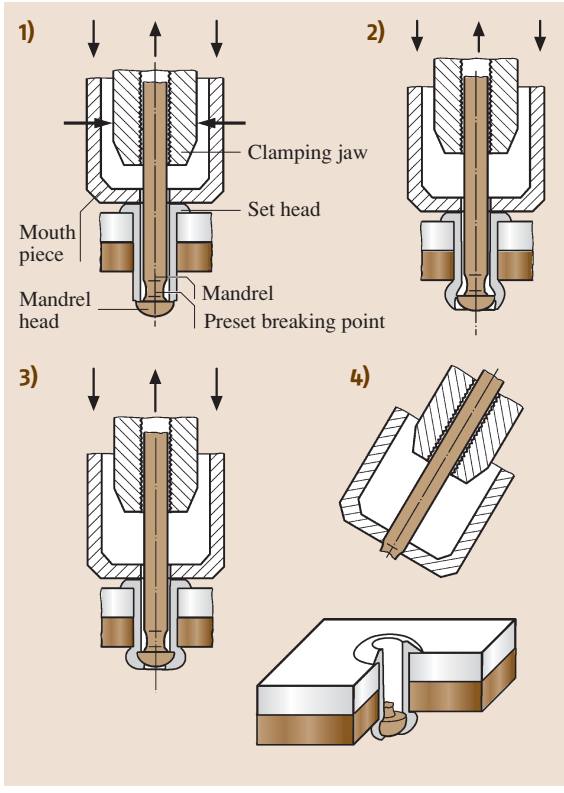

Fig. 7.255 Process steps of blind riveting (after [7.236])

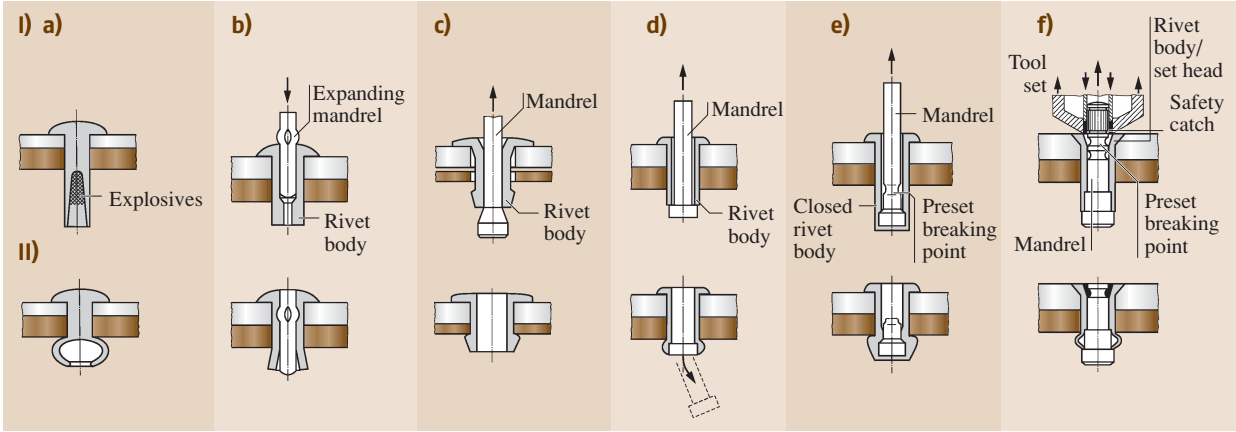

Fig. 7.256a–f Selection of different blind rivet types and schematic process of joining (**I** point of origin transforming closing head; **II** joined connection): **(a)** explosive rivet; **(b)** expanding rivet; **(c)** pull-through blind rivet; **(d)** blind rivet with loosen mandrel; **(e)** blind rivet with closed rivet body; **(f)** planar breaking countersunk-head blind rivet with mechanical mandrel safety catch

Along with other developments blind rivets were developed consisting of two or more parts that have different mechanical properties and requirements. Most common blind rivets have two parts, the rivet body and the mandrel, which form the closing head.

Blind riveting does not have special requirements for surface preparation like all mechanical joining processes. Different materials can be permanently joined with blind rivets. Releasing the connection is only possible by the destruction of the blind rivet. All parts need to be congruent, predrilled, and fixed to achieve joining with blind rivets. Holes can be drilled, punched, or brought in by another prior manufacturing step. The size and tolerances of the hole depend on the diameter and type of blind rivet.

Process steps are very similar for different types of blind rivets and are shown in Fig. 7.255. At first, the blind rivet is introduced into the setting hole and the rivet head is pressed against the set-head material. The mandrel is pulled by the clamping jaw of the setting tool and slips into the rivet body. The workpieces are pressed together by an increasing pulling strength. With this the mandrel head transforms the rivet body and creates a closing head. Depending on the kind of rivet, either the mandrel is pulled completely out of the rivet body or the mandrel breaks at the preset breaking point and is extracted by the setting tool. The required breakload will be determined by the cross section of the mandrel preset breaking point and by the material of the mandrel. Some kinds of rivets surround and fix the mandrel head and prevent it from loosening with vibrating loads. Different types of blind rivets differ in their required joining forces, connection strength, and mechanical properties as well as in costs associated with manufacturing the rivet connection.

Blind rivets were developed by the necessity of joining comparable connections of full rivets but having only one-sided accessibility. For that reason blind rivets can join almost every material and material combination without having special requirements of deformability or other material properties. The only precondition is that joining parts must have a premanufactured hole. Important for a good quality of blind rivet connection is the right choice of rivet diameter and rivet length for the joining task.

Since the mandrel has to transform the rivet body, it should have a higher tensile strength. For that reason, the mandrel and rivet body mostly consist of different materials. Although rivet bodies used to be made of aluminum because of its better deformability, nowadays also mild steel, stainless steel, and nickel and copper alloys are used to match the material of the workpieces and prevent corrosion. Blind rivets can be provided with different coatings.

Some criteria on the selection of materials for blind rivets are as follows:

- Avoidance of exposure to corrosion of workpieces
- Connection strength
- Cost

Most relevant applications of blind rivets are parts where a two-sided accessibility is not possible, such as closed sectional profiles, e.g., interior pressure-shaped profiles or large-area parts where connections should be set far away from the edges. But blind rivets mostly have a lower shear connection strength than punch rivets or locking ring bolt systems, especially those types of blind rivets where only the rivet body supplies the power between the workpieces.

The mechanical properties of blind rivet connections depend on the properties of base materials and the blind rivets used. Overall sheet thickness of workpieces to be joined can vary in a wide range from 0.5 mm to more than 20 mm.

Punch Riveting. Until the development of punch riveting for joining two or more parts it was necessary to have premanufactured holes for setting the full or hollow rivets. Holes could be set by drilling, punching, or some other thermal or nonthermal cutting process, such as watercutting. These additional working steps were problematical for increasingly automated production. In particular, hole-congruent positioning of more than two workpieces required high manufacturing precision. The additional process steps reduced the economic efficiency of the whole joining process.

With punch riveting workpieces are directly form and force closed and permanently joined without premanufacturing a hole. The cylindrical solid rivet produces the necessary hole itself while joining by punching a small slug out of all workpieces to be joined. The rivet itself is not deformed. Only parts are deformed locally, because the die-side material needs to be deformed in one single or multiple ring grooves of the punch rivet. Workpieces need to have two-sided accessibility for joining. Transmission of connection strength between joined parts happens exclusively by the punch rivet.

Because of its simple technology and less surface damage around the joining spot, especially on coated and painted parts, this connection is an economical alternative to resistance spot welding.

The tool set for punch riveting consists of a ring-shaped die, a retainer, and a punch (Fig. 7.257). The die is ring-shaped to enable throw-out of the slug while joining.

While the tool set moves to the joining spot, the punch rivet will be fed into the retainer and positioned to the workpiece surface. The retainer fixes parts before joining and guides the punch rivet until the joining starts. The punch presses the punch rivet into the work pieces. The punch rivet will be moved till the countersunk set head of the punch rivet is installed flush with the surface of the punch-side workpiece. The ring-shaped die has a small offset at its inner diameter, which causes the material of the die-side workpiece to flow into the ring groove of the punch rivet. With this the punch rivet is fixed permanently to the workpiece and the connection is established.

The joining process is distance controlled, meaning the stroke of the punch is defined by an adjustable stop collar. The required joining force is automatically adjusted and only limited by the nominal load of the riveting machine.

Materials of punch rivets and workpieces can differ, but the material of the rivets needs to have a higher tensile strength and hardness than the material of the workpieces, because the cutting lip of the rivet needs to punch holes into the parts. Similar materials or material combinations can be joined by punch riveting, but the die-side material must be deformable, so that the ring groove can be filled with base material.

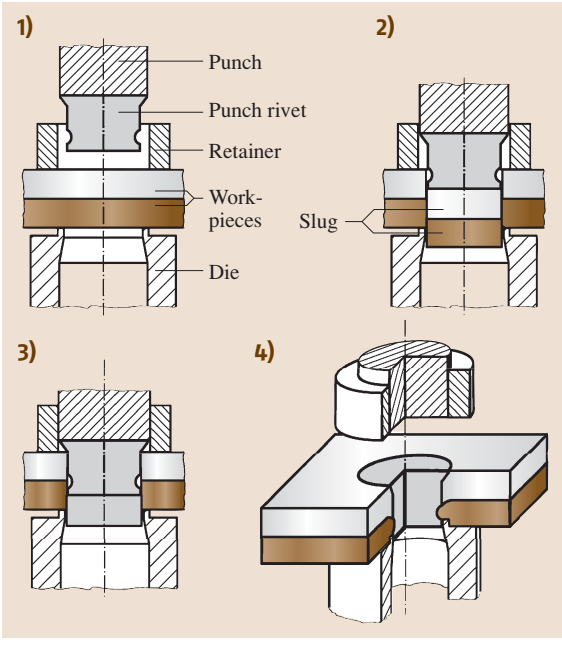

Fig. 7.257 Process steps of punch riveting (after [7.237])

Typical materials of the punch rivets are mild and stainless steels as well as aluminum, but most of the rivets are heat-treated steels. Since the rivet will not be deformed, higher hardness and lower deformability of rivet materials is possible; therefore, martensitic (stainless) chrome steel can be used too.

With punch riveting two or more parts can be joined at one time between an overall sheet thickness of 1 – 14 mm. These values are lower for high-strength steel.

Mechanical, thermal, chemical, and electrical properties depend on the base material and the punch rivets used. Punch-riveted joints commonly have a higher connection strength than, e.g., clinch connections because of their special force transmission with additional fasteners.

A material combination of punch rivets and workpieces can lead to electrochemical corrosion and should be prevented by coatings or paint of the joining area.

Self-Pierce Riveting. The reasons for and steps of development of self-pierce rivets took place in the same way as punch rivets. In contrast to a solid punch rivet, for self-pierce riveting partly trepanned cylindrical rivets are used. These self-pierce rivets expand while joining to a form and force closure. Both workpieces and self-pierce rivets are partially deformed at the joining process. The first self-pierce rivets punched workpieces completely, but current types of self-pierce rivets only punch the set-head side of workpieces and only deform the die side, where they create an interlocked close head. With this an air- and watertight connection is created without cutting and less damage at the die side. Self-pierce riveting requires a two-sided accessibility of workpieces.

Process steps differ just a little in comparison to punch riveting (Fig. 7.258). Parts to be joined will be positioned between the tool set, the punch, and the die and will be fixed by the retainer. Now, self-pierce rivets are automatically fed inside the retainer just under the punch. The connection will be set with one stroke of the punch. In contrast to punch riveting, here a die with a cavity is used that will be completely filled with material at the joining process. Self-pierce rivets also have a cutting lip, which punches a slug into the workpiece of the set-head side. This slug will be enclosed inside the rivet. The cylindrical shape of the die with a frustoconical punch in the middle of the

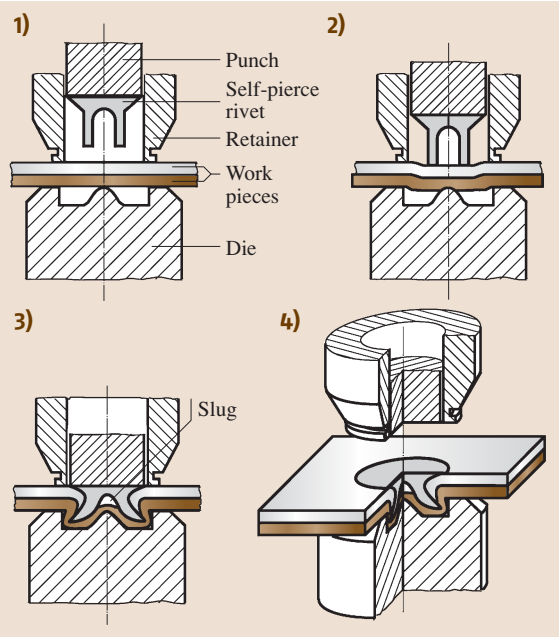

Fig. 7.258 Process steps of self-pierce riveting

cavity causes the self-pierce rivet to expand and creates a form- and force-close interlocking within the die-sided workpiece. For this reason it is necessary to adjust the length of the self-pierce rivet at the overall thickness of the workpieces and the die depth. In contrast to a punch rivet connection, the self-pierce rivet connection forms a protrusion at the die-sided workpiece.

In contrast to punch riveting, self-pierce riveting requires special properties of the rivet material. The rivet has to have a high enough tensile strength and hardness to punch into the set-head side of the workpieces and must be deformable by the frustoconical punch in the middle of the die without breaking or tearing.

With self-pierce rivets metals and nonmetal materials can be joined, but die-sided materials must have a sufficient malleability to be transformed into the cavity.

Workpieces can be joined with lap joints, where the minimum lap size depends on the size of the used self-pierce rivets and the tool set. More than two parts can be joined with an overall sheet thickness at a range of 1–6 mm [7.238]. High-strength material may reduce the maximum thickness that can be joined.

The properties of self-pierce riveted joints depend on the mechanical, thermal, chemical, and electrical properties of joined working pieces and the rivet materials used. To prevent electrochemical corrosion, parts and rivets should be coated or painted after the joining process.

Locking Ring Bolt Connections. Joining with locking ring bolts is a special kind of riveting. The locking ring bolt, also known as locking ring bolt system, consists of two components – a ring and a bolt. Locking ring bolt connections have unique properties. These connections possess high strength like full rivets and the possibility to join high-strength materials, similar to preloaded screws. Originally, locking ring bolt connections were developed for aircraft and aeronautics but are used extensively in the fields of structural-steel erection, cranes, rolling stock, utility vehicle manufacturing, and shipbuilding. In contrast to screws, the original preload of the connection is permanently retained. Therefore, locking ring bolt connections are vibration resistant. The parallel grooves of the bolts avoid preload reduction, even in case of vibrating load.

Locking ring bolt connections are permanent. The only way to separate the joined parts is to destroy the locking ring bolt. Prepunched parts and accessibility from both sides are prerequisites. Ordinary locking ring bolts have parallel grooves (Fig. 7.259). But there are variants with threadlike grooves and bolts with additional regular thread to join other components with nuts.

The joining process of ordinary locking ring bolts is shown in Fig. 7.260. The process can be divided into the following steps:

1. The bolts are plugged into the punched parts, and the ring is slipped over the bolt. The manufactured head and the ring are in contact with the parts. The rivet tool is fit to the pull zone of the bolt.
2. The clamping jaws of the rivet tool fix the bolt. The die of the rivet tool set is pressed against the ring and the workpieces.

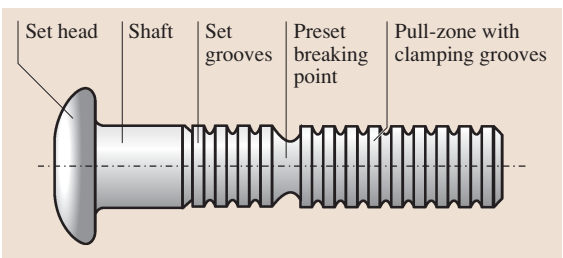

Fig. 7.259 Sections of a locking ring bolt

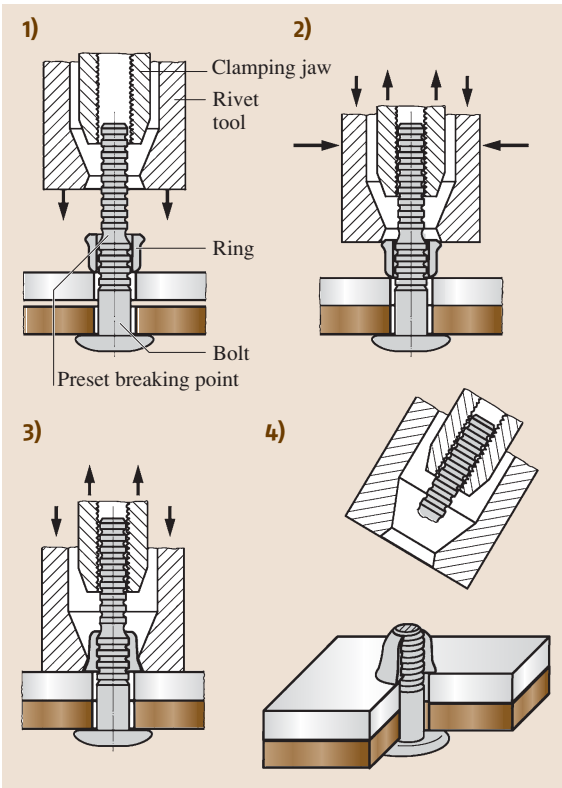

Fig. 7.260 Process steps of locking ring bolt technology (after [7.239])

3. The die of the rivet tool is moved continuously toward the manufactured head. In this way, the ring is formed into the grooves of the bolt. Axial pressure is balanced by clamping of the bolt. With this additional stress to the parts can be avoided.
4. The bolt is loaded by the tensile force of the clamping jaws until the bolt breaks at a preset breaking point. All tensile forces are balanced inside the tool. There are no loads to the workpieces.

All materials that allow manufacturing of holes by punching, drilling, and other processes are able to be joined by locking ring bolt connections. There are no special requirements for the materials regarding formability and other properties. The material of the locking ring bolt has to be adapted to the material of the parts in order to reach an optimum in strength and corrosion resistance. The fracture area of the bolt at the preset breaking point should be coated, unless the bolt is made of stainless steel or aluminum alloys.

As a result of the high-level strength, locking ring bolt connections are suitable for parts with overall thicknesses of more than 3 mm as well as materials of higher strength.

Pre- and Posttreatment

The outstanding features of mechanical joining are its robust and simple technology. Processes are very tolerant of varying material properties and especially workpiece surface preparation. Depending on the specific technology (e.g., for blind riveting) congruent pierces by hole punching, drilling, or water cutting can be required. Surface preparation is mostly unnecessary. Workpieces with coated and raw surfaces can be joined by most joining by forming technologies.

Posttreatment of mechanical joined workpieces is usually not required either. In case of surface coatings of joined parts it should be determined by inspection whether the surface was damaged by the joining process. Since process-required pierces are manufactured before joining, coatings can be restored before joining as well. In the case of used fasteners, corrosion prevention must be investigated.

General Topics of Quality Inspection

Quality inspection includes among other things inspection of the manufacturing process and the inspection of connections. The inspection procedures of the manufacturing process can be automated. For this, significant process parameters are measured using sensors. The actual indication and ideal indication are compared. Using this method, it is possible to assess the quality of a connection during the manufacturing process and to classify as required the quality level. As a consequence of increasing requirements on quality inspection, these inspection systems are common not only in automated manufacturing processes but also in partially automated ones. The most important parameters of joining by forming are the force of male die and its length of stroke, which can be monitored online. It is possible to draw curves of actual force vs. actual stroke and to compare these curves with ideal curves. The data of the actual curve are compared with the separate data of the ideal curve using tolerance ranges (Fig. 7.261a) or with overall data using tolerance bands of the parameter (Fig. 7.261b).

Connections can be proofed after manufacture by visual inspection, measuring of the bottom thickness (for clinch connections), or destructive tests [7.240]. Visual inspection is used to determine cracks on the

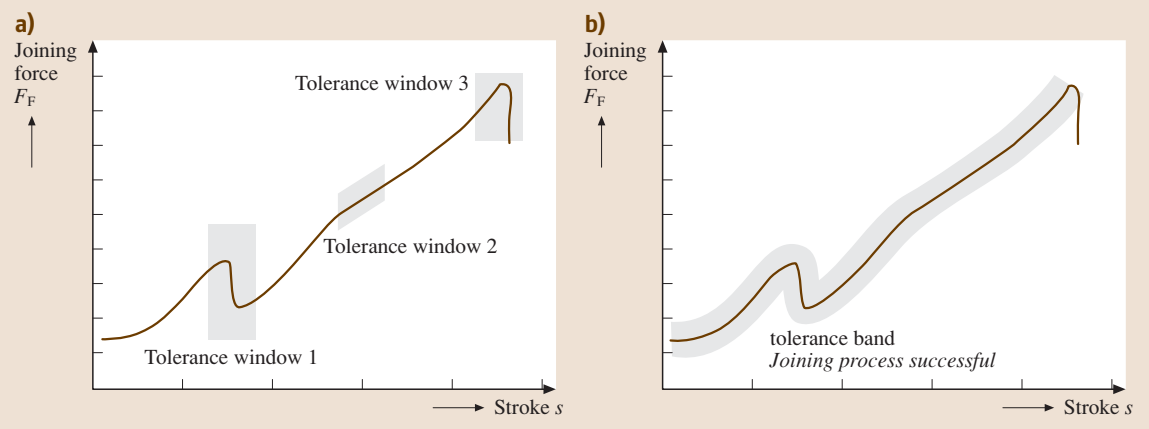

Fig. 7.261a,b On-line quality inspection of clinch connections with (a) tolerance ranges, (b) tolerance bands

surface, the symmetrical shape of the connection, and surface failures. The bottom thickness is an important property because other geometric parameters such as undercut and neck thickness relate to the bottom thickness for the used tool set. Until now, the strength of a connection was determined with tensile shear tests resp. peel test recording of the maximum forces reached.

Metallography enables one to investigate the inner structure of mechanical joined connections. For this, macrosections are useful. For dot-shaped connections, the section plane should divide the connection symmetrically. The dimensions that are responsible for the properties of the connection can be measured. Figure 7.262 shows the cross section of a clinch connection with characteristic dimensions.

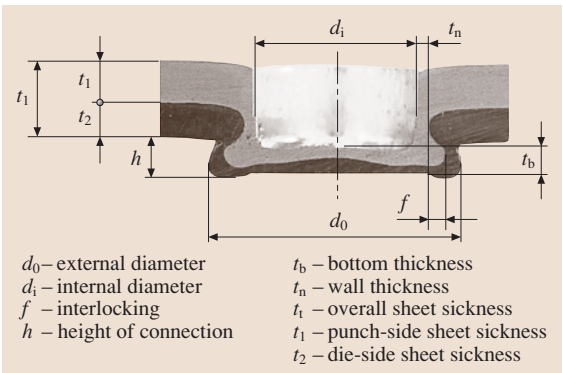

Fig. 7.262 Metallographic evaluation of clinch connection showing characteristic dimensions (after [7.233])

Safety in Operation and Environmental Protection

In the field of mechanical joining, the general instructions for machine operation and safety codes must be kept. Because presses or presslike machines are used for mechanical joining, the special safety codes for these machines have to be observed. In particular, high-speed moving machine components, e.g., in common use for setting full rivets, can cause dangerous noise. In this case, noise abatement or noise barriers are necessary.

Regarding environmental protection, all processes of mechanical joining can be estimated as being favorable. Emissions, such as fumes, gases, or hazardous substances, are not released. Most process steps do not need any surface treatment. Thus, no pickles or detergents are necessary.

7.4.6 Micro Joining Processes

Microstructure technology is used for the fabrication of microstructures and microcomponents, whose dimensions lie in the micrometer range and extend to the nanometer range. Microsystems technology is the consistent further development of microelectronics toward nonelectronic fields [7.241]. It links miniaturized, microstructured components and suitable sensors as well as actuator technology to form intelligent systems.

Microsystems technology makes use of techniques used in microelectronics, micromechanics, and microoptics as well as in mounting and connecting technology. Figure 7.263 shows the single procedural steps for the fabrication of a microsystem.

Microsystems have a broad range of applications, e.g., in microelectronics, in air and spacecraft, chemistry, biology, and medicine. The application of novel

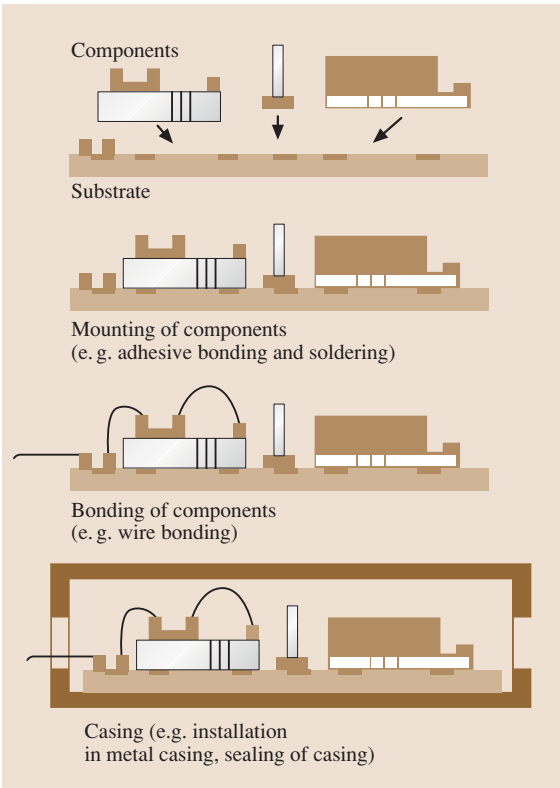

Fig. 7.263 Layout of a microsystem (after [7.243])

materials and the adaptation of manufacturing techniques in the field of miniaturization have decisively contributed to the success of microsystems technology. Within this framework, hybrid constructions have become of particular importance. The development of a hybrid, i. e., nonmonolithic construction in microsystems technology with single components from different technological fields, requires an adapted microjoining and processing technology [7.242].

Microwelding Processes

Among the microwelding techniques, pressure welding methods are of particular importance and most frequently used due to the advantages they offer. However, for special applications and the individual fabrication of precision parts fusion welding is used, too.

Resistance Welding. The majority of resistance welding techniques can be applied to microwelding processes. By means of transistor-controlled direct-current and medium-frequency inverters, welding times from 10 µs are programmable in 10 µs intervals by which an exact dosage of the welding energy required is achieved.

Spot Welding. Spot welding for the manufacture of extremely small and microwelded joints is applied for components used in the electronic, optical, and precision mechanics industry. This applies mainly to wires, foils, and strips made from different metallic materials and their alloys. To date, more than 170 combinations of the most important metals have been welded.

Seam Welding. Seam welding is used for the welding of cases of electronic elements and circuits. It is also applied for the manufacture of cushion-type membranes (bell-shaped and flat membranes), overlay-plated and inlay profiles for bimetal contact strips.

Projection Welding. Projection welding is used for the welding of wires and structural parts made from different metallic materials, and for the fabrication of hollow bodies for electronic components, sensor casings, contact bars, plugs, joint bars, and litz wires.

Parallel Gap Welding. Parallel gap welding is a process variant of resistance spot welding and comparable with indirect spot welding [7.244]. Figure 7.264 shows the typical arrangement of the electrodes. Both electrodes are lowered onto the piece to be welded from above at a very small distance.

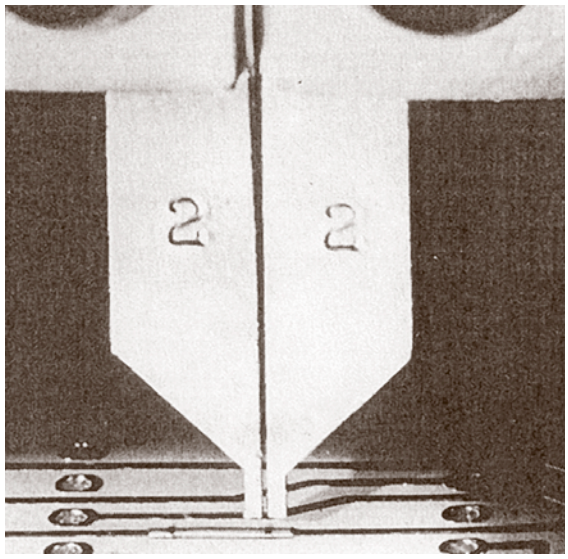

Fig. 7.264 Parallel gap welding used for repair work of strip conductors (after [7.244])

The electrodes are clamped in adjustable fixings. The gap width depends upon the material used and is continuously adjustable from 0.025 to 1.00 mm. Welding currents from 100 to 1000 A, welding times from 1 to 100 ms, and electrode forces from 0.2 to 100 N are used.

By using parallel gap welding, silver contacts of solar cells made from silicon (thickness 180–250 µm) are connected with silver strips (20–35 µm) to form batteries. 25 000–65 000 solar cells form a battery that is used for the direct transformation of sunlight into electrical energy to generate energy for spacecraft and satellites [7.245]. Further applications include the welding of thin wires and strips onto circuit elements, the bonding of sensors, and the repair of tracks of printed circuit elements with bonded strips from kovar, copper, silver, or gold.

Wire Bonding. Wire bonding is a highly developed microwelding technology and guarantees reliable joining in the micro range. Wire bonding is the most important joining technique for the manufacture of conductive welding joints in microelectronics. It is used for the manufacture of electric connections between semiconductor chips, structural components, and cases (metal, ceramics, and plastic casings). Bonding is accomplished by using a metallic wire loop that is welded at its ends onto the connecting metallizations of the components to be joined. In addition to lateral bridging, a difference in height can be bridged as well [7.246].

Welding techniques that are used for wire bonding differ with respect to:

- The manner of energy input
- The shape of the bonding tool
- The wire diameters applied

All techniques have one thing in common, i. e., joining is accomplished in the solid state of the materials (solid-state welding) [7.247].

Thermocompression Bonding. The joining of bond wire and connective metallizations is produced by the input of heat (150–350 °C) and power (0.1–0.9 N) using welding times from 0.3 to 0.6 s. Commonly, the substrate is preheated by means of a hot plate to about 150 or 170 °C. The bonding tool heats the area to be joined to the required process temperature in pulsed mode. Predominantly thin bond wires made from gold (wire diameter from 7 to 50 µm) are welded onto the bond pads of the chip and the wire bond face of the casing.

Ultrasonic Bonding. Bonding is produced by the effect of mechanical vibrations and the bonding force which are introduced by means of the bonding tool (operating frequency of 60 kHz, ultrasonic power from 0.1 to 30 W, vibration amplitude from 1 to 2 µm). Bond wires made of AlSi1 and AlMg1 (18–50 µm) are mainly used; for high-performance structural elements also wires made of highest-grade aluminum with a diameter of 100–500 µm.

Thermosonic Bonding. Thermosonic bonding is a combination of thermocompression bonding and ultrasonic bonding which unites the advantages of both techniques at low temperatures (100–180 °C) and shorter welding times as well as bonding forces. It is standard procedure used for the contacting of integrated circuits (ICs), single diodes, and transistors on ceramic substrates with thick-layer and thin-layer circuits. Gold wires with a diameter of 17 to 100 µm are preferably used.

For wire bonding, ball–wedge bonding (Fig. 7.265) and wedge–wedge bonding are applied (Fig. 7.268).

The manufacture of ball–wedge bonds can be accomplished by both thermocompression and thermosonic bonding. Due to the special shape of the tool

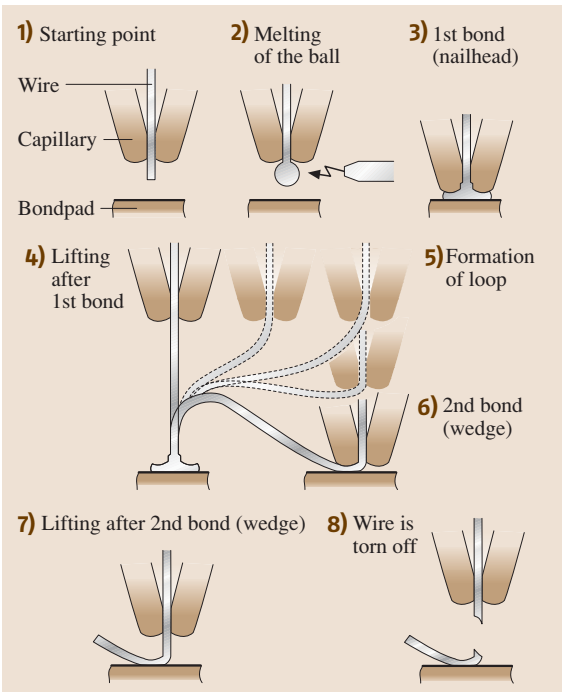

Fig. 7.265 Procedural scheme of ball–wedge bonding

Fig. 7.266 Nailhead-joint (after [7.248])

(bonding capillary), wire bonding can be accomplished in each direction without turning the tool or structural element. The meltdown of the ball is only possible by using gold wire (diameter 12.5–50 µm). Figure 7.266 shows the first bond (nailhead) and Fig. 7.267 the second bond (wedge).

In the case of wedge–wedge bonding (Fig. 7.268), the formation of the first and the second welding shows a similar geometry (Fig. 7.267).

Thermocompression, ultrasonic, and thermosonic bonding are suited for the manufacture of wedge–wedge joints. Bond wires and thin aluminum, copper, and gold strips can be used. Due to the shape of the bond wedge, the direction for the second bond is already defined by the formation of the first bond.

Automatic wire bonders can bond up to 18 wires/s using the ball–wedge technique and up to 5 wires using the wedge–wedge technique [7.251].

Laser Beam Welding. In the field of microjoining technology mainly pulsed Nd:YAG lasers operating with wavelengths of $\lambda = 1.064\,\mu m$ are used. The pulsing of

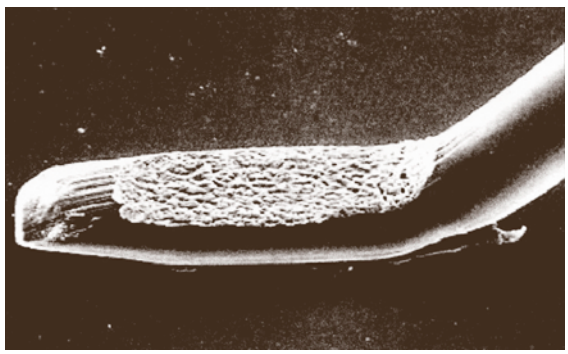

Fig. 7.267 Wedge-joint (after [7.249])

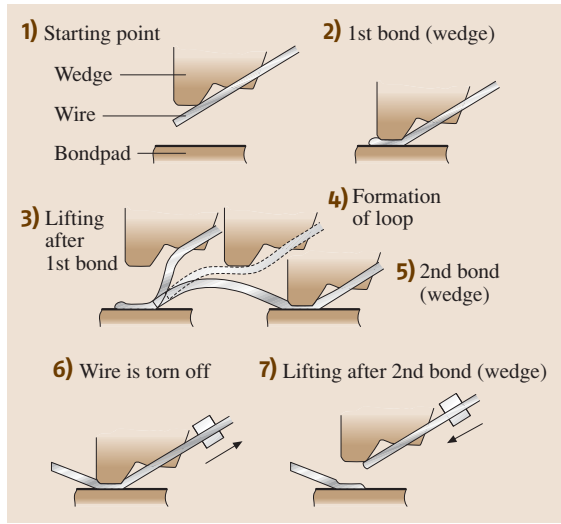

Fig. 7.268 Procedural scheme of wedge–wedge bonding

the beam results in an improved energy input and offers a more appropriate adaptation to the welding job. The parts to be welded have to be exactly positioned as an existing gap can hardly be bridged. Therefore, an easy-to-manufacture perfect fitting accuracy or a sufficient

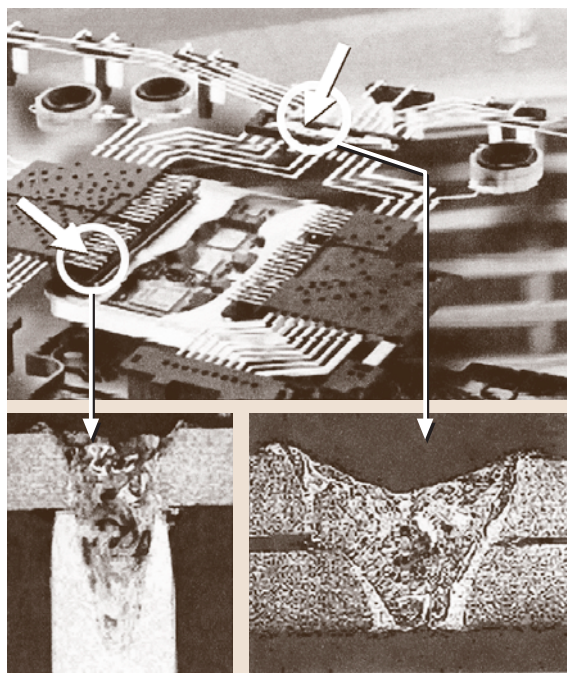

Fig. 7.269 Laser beam welding of electronic parts of a gear control system (after [7.250])

material reserve for melting have to be considered in the designing phase of the parts. An enormous advantage relies on the accessibility of the laser beam to low-lying welding locations. By means of a long welding pulse, limited welding seams are also possible (Fig. 7.269).

Laser beam welding is especially suited for the fabrication of precise mechanically and thermally highly strained components of the ancillary industries in automobile manufacturing and precision mechanics, predominantly in situations where the use of metallic materials exhibiting a reduced weldability is required. In medical technology with its high demands on the surfaces of components as regards cleanliness, sterility, and biocompatibility, precision weldments of pacemaker casings are made without damaging their complex interior. The dental lab uses this technique for the fabrication of bridges and braces. In electrical engineering and electronics it is applied for the manufacture of small parts and electrical contacts. Laser beam welding replaces the previously used soldering techniques in those cases where high thermal demands on precision parts prevail.

Microsoldering Processes

Electronic units made by soldering consist of a combination of single elements that are connected by means of a carrier board. Each of those elements can be a single component, a combination of parts, a highly integrated unit, or an already joined subelement fulfilling an electronic function. The printed circuit board is often part of the mechanical structure and carrier for the conductor tracks connecting the structural elements. In addition, it supports the distribution of heat of the structural elements applied to it. Depending upon the mode of the structural elements applied, the carrier boards are equipped with holes (through hole technology) or without holes. The conductor tracks are situated on one side, on both sides, or in the inside of the boards in the case of multilayer boards [7.252, 253].

The components are placed either on one side of the substrate or on both. The different positions of the elements determine the options for the application of a certain soldering technique (Fig. 7.270).

For microsoldering techniques, SnPb, SnPbCu, and SnPbAg solders are predominantly used. The disposal of used electric and electronic appliances and the restrictions as regards the use of dangerous substances in such devices require a change in manufacturing toward unleaded solders (e.g., solder $Sn_{0.7}Cu$ for wave soldering and solder SnAgCu for the reflow soldering process) [7.254].

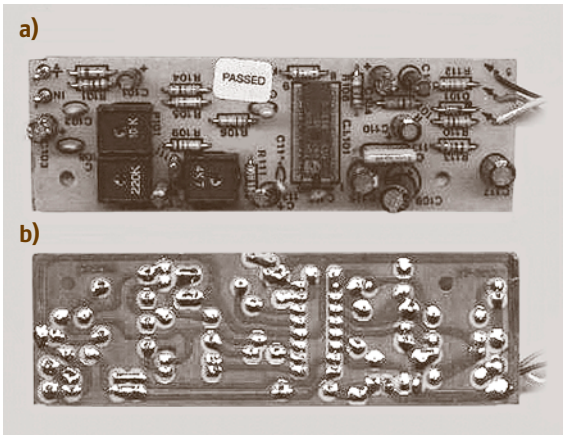

Fig. 7.270a,b Printed circuit board, top **(a)** and bottom side **(b)**

Manual Soldering. Iron soldering is preferably used for small numbers of pieces that have to satisfy extremely high demands as regards the reliability of the soldered joints in the field of air- and spacecraft engineering as well as the repair of microsystems. To reach a consistent soldering temperature, controlled manual soldering devices with corresponding soldering stations are applied. Overheating of the soldered joint and the resulting damage of the board can thus be avoided. However, the quality of the soldered joints depends to a high degree on the skill and experience of the solderer. The industrial manufacture of high numbers of pieces always requires the application of mechanical soldering techniques.

Dip Soldering. In dip soldering, the surface-mounted board is lowered nearly horizontally into the solder bath until the face to be soldered reaches the surface of the liquid solder (Fig. 7.271). After a predetermined dwell time, the board is lifted from the bath surface again. The soldering process is complete.

As a rule, flux application, preheating, soldering, and board transport are not mechanized. Generally, the removal of surface contamination, the lowering of the

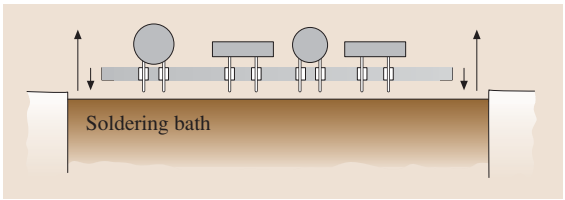

Fig. 7.271 Principle of dip soldering

printed circuit boards until the contact of the face to be soldered with the surface of the liquid solder is reached, and the lifting of the boards after the given dwell time are done automatically.

Drag Soldering. In drag soldering, the surface-mounted board is clamped in a frame with the side to be soldered in the downward position. The frame moved by a chain transport system is lowered into the soldering bath until contact with the liquid solder is reached. Then the board is dragged through the bath over a given distance which corresponds to the soldering time and after that lifted from the bath again (Fig. 7.272). For reaching an optimum soldering quality, the angle of dipping and lifting of the printed circuit board can be changed by adjusting the chain guide.

Drag soldering is a continuous process. Flux application is accomplished by foaming. An oxide slide is used for the removal of the oxide skin which always forms on the surface of the soldering bath prior to the soldering of a new board.

Wave Soldering. In wave soldering, a stationary, regularly recurring soldering wave is generated in the solder bath. The face of the printed circuit board to be soldered is moved in one direction through the wave with a set angle of approx. 7 °C. Frequently, several successively arranged solder waves are applied. Figure 7.273 shows the soldering of printed circuit boards with mixed insertion by means of a wave soldering device. Wave soldering devices operate fully automatically and are controlled by microprocessors.

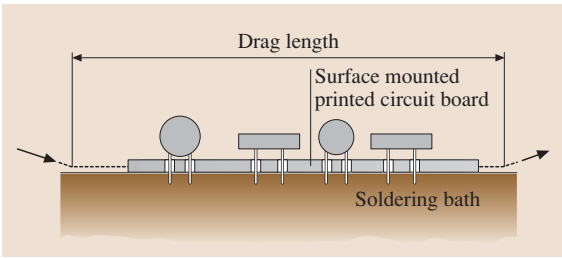

Fig. 7.272 Principle of drag soldering

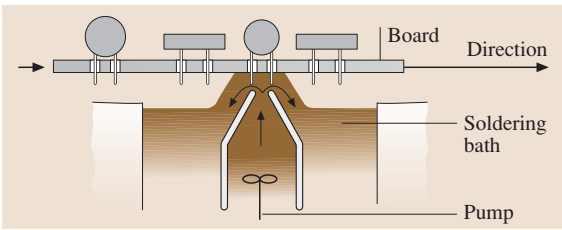

Fig. 7.273 Principle of wave soldering

Reflow Soldering. Surface-mounted devices (SMDs) are miniaturized components that are delivered with pretinned contact faces. They are placed on the pads of the substrate, which are pretinned as well. In the case of small series, the positioning of the components can be done manually; in big series, this is done with the help of pick-and-place as well as positioning machines. The single components are first glued provisionally and then finally integrated into the circuit by the subsequent soldering process. In this case, the reflow soldering process is almost exclusively used.

Nonglued components align themselves by the surface tension of the liquid solder.

In reflow soldering, a previously applied solder is molten during the soldering processes to produce the joint. A further solder application is not required. The single process cycles comprise the manufacture of printed circuit boards with solder pads, the SMDs, and the heat input required for melting the solder. Depending upon the type of SMDs, the quantity of the solder required per soldered joint amounts to 0.5 up to 1.2 mg [7.252].

Reflow soldering comprises the large-scale soldering fabrication and sequential soldering techniques. They can be differentiated by their manner of heat input. In the case of soldering accomplished by the total heating of the workpiece, techniques using hot gas, saturated vapors, and infrared radiation are of major importance as they are well-suited for a continuous soldering process.

For soldering multicontact components and for the repair of soldered joints of surface-mounted components, local heating is deliberately used. Soldering with hot gas (hot air), pulse soldering using a resistance-heated strip or U-strap support (thermode), soldering with infrared radiation, as well as laser beam soldering are of special importance. By using the laser beam also barely accessible soldered joints can be reached.

Fixation and clamping of the components during the soldering process are accomplished by glass plates that can be penetrated by the laser beams. CO_2 lasers and Nd:YAG lasers are preferably applied for soldering.

7.4.7 Microbonding

A few years ago, the market trends for microsystems were primarily determined by silicon-based monolithic systems from the field of information technology.

Efforts to realize functions that are more and more complex and have constantly higher integration densities, however, increased the demand for microsystems that combine different mechanical, optical, fluidic, and electronic components on one common carrier structure. The manufacture of this type of hybrid microsystem demands efficient joining techniques that can be adjusted flexibly to different batch sizes, materials, geometries, and technological requirements. In this connection, microbonding represents a method with many advantages and it is, in some cases, the sole possibility to join dissimilar materials. The term *bonding* stands for the manufacture of a permanent positive substance joint between two joining members by means of adhesion (interfacial bonding) and cohesion (internal strength). The possibility of joining a multitude of different materials and geometries with low temperature is particularly advantageous. In the microrange, the adhesive layer frequently fulfills, apart from mechanical fixing, other additional functions, such as conducting and/or separating of light, electricity, heat, and fluids. In comparison with competitive joining methods, e.g., microwelding and brazing or bonding, the restricted aging and thermal stability exert a negative influence on the creeping behavior of the adhesive layer.

Adhesives

In principle, the same monomer and polymer base materials as are used in the macrorange are applicable.

The demands made on the adhesives are a direct result of the defined application case. They are mainly determined by the joining part materials, the geometrical design, the type and extent of the scheduled duties, and the requested functionality. The properties of the adhesive and/or of the adhesive layer (Fig. 7.274), are important decision criteria.

It is generally valid that, in the microrange, the large ratio that the surface bears to volume may lead to the escape of volatiles from the adhesive layer and thus to a substantial change in the adhesive composition. This effect is increased when the surfaces show strong curvatures. Apart from this, the large surface of small adhesive volumes is characterized by a stronger susceptibility to secondary reactions with the environment, which results in, e.g., the inhibition of the hardening reaction through atmospheric components. For application in the field of microsystem technology, mainly reaction adhesives based on epoxy resin, acrylate, silicon, and polyamide are used. Here, a distinction is made between filled and unfilled adhesives. A summary of the properties of unfilled adhesive systems for the microrange is, among other data, shown in Fig. 7.274.

Selection criteria for suitable adhesives	Characteristic parameters
Material compatibility between adhesive, joining part and surrounding media	• Development of sufficient adhesive forces • No secondary effects through active ions • Physiologically uncritical
Mechanical properties	• Tensile-, pressure-, shear strength • Elasticity modulus, shear modulus • Elongation after fracture • Hardness
Behavior under increased load	• Temperature area of application and temperature behavior – change of the mechanical properties – thermal expansion coefficient • Effects of permanent load – creeping behavior under constant static load – mechanical properties under cyclic load • Aging stability under influence of humidity or corrosive media
Processing requirements and stetting conditions	• Requested storage conditions • Pot life, setting time • Processing time and setting time (pressure)
Functionality of adhesive layer	• Electrical insulation and/or conductivity – specific resistance • Thermal conductivity – thermal transfer resistance • Optical properties – refractive index, transparency

Fig. 7.274 Typical criteria for the selection of suitable adhesive systems

Fillers. Filled adhesives are composed of the same base material as unfilled systems and, as far as quality is concerned, show, therefore, equal material behavior. They contain, in addition, particles that exert a defined influence on the property profile of the adhesive layer. Through the addition of approx. 70 mol % of silicon oxide particles to the epoxy base material, the modulus of elasticity is, for example, increased from 3 to 20 GPa and the thermal expansion coefficient is decreased from 30 to 15 ppm/K [7.255]. The addition of 70 mol % Al_2O_3 increases the heat conductivity from 0.4 to 2.0 W/(m K) and 60–80 mol % Ag, Ni, Au flakes

reduce the conductivity of the set adhesive layer down to values of less than $10^{-5}\ \Omega\,\mathrm{cm}$.

Filled adhesives require special storage. Apart from the premature hardening of the reactive components, the attachment of particles to one another must be avoided. High temperatures intensify this process. During the dispensing process, partly high shear forces that may lead to the separation of matrix and fillers are acting upon the adhesive. The dispensing volume flow must, in this case, be adapted. With decreasing joint geometries the fillers may lead to nonreproducible bonding results as their dimensions are, partly, within the same order of magnitude as those of the adhesive layer. Based on recent research work, nanoscaled fillers are in this connection increasingly part of the adhesives formulas [7.256].

Process Technique

Joining and Setting. The transfer from the macrorange to the microrange entails, apart from the described differences in processing and hardening of the small quantitites of different adhesives, substantially increased demands on the handling precision during joining and setting. The geometrical precision and the rigidity and/or placement force of the system determine the evenness and thickness of the adhesive layer thickness and also the spreading behavior of the adhesive. Typical layer thicknesses in the microrange are between 1 and 20 µm. For component handling, normally pick-and-place systems with precision degrees in the micrometer range are used. Reproducibility and handling precision are, therefore, increased by suitable adjusting structures, Fig. 7.275. Critically positioned adhesive joints are, generally, fixed until the adhesive has set completely and/or at least almost completely.

Surface Treatment. In adhesive bonding, surface treatment is of special importance. Cleaned, degreased, and homogeneous joining part surfaces are a precondition for uniform wetting conditions and for the development of sufficient adhesive forces between adhesive and base material. The adhesive forces which are responsible for adhesion are in the subnanometer range. Treated surfaces show, even after superfinishing, surface roughnesses of more than 25 nm, thus low-viscosity adhesives are frequently connected with improved wetting conditions and a more effective surface. Cleaning and degreasing of the surfaces demands special attention as also supposedly cleaned surfaces may show adsorbate layers which locally change the wetting capability. Due to the naturally small dimensions this leads, in the microrange, to uneven adhesive spreading and to reduced adhesive strengths, Fig. 7.276.

Dispensing and/or Application Technique. For dispensing and applying defined minimum adhesive quantitites, various dispensing techniques have, due to the multitude of different types of adhesives and requirements, been established. A distinction is made between large-surface application methods, such as screening/adhesive printing and point-shaped application methods, such as the pin-transfer technique or the different dispensing techniques by means of which also a linear-shaped adhesive application can be realized. Important properties of the mentioned methods are explained in what follows.

Screening/Adhesive Printing. In screening, the adhesive is pressed through a screen by means of a coating

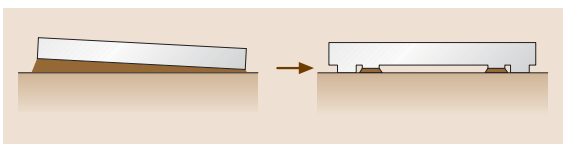

Fig. 7.275 Passive increase of the measuring accuracy through application of spacers

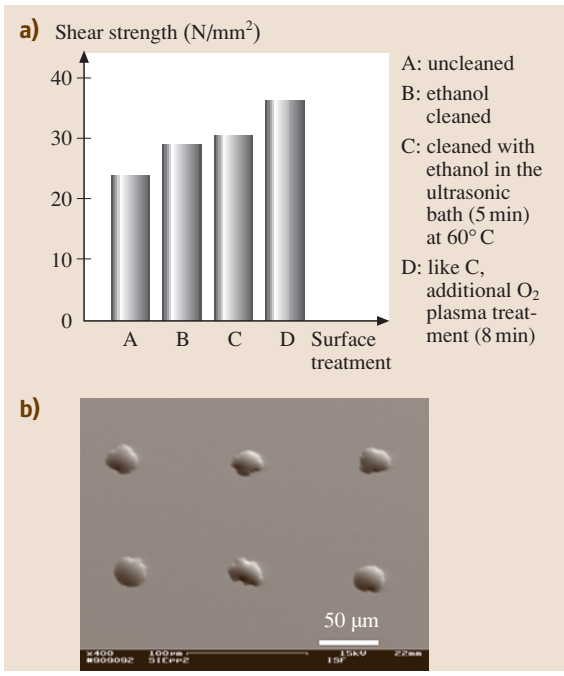

Fig. 7.276a,b Shear strengths on differently cleaned surfaces **(a)**, glass substrate cleaned with ethanol **(b)**

knife which shows recesses in the form of the demanded application geometry. The screen is, in principle, made of steel or nylon and is, by coating knife movement, pressed elastically onto the substrate surface. The application result is determined by the rheological characteristics of the adhesive, the coating knife pressure and speed, and also by the screen geometry and material. The bottom sides of the screen are partly coated in order to prevent threading of the adhesive during the elastic springback of the screen. The stamping method is similar to the screening method. In adhesive printing, the adhesive is, by means of the coating knife, pressed through a metal sheet which is equipped with recesses in the form of the demanded application geometry. In comparison with screening, the adhesive printing method allows the realization of larger printed-layer thicknesses. Both technologies are only suitable for applications on plane surfaces, as, for example, the application of electrically conductive adhesives on printed boards.

Pin-Transfer Technique. For carrying out the pin-transfer technique, a hollow or massive pin is, as a first step, dipped into an adhesive reservoir. Then, a part of the adhering adhesive is transferred to a substrate. The method is simple and characterized by inexpensive design which is easy to parallelize (Fig. 7.277). The technique is suitable for a large viscosity range (100–100 000 mPa s) with, at the same time, large volume spectrum. This includes filled adhesives. The pin-transfer technique, however, is most inflexible as regards a change of the applied volume and of the application geometry. Moreover, the method is characterized by comparatively bad volume exactitudes, a low degree of reproducibility, and high off times.

Dispensing Techniques. The dispensing techniques show, in comparison with the pin-transfer technique and the screening/stamping techniques, substantial advantages as far as flexibility is concerned. The different dispensing techniques allow realization of close to any desired spot or linear-shaped application geometries. With regard to volume and geometry, the individual drops and/or lines are variable over a large range. Typical dispensing volumes reach from the microliter range far into the subnanoliter range. Various dispensing systems which can be differentiated into contact and noncontact systems are used (Fig. 7.278).

In contact dispensing techniques, the adhesive is provided at a capillary by means of a feeding unit

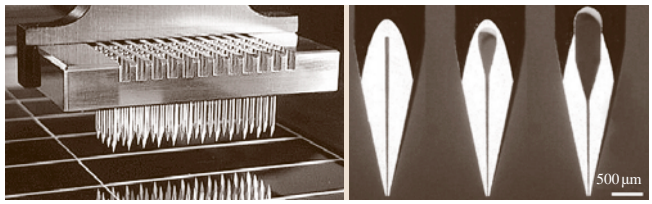

Fig. 7.277 Pin-transfer technique

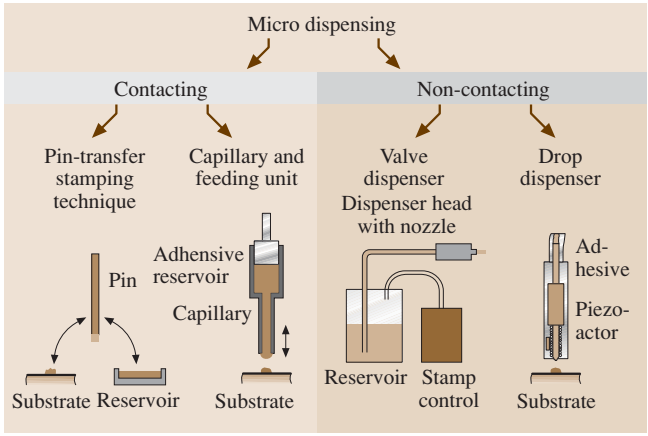

Fig. 7.278 Contact and non-contact micro dispensing

and then transferred to the substrate. The application volume depends mainly on the properties of the adhesive, the capillary, and the substrate [7.257]. The contact methods are characterized by a simple and comparatively inexpensive design. They show advantages particularly in the application of the smallest possible adhesive volumes with, at the same time, large viscosity ranges. The feeding units operate according to different displacement principles. Most frequently applied are piston, screw, peristaltics, and compressed air systems. Figure 7.279 shows a piston dispenser that was developed in the ISF. This unit allows the dispensing of adhesive volumes within the range of a few pl [7.258].

Examples of noncontact dispensing systems are the piezo drop dispenser and the valve dispenser. The piezo dispensers have different designs and operate according to the same principle as ink jet printers. A design which has been established for adhesives application is, for example, a piezoactor, which encloses a glass tube filled with adhesive. The piezoactor is driven and contracted via the voltage, pulse duration, and frequency. As a consequence of the pressure impulse, the adhesive is expelled from the nozzle. The individual drops are within the volume range of 30 and 500 pl. Larger

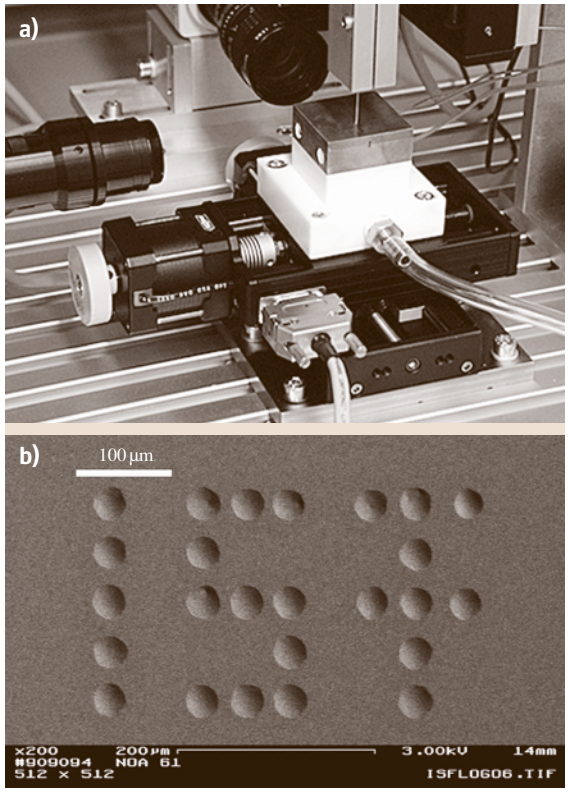

Fig. 7.279a,b Micro piston dispenser (a) and example of dispensing (b)

volumes are realized through multiple dispensing of individual drops at up to 2000 Hz. The volume error is, in this case, lower than 1%. The frequent errors during process interruption and the restricted range of viscosity are disadvantageous. In principle, only unfilled, low-viscosity liquids with viscosities of less than 20 mPa s can be dispensed. With a heated nozzle this range can be increased up to a maximum of 20–10 000 mPa s.

Valve dispensers in general operate with piezo-driven, fast-action needle valves that release an adhesive reservoir that has been under pressure. Modern, heated dispensing systems are capable of dispensing low-viscosity adhesives with viscosities of 70 mPa s up to thixotrope adhesives with viscosities greater than 150 000 mPa s. The minimum adhesive quantities of the individual droplets lie between 2 and 100 nl, where, as a rule, low viscosities make small individual droplets possible. Quantitites of up to 150 individual droplets per second can be dispensed.

A comparison of contact and noncontact dispensing systems shows that the latter have their limits in dispensing very small quantitites and high viscosities. In contrast with contact systems, however, the setting process does not take place. These systems are, therefore, applicable in a much more flexible way and operate mainly independently of the substrate.

7.4.8 Modern Joining Technology – Weld Simulation

Computer simulations are often used to predict useful engineering information regarding weld residual stress and distortion, thus minimizing costly experimental testing and measurements. Simulations are also helpful in the analysis of weld failures, giving insight into which cracking mechanisms are pertinent and which controlling parameters are most important. They are also useful in the development of cracking models, helping to identify which proposed mechanism best fits the observed behavior. Thus, weld simulations have a multitude of uses, but must always be performed in conjunction with experimental tests for verification.

Weld simulations generally require a coupling between two or more models describing thermal, mechanical, or metallurgical behavior. Because welding inherently involves a moving heat source, all things subsequent to welding are related to the weld thermal cycle and its characteristic high temperatures and steep gradients. However, stresses are not all thermal in origin and can be supplemented by stresses associated with solidification and solid-state phase transformations. Reaction stresses, controlled by material resistance and restraining forces, will interact with the local stresses around a moving weld pool to result in global residual stresses upon weld cool down.

A simulation is only as good as the model upon which it is based. It follows therefore that one must have an understanding of the models used and their limitations. Because simulations are based on the coupling of different models for the purpose of predicting weld behavior, the topic of weld simulation must by nature include a discussion of various models as outlined below. Generally, there a two ways to distinguish the various weld simulation procedures. Usually, such simulation tools are divided into weld process simulation and computational weld mechanics.

Taking into account weldability as a component property, being governed by a combination of welding process, construction, and material following DIN 8528 [7.259], a more precise distinction of the various modeling tools is appropriate. Different models in comprehensive simulations, including thermal, structural,

and metallurgical models, interact with each other as shown in Fig. 7.280. Since most simulations are based upon a thermal analysis of weld heat flow and those factors affecting the thermal cycle, this will be addressed first. The subsequent sections then show how structural analyses can be coupled and, finally, it is highlighted how metallurgical models can be incorporated.

Thermal Analysis

Temperature Fields

Heat Conduction. Mathematical modeling of welding heat effects can be carried out analytically or numerically. The well-known anaytical model and associated equations for heat distribution in welding were first developed by Rosenthal [7.260,261]. This model specifically represents heat conduction from a moving heat source in a homogeneous and isotropic continuum, where the field equation is of the differential type of second order

$$\frac{\partial T}{\partial t} = a\left(\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2}\right), \text{ with } a = \frac{\lambda}{c\rho}. \tag{7.176}$$

It contains the local volume-specific heat capacity $c\rho$ (J/(mm^{3}K)), mass-specific heat capacity c (J/(g K)), density ρ (g/mm^3), as well as the material- and temperature-dependent quantity $\lambda/c\rho$ (thermal diffusivity (mm^2/s)).

Analytical calculation of the temperature condition is by nature quasi-steady state. Further necessary simplifications are made by using idealized geometries and a concentrated heat source in the heat-conductive continuum. *Rykalin* [7.262], for instance, considered idealized basic bodies for determining the temperature distribution during welding, depending on the extent of heat distribution in the component: e.g., single-edge limited body, plane layer in space, plate (plane layer with small thickness), and rod (body with straight or only slightly curved axis and small cross-section).

Due to the development of fast computers and increasingly improved software programs available for PC applications, numerical simulations using a finite-element or finite-difference method have become common. Numerical modeling appears also to be more accurate than simple analytical solutions. For this, the field equation describing heat conduction is transformed into a system of linear equations that can then be solved using linear algebra solutions.

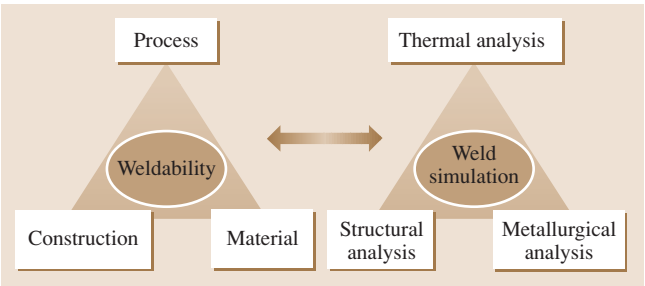

Fig. 7.280 Relation between weldability as a component property, according to DIN 8528 (after [7.259]), and weld simulation

It has to be emphasized that knowledge of the nonlinear material physical properties is important for accurate determination of the location- and time-dependent temperature distribution. For thermal analyses, heat conductivity and arc efficiency are of vital importance [7.263]. However, exact material characteristics for high-temperature applications are available only to a very limited degree [7.264, 265]. For this reason, thermal analytical and numerical calculations of the time-dependent temperature distribution must always be verified by the respective experiments.

Practical and adaptive model networking is essential to achieve economically justifiable computing times. Accordingly, relatively rough model networks or the use of a new style line Gauss heat source are reasonable for numerical temperature field calculations, to achieve agreement between experiment and simulation [7.266–268]. A compilation of typical welding temperature field calculations can be found in Table 7.53.

Specific Heat Sources for Welding. The shape and intensity of the heat source during welding can be completely different from those of other engineering heating processes and, thus, must be incorporated properly into the total thermal model. It must also be mentioned in this context that the temperature field in the component is only dependent on the weld pool up to a distance corresponding approximately to the diameter of the welding heat source. At larger distances the evolving temperature field is determined by the dimensions of the component. For this reason, simplified heat source types have been introduced [7.269], e.g., spot source, linear source, and areal source. In analytical calculations, for example, the spot source can be applied for overlay welding, the linear source for butt welding, and the areal source for friction welding. *Rykalin* [7.262] showed that the heat flow density q for a surface source provides a normal distribution defined by (7.177), and a hemi-

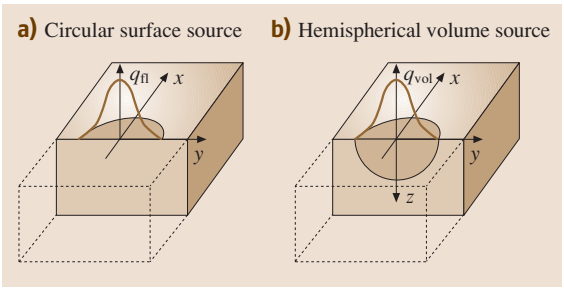

Fig. 7.281a,b View of welding heat sources: Circular surface source **(a)** and hemispherical volume source **(b)**, as defined by *Radaj* (after [7.269])

spherical volume source with normal heat flow density distribution is defined by (7.178) (both are depicted in Fig. 7.281)

$$q_{fl}(x, y) = \frac{3q}{\pi r_{0.05}^2} e^{\left(-\frac{3(x^2+y^2)}{r_{0.05}^2}\right)}, \quad (7.177)$$

$$q_{vol}(x, y, z) = \frac{6\sqrt{3}q}{\pi\sqrt{\pi} r_{0.05}^3} e^{\left(-\frac{3(x^2+y^2+z^2)}{r_{0.05}^2}\right)}. \quad (7.178)$$

There also exist heat source equations that account more appropriately for specific welding processes, like the nonsymmetric-ellipsoidal volume heat source developed by *Goldak* [7.263] shown in Fig. 7.282. This heat source is characterized by front and rear quarter ellipsoids, which can be defined independently of each other. This model takes account of a realistic nonsymmetric heat source density distribution, (7.179), which is always greater in the front semiaxis $x_{0.05f}$ than in the rear semiaxis $x_{0.05r}$. A further advantage is to be seen in the fact that the thermal output figures (f_f and f_r) may be assumed to be different in the front and in the rear ellipsoid

$$q_{volf,r} = f_{f,r} \frac{6\sqrt{3}q}{\pi\sqrt{\pi} x_{0.05f,r} y_{0.05} z_{0.05}} \times e^{\left\{-3\left[\left(\frac{x}{x_{0.05f,r}}\right)^2+\left(\frac{y}{y_{0.05}}\right)^2+\left(\frac{z}{z_{0.05}}\right)^2\right]\right\}}. \quad (7.179)$$

In order to support the modeling of different thermal weld cycles and their respective heat source types, numerous temperature field calculations are listed in Table 7.53.

Thermomechanical Analysis

Calculation of Welding Stresses and Strains. The thermal heating and cooling cycle during welding causes stresses and strains in the longitudinal, transverse and thickness directions of the joint, which are most relevant

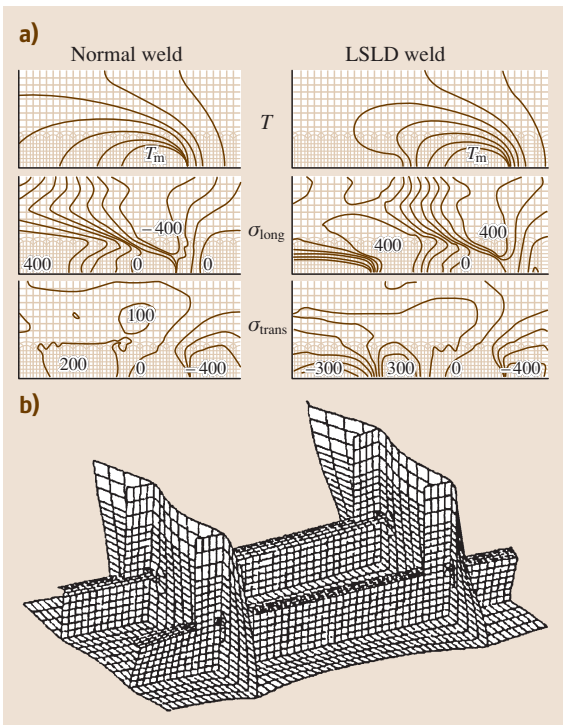

Fig. 7.283a,b Thermo-mechanically calculated distributions of residual stresses and strains in welded joints: **(a)** Temperature and stress contours (after [7.284]), **(b)** welding deformation in test model (after [7.285])

Table 7.54 Approaches to transverse shrinkage assessment of single-pass butt welds (after [7.297])

Method proposed by	Heat input q_s, $S_y = f(q_S)$	Weld cross section A_0, $S_y = f(A_0)$

Capel [7.299]	$S_y = 17.4 \frac{q_s}{h}$ (7.187)	
Spraragen and Ettinger [7.300]		$S_y \approx 0.25 \frac{A_0}{h}$ (7.188)
Richter and Georgi [7.301]		$S_y = n \frac{A_0}{h} + m$ (7.189)

for the fabrication process and, in particular, for the in-service behavior of the respective component. It is thus a major goal of analytical and numerical simulations to assess such stresses and strains, in order to predict buckling and load-bearing capacities. Such stresses and strains should thus be determined in the design phase, when considering the life cycle of a structure or a component. Significant work has been initiated to improve analytical and, in particular, numerical calculations of weld stresses and distortions, and it has to be

expected that such procedures are increasingly applied during the design of welded constructions, as shown in Fig. 7.283a. In this context, stresses and strains transverse to the welding direction will be of major interest in the future, because with the increasing application of high-strength materials, modern lightweight structures will be designed with more stiffeners transverse to the joint direction. Finite-element analyses [7.286] have already demonstrated that transverse shrinkage is, for the most part, caused by thermal contraction of the constructional members adjacent to the weld and that shrinkage of the weld itself only accounts for approx. 10% of the total shrinkage. A summary of simple formulas [7.287] is given in Table 7.54.

More and more, such thermomechanical calculations are connected to respective metallurgical modeling like the investigations of the effects of low-temperature phase transformations on the residual stress distribution, which will be described in the next section. Although there is a general tendency away from the thermomechanical calculations of welding stresses and strains at simple butt joints toward more complex structures (Fig. 7.283b), only a few attempts have been made to consider the thermomechanical interaction that a specific joint may be subjected to in a real construction. Such calculations are applied to real components only to a limited extent, usually due to extremely high computation time and storage capacities, which are required for accurate computational weld mechanics.

An alternative approach to transferring the thermomechanical interaction between the component and a weld joint, from simulations to reality and vice versa, is given by the concept of the intensity of restraint. This approach considers the transverse stresses and strains in a welded joint, which significantly increase the more the shrinkage is hindered by respective assembly parts. In order to quantify such shrinkage restraint, *Satoh* et al. [7.293–295, 302] introduced the restraint intensity principle shown in Fig. 7.284. It is based on the consideration that the suppressed shrinkage transverse to the welding direction S_y is taken up by the weld metal and base metal. Under the assumption that the base metal behaves elastically and that the weld might also plastify to a limited extent, the intensity of restraint of the weld by the surrounding construction is given by the reaction force F divided by that part of the suppressed shrinkage that is taken up by the base metal S_{yB}. The intensity of restraint thus, in principle, represents a spring constant of the construction part transverse to the welding direc-

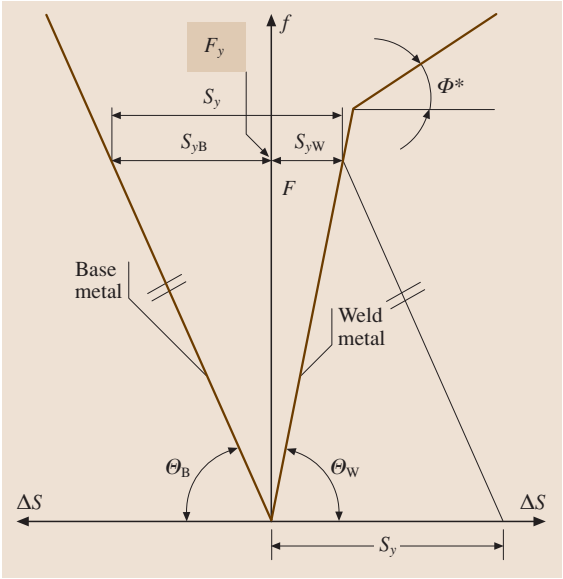

Fig. 7.284 Restraint diagram for the intensity of restraint concept (after [7.293–295, 302])

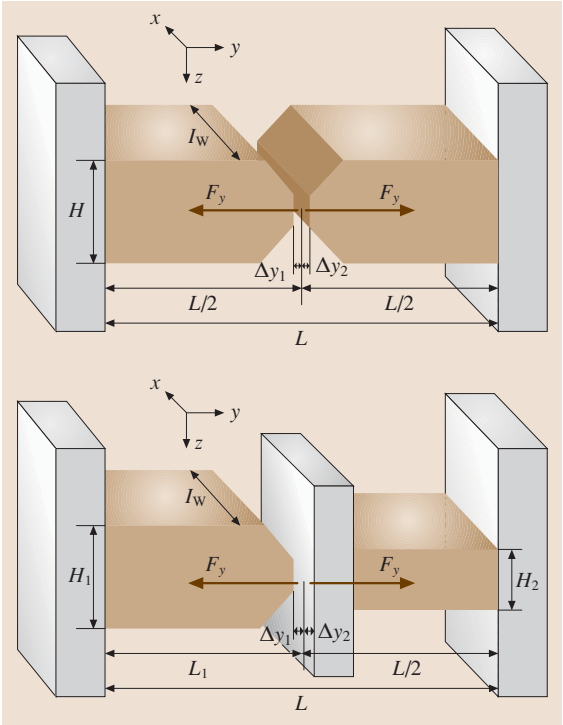

Fig. 7.285 Restraint and reaction forces at symmetric and at asymmetric joints (after [7.303])

tion, normalized to the weld metal length l_W as depicted in Fig. 7.285 [7.293–295]

$$R_{F_y} = \frac{F}{s l_W}\,, \quad R_{F_y} = \frac{F}{2\Delta_y l_W}\,,$$
$$R_{F_y} = \frac{F}{(\Delta_{y1} + \Delta_{y2}) l_W}\,,$$
$$R_{F_{y,tot}} = \frac{1}{R_{F_{y,1}}} + \frac{1}{R_{F_{y,2}}} + \frac{1}{R_{F_{y,3}}}\,. \qquad (7.190)$$

Since the base material behaves elastically, the transverse shrinkage restraint of a specific weld joint can be evaluated by application of a respective force transverse to the welding direction and by measurement or calculation of the respective root gap displacement Δy. More conveniently, the intensity of restraint can be calculated with finite-element analysis during the design phase, where the transverse residual stresses can be assessed, knowing the transverse shrinkage restraint [7.303, 304]. Such calculations confirm that the intensity of restraint for T- and orbital joints can become significantly higher than that of similarly dimensioned butt joints (Fig. 7.287). Dividing the region around a restrained component weld into a near and far field [7.305], it has been found that the total restraint of a joint results from a combined contribution of weld edge preparation, $R_{F_{y,1}}$, plate dimensions, $R_{F_{y,2}}$, and surrounding assembly, $R_{F_{y,3}}$, respectively, as illustrated in Fig. 7.286 and defined in (7.190) [7.303].

For numerical thermomechanical analyses using finite elements, the temperature field analysis and

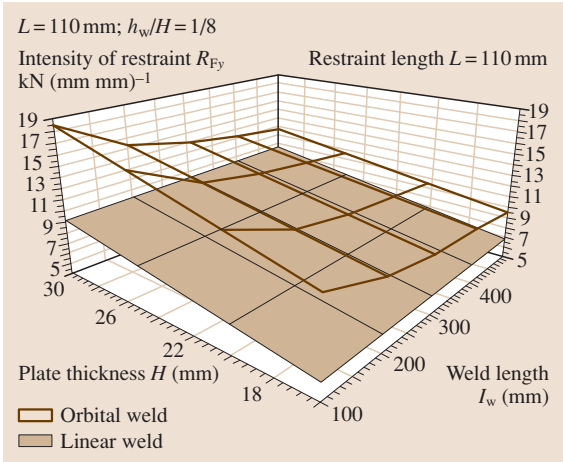

Fig. 7.286 Restraint intensity for linear and orbital welds as a function of plate thickness and weld length (after [7.303])

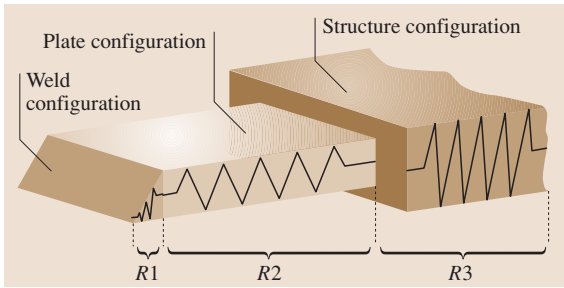

Fig. 7.287 Restraint intensity subdivision model (after [7.283])

the structural analysis can be linked in various ways [7.283]. Usually, such simulations are carried out in an indirect coupled or in a decoupled modus. In a completely decoupled calculation, the temperature data determined by thermodynamic analysis are transferred to the thermomechanical model as time- and location-dependent input data for computation. For such a procedure, the time step intervals have to be identical in the temperature field analysis and the subsequent structural analysis.

A factor of crucial importance for numerical analyses of the temperature-dependent stress–strain distribution in welds is the availability of appropriate material properties. Depending on the computation objective, various accuracy categories have been established in welding engineering (Table 7.55).

As already mentioned with respect to restraint intensity, the accurate transfer of the real component geometry to the finite element code is additionally important in numerical calculation of welding-specific residual stresses and component distortion. The model depth (degree of detailing) can thus be structured in the following ways [7.283]:

2-D Models. Numerical calculation of welding-specific stress conditions using 2-D FE models constitutes a strong simplification of real conditions. With a very low stress gradient in the thickness direction (thin sheet metal), the existent plane stress condition (PSC) can be represented with the help of a 2-D model.

Combined Models. Combined models of the area near the weld usually consist of 3-D networks which allow statements to be made regarding stress as well as component distortion in all coordinate directions. Component areas at a greater distance from the weld, in which a stationary stress distribution prevails, are two-dimensionally networked (3-D–2-D model). Furthermore, the influence of the component/surrounding

Simulation accuracy	Computation objectives
Reduced accuracy level simulation	Simple, fast models
Basic simulation	Calculation of residual stress and distortion for simple geometries Neglect of the material behaviour in the high-temperature range
Standard simulation	Calculation of residual stress and deformation for complex geometries Calculation of transient stress and deformation
Accurate simulation	Calculation of residual stress and deformation for complex geometries taking account of the microstructure
Very accurate simulation	Extended detailed simulation, e.g. hot cracking

Table 7.55 Accuracy categories for welding simulation (after Lindgren [7.283])

structure can be represented by 1-D rod or spring elements (3-D–1D model).

3-D Models. For detailed calculation of the residual stress and distortion behavior of welded components, 3-D models are now used for the most part. In order to optimize the computation time, super elements and/or (statically, dynamically) adaptive networks are employed in the procedure. Super elements allow it to integrate the properties of complete workpiece regions and to reduce at the same time the number of degrees of freedom. The idea behind adaptive networking is a network refinement of the areas with expected high temperature and stress gradients. The welding residual stress histories of multipass welds change with specimen thickness, heat input, and phase transformation effects.

Numerical calculations of the thermal stress–strain still have some limitations, as for instance:

- Exact simulation of the specific volume increase in the case of phase transformations
- Limited thermophysical and mechanical properties in the high-temperature range (200–400 °C)
- Incorporation of exact welding TTT diagrams
- Application of elastoplastic principles
- Calculation convergence at high strains and accuracy of results

Goldak [7.306] turned these unsolved tasks into ten major challenges for future thermomechanical simulations, and it can only be emphasized that computational thermomechanical results should generally be confirmed experimentally. Figure 7.288 illustrates the significance

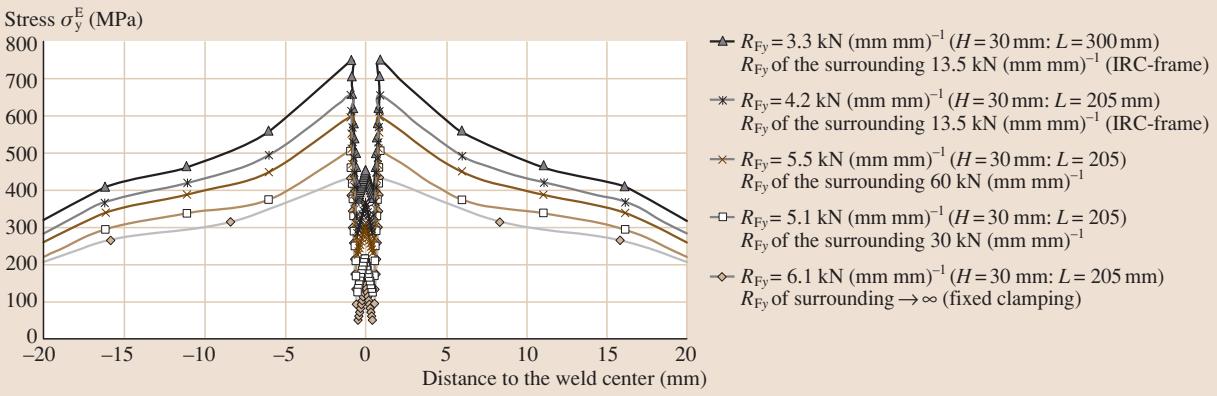

Fig. 7.288 Reaction stresses transverse to the welding direction dependent on the intensity of restraint R_{F_y} (after [7.283])

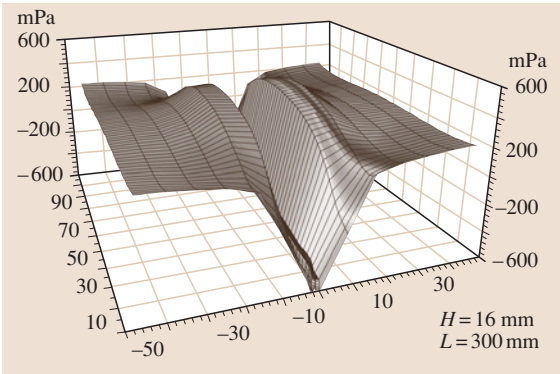

Fig. 7.289 Distribution of transverse reaction stresses in a V-beveled butt joint at $R_{F_y} = 2.1\,\mathrm{kN(mm\,mm)^{-1}}$ (after [7.283])

of an increasing restraint intensity on the reaction stresses transverse to the welding direction; thus the experimentally validated numerical simulations should be carried out with the best possible specimen analogy and representation of the actual shrinkage restraint of the real surrounding structure. This can most conveniently be accomplished by respective component weld tests or full-scale tests. This means the numerical simulation and its experimental validation have to be carried out considering very carefully the intensity of restraint for an accurate transfer of the simulations. Under such conditions, the results of thermomechanical numerical simulations can be transferred into reality and vice versa. Three-dimensional diagrams of the stresses and strains, as shown in Fig. 7.289, can significantly support design optimization of welded components to avoid high local stresses and strains introduced during welding, and to provide respective larger service load capacities.

Weld Pool Fluid Mechanics

Weld Pool Shape. The shape of the weld pool in arc welding is of significant practical importance and the depth of penetration is usually of particular interest. Most engineering applications require that a certain penetration be achieved to meet specific structural and quality assurance requirements (e.g., to avoid lack of fusion). Considering heat conduction alone, and assuming a point heat source (e.g., the Rosenthal equation discussed earlier), the pool cross-section is predicted to be a hemisphere with a 0.5 depth-to-width (D/W) ratio. That this shape is seldom achieved (e.g., normally, D/W ≈ 0.4 for GTAW) can be attributed to two things: (1) a broad, Gaussian heat source (see discussion on heat flow above) and (2) convective heat flow, transferring heat from directly under the arc to outer regions in the pool.

Numerous factors control the convective flow of liquid in a weld pool including arc force, buoyancy force, magnetic force (Lorentz), and surface tension (Marangoni). The arc and buoyancy forces are small relative to Lorentz and Marangoni forces, and are often neglected. The Lorentz force dominates at high currents (> 100 A), whereas the Marangoni force may dominate at low currents. The Lorentz force causes fluid flow towards the pool center and downward, regardless of current polarity, and thus contributes to improved penetration. The magnitude of this force varies directly with current raised to the fourth power (I^4). Because of this strong dependence on current, this is the process parameter normally used to control penetration. It is also commonly observed in empirical equations used to predict penetration (P), e.g., the Jackson equation given below [7.307]

$$P = k\left(\frac{I^4}{SV^2}\right)^{1/3}, \qquad (7.191)$$

where k is a constant, S is travel speed, and V is arc voltage. It should be pointed out from this equation that increases in voltage or travel speed normally result in diminished penetration. At higher voltage the arc spreads out, distributing heat over a larger area. At higher travel speeds, the heat input per length of weld is reduced.

The Marangoni force is related to surface-tension temperature-gradient-driven fluid flow, where flow at the pool surface progresses from regions of low surface tension to regions of high surface tension [7.308]. It is assumed that the center of the pool, directly under the arc, is hotter than at the pool perimeter. How surface tension varies across this temperature gradient depends upon the presence of surface active elements, primarily sulfur and oxygen. For alloys with $\mathrm{d}\gamma/\mathrm{d}T > 0$ (e.g., steel with high sulfur: $S > 300$ ppm), the center of the pool will have the highest surface tension, thus the flow will be toward the pool center and down, enhancing penetration. For alloys with $\mathrm{d}\gamma/\mathrm{d}T < 0$ (e.g., steel with low sulfur: $S < 30$ ppm), flow will be from the pool center to the pool periphery, thus inhibiting penetration. This unusual behavior caused considerable concern when ultra-high-purity, vacuum-arc-remelted stainless steels were first introduced in the 1970s; they were considered unweldable because they could not be penetrated.

Numerical simulations have been used effectively to accurately predict weld pool shape, accounting for

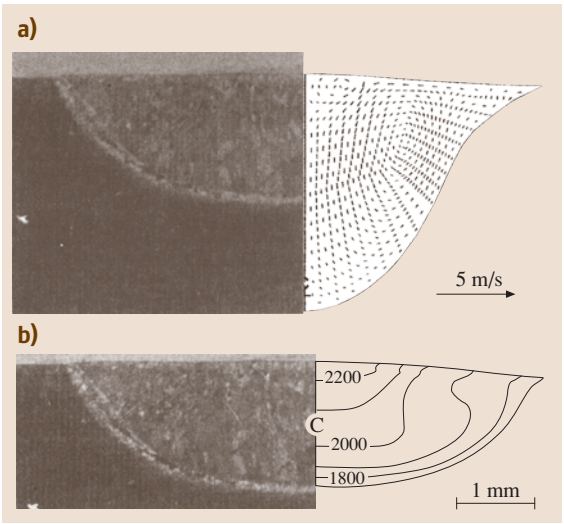

Fig. 7.290a,b Cross-section of a weld made on AISI 304 stainless steel (0.005 wt % S) compared with two different predicted weld pool shapes assuming **(a)** laminar flow and **(b)** turbulent flow (after [7.313])

the forces outlined above [7.309–312]. In more recent work, a distinction has been made between conditions giving laminar versus turbulent flow, permitting more accurate pool shape predictions [7.313], an example of which is given in Fig. 7.290.

In joining processes where the heat source power density is much higher than for normal arc welding (e.g., plasma arc, EB, and laser beam processes), considerable vaporization of the weld pool may occur allowing formation of a keyhole (i. e., a vapor cavity extending thru-thickness). When operated in the keyhole mode, these high-power density processes permit the welding or cutting of thick material in a single pass. This offers considerable savings in terms of labor and consumable costs, plus these joints typically have better mechanical properties due to smaller weld cross-sections and HAZs, and fewer defects normally attributed to multiple pass welding. Popular today is a hybrid combination of processes (e.g., plasma arc plus laser) which combine the keyhole-forming ability of lasers with the better seam tracking, penetration, and stability characteristics of plasma [7.314]. Stability is a topic of special interest in modeling keyhole welding, due to the tendency for molten metal at the trailing edge to collapse the keyhole, resulting in spiking (i. e., variable penetration) and entrapment of large pores. One can consider the force balance associated with a stable keyhole [7.315], where the pressure of the gas flow must be equal to or greater than the surface tension pressure plus the hydrostatic head

$$\frac{\rho_g v^2}{2} \geq \frac{\gamma}{r} + \rho_L g t \,, \tag{7.192}$$

where ρ_g and ρ_L are densities of the gas and liquid metal, respectively, v is the gas velocity, γ is the surface tension, r is the radius of curvature of the liquid surface, g is the gravitational acceleration, and t is the plate thickness. This process has been numerically modeled to show keyhole formation and collapse [7.316].

Weld Pool Oscillation. Weld pools are observed to oscillate at a characteristic, natural frequency dependent upon pool size, geometry, material, and mode of oscillation. Fundamentally, the natural frequency of an oscillating molten droplet is described by the relationship [7.317]

$$f = N\sqrt{\frac{\gamma}{\rho V}} \,, \tag{7.193}$$

where N is a mode-dependent constant, γ is the surface tension, ρ is the density, and V is the volume. If simple pool shapes are assumed (hemisphere for partial penetration, cylinder for full penetration), the volume term above can be expressed in terms of pool diameter (D). The following expressions evolve, with constants determined from experimental data for plain carbon steel welds on a 4-mm plate [7.318]

Mode 1 (partial penetration, peak–valley)

$$f = 2.030 D^{-3/2} \,; \tag{7.194}$$

Mode 2 (partial penetration, slosh)

$$f = 967 D^{-3/2} \,; \tag{7.195}$$

Mode 3 (full penetration)

$$f = 260 D^{-1} \,. \tag{7.196}$$

Use has been made of natural frequency measurements in order to monitor and control weld penetration. When a weld goes from partial to full penetration, its mode of oscillation changes (e.g., Mode 1 to Mode 3). This typically results in a large decrease in natural frequency and a higher amplitude of oscillation. This change can be detected from pool oscillation measurements and can be used for computer feedback control of penetration, where the arc current is normally adjusted to maintain penetration [7.319, 320]. Pool oscillation can be measured indirectly from arc voltage or light intensity measurements, with signals processed using a fast Fourier transform (FFT) to identify natural frequencies [7.321–324].

Thermo-Mechanical-Metallurgical Analysis

Diffusion Analysis. Most of the metallurgical phenomena related to welding are dependent on the kinetic process of diffusion, which can be defined as an atomic transport of matter in a metal matrix [7.325, 326]. In welding, diffusion normally occurs under conditions of high stress and temperature gradients. Because most diffusion processes can quite conveniently be numerically simulated, modeling of diffusion will be discussed ahead of the other simulations related to weld metallurgy. With regard to welding applications, diffusion is often used to investigate the transport of interstitials, e.g., monatomic hydrogen or nitrogen moving through a homogeneous metal lattice.

Under ideal conditions, i. e., by exclusion of additional effects, the flux of the interstitial atoms passing through a unit plane is proportional to the concentration gradient, where the proportionality constant is the diffusion coefficient. This is Fick's first law, which in the 1-D case can be written as

$$J = -D_x \left(\frac{\partial C}{\partial x} \right) , \tag{7.197}$$

where J is the flux of the substance passing through the specific plane and C is the concentration of the substance. The diffusion coefficient varies with temperature and can be described by an Arrhenius relationship as

$$D_x = D_0 \exp \left(-\frac{E_A}{RT} \right) , \tag{7.198}$$

where D_0 is the diffusion coefficient and E_A is the activation energy. Usually, the continuity equation of the conservation of matter is true under such conditions. This means that the time-dependent change in concentration equals the divergence of the flux, and thus for the 1-D case

$$\frac{\partial C}{\partial t} = -\frac{\partial J}{\partial x} . \tag{7.199}$$

The combination of (7.197) and (7.199) gives Fick's second law in the 1-D version [7.325]

$$\frac{\partial C}{\partial t} = D_x \left(\frac{\partial^2 C}{\partial x^2} \right) \text{ and } \frac{\partial C}{\partial t} = \nabla (D \nabla C) ,$$

for the multidimensional version. (7.200)

Such diffusion processes can be numerically modeled using the thermal module of commercial finite-element programs by assignment of the heat conductivity K to the so-called effective diffusion coefficient D_{eff} ($K \Leftrightarrow D_{\text{eff}}$) and by setting the specific heat C_p and the density ρ to unit one ($C_p = 1$, $\rho = 1$) [7.327–329]. Modeling by Fick's laws can be applied in good agreement with experimental results not only for the diffusion of an interstitial like hydrogen, nitrogen, or carbon in a metal lattice, but also for the diffusion of such atoms in homogeneous microstructures, if they are bound at specific sites, but they can all still be activated at the respective thermal conditions. The latter process is generally regarded as reversible trapping.

In the case of irreversible trapping, part of the hydrogen will be kept tenaciously so that this fraction will no longer take part in the diffusion process. Beginning with McNabb and Foster, quite a number of researchers have developed models for such trapping processes, in particular for hydrogen, in the past 50 years [7.327–329], but still with a lack of consistency in experimental results.

In particular, hydrogen has often been reported to be accumulated in weld regions with high residual stresses and strains. Such attraction of hydrogen in crack-susceptible regions is considered to be based on diffusion-enhancing effects, like hydrogen transport with moving dislocations, etc.. Such diffusion enhancing by mechanical stressing or straining of the microstructure can be modeled by inserting an additional potential field in the 3-D version of Fick's second law, which has been investigated extensively by Sofronis et al. [7.330]. However, such numerical analyses have not yet been sufficiently verified by experimental results.

It has been discovered in the past 10 years that modeling hydrogen diffusion in weld microstructures, in particular for carbon, martensitic, and ferritic steels, can be carried out quite consistently by experimentally validated numerical analyses based on Fick's laws [7.327–329]. This means that numerical simulation of a hydrogen concentration profile is possible for the most hydrogen-susceptible weld microstructures. The most important results of such modeling procedures are the development of geometrical hydrogen distribution versus time and the determination of respective removal heat treatments. It can only be emphasized that for such calculations the correct temperature diffusion coefficients (Fig. 7.291) for the particular weld microstructures and thermal cycle have to be inserted into such numerical simulations [7.328]. More recently, the numerical calculation of the geometrical and thermal hydrogen distribution in weld microstructures has been extended by simulation of respective crack initiation and propagation [7.329].

Solid-State Transformations

Welding Specific Transformation Behavior. Knowledge of the thermomechanical relationships between material (welding-specific microstructure transformations) and structure (external structural shrinkage restraint) is becoming of great interest to welding fabrication. Deliberate load-relieving reactions, resulting from the phase transformation behavior of a particular base or filler metal combination, are gaining increasing importance with regard to their influence on the global structural load during fabrication and service. Effects of filler materials with low transformation temperatures on reducing the reaction forces and respective stresses in restrained joints have been reported for high-strength structural steels [7.331] as well as for supermartensitic stainless steels (Fig. 7.292).

The current simulation tasks thus include, above all, studies of the effects of microstructural transformation (martensitic transformation) on various base and filler material combinations (mismatch) as well as studies of the effects of varied heat input during single-pass and multipass welding on the structural load level and distribution of a welded component. The observed significant effects of low-temperature phase transformations on the residual stress distribution were confirmed by *Karkhin* et al. [7.332] by numerical simulations of laser welds (Fig. 7.293). As also stated, the accuracy of such simulations is very sensitive to the measurement of steel properties in the phase transformation range, which thus represent the most important input data for the numerical analyses. In addition, it has to be pointed out that it is essential in the numerical calculation to also take into account the influence of latent heat (transformation enthalpy) on the temperature field which, depending on the weld volume, is basic to an accurate analysis of the global structural load as a result of shrinkage restraint and phase transformation. As concerns higher- and ultra-high-strength materials, the aspect of a load-dependent accelerated phase transformation and of a correspondingly induced transformation plasticity (load-dependent transformation behavior) has additionally to be considered, specifically at high weld stiffness with potential plastic predeformations.

Investigations of the phase transformation behavior in freely shrinking welds generally entail highly simplified assumptions of residual stress levels and distributions in welded structures, e.g., general existence and equal distribution of tensile residual stresses in the amount of the yield strength (or of a specific percentage) and thus, still lead to too conservative designs [7.333]. Thus it is again emphasized that one must clarify the interaction of basic microstructure-specific processes in a real welded structure as well as provide quantitatively correct numerical and experimental coverage of the timely and locally nonstationary metallurgical and thermomechanical processes in the weld. This must be done in consideration of the influence of defined external geometric and structural shrinkage restraints.

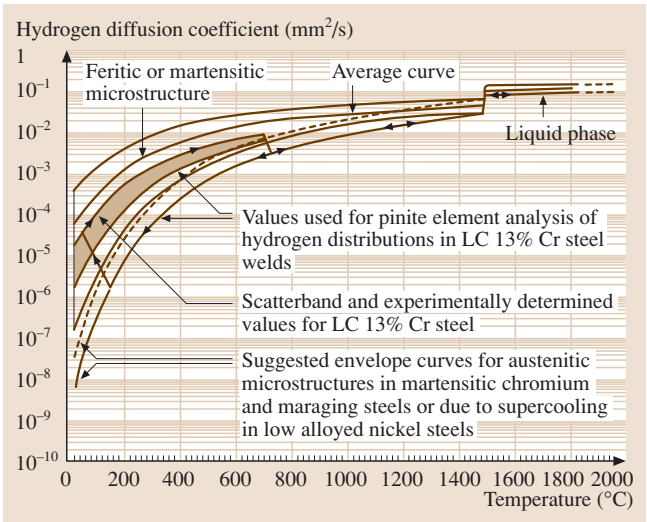

Fig. 7.291 Temperature dependent hydrogen diffusion coefficient in microalloyed structural steels (compilation of respective literature data into a scatterband) (after [7.328])

Hydrogen-Assisted Cold Cracking. Hydrogen-assisted cracking (HAC) of welded components has to be distinguished as two separate phenomena: hydrogen-assisted cold cracking (HACC) and hydrogen-assisted stress corrosion cracking (HASCC). The first appears predominantly during or in a limited time after the fabrication process, while the latter occurs during service of welded components, usually significantly reducing its life time. From the engineering standpoint, both phenomena most conveniently and more macroscopically can be regarded as an interaction between the local hydrogen concentration, mechanical load, and weld microstructure.

HACC and HASCC can then be considered as very similar failure phenomena with their differences only in the source of hydrogen. Regarding HACC, hydrogen is primarily transferred to the liquid weld pool after dissociation in the arc. It usually is introduced into the welding process by moisture on the base and filler materials, leaking cooling systems, and, sometimes, by nonremoved primers and coatings before welding. Regarding HASCC, hydrogen is taken up from a corrosive

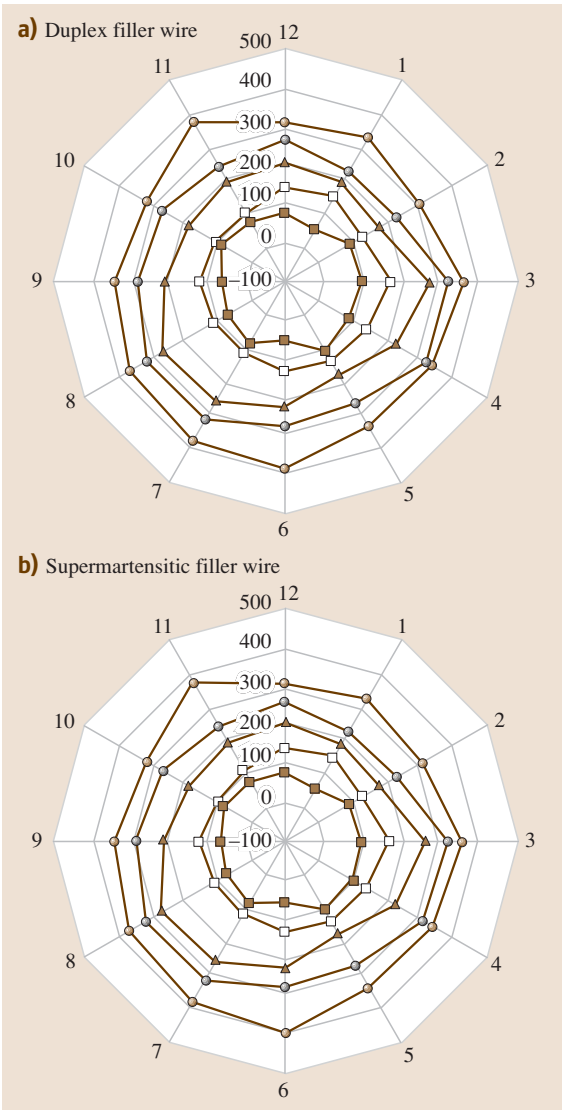

Fig. 7.292a,b Effect of selection of low temperature deforming supermartensitic stainless steel filler wire selection on the reduction of the circumferential stress distribution in an orbital pipeline weld (after [7.334]): **(a)** Duplex filler wire, **(b)** supermartensitic filler wire

sour aqueous environment, frequently containing hydrogen sulfide acting as a promotor.

With increasing application of high-strength structural materials and increasing mechanical loads introduced during fabrication welding, by lightweight design and respective high shrinkage restraints, but also during service by increasing acidity during prolonged life times of welded components, failure cases, some of catastrophic dimensions, originated by HACC or/and HASCC have been increasing recently. There is thus an increasing demand for modeling procedures to calculate hydrogen removal during welding pre- and postweld heat treatments, to assess crack propagation, and to predict the lifetime of welded components in corrosive environments.

Quite a number of analytical models have been developed to simulate HAC, predominantly HASCC, which are mainly based on stress–strain thresholds and, thus, have to be regarded as crack-no-crack models. Rates of HAC growth have less often, though still been modeled analytically [7.335]. A numerical procedure to simulate HAC has thus been developed [7.336, 337], considering the cracking process as the propagating failure of fictive tensile specimens alongside the crack path [7.338], each being represented by a finite element in the numerical procedure (Fig. 7.294a).

As shown by the flow chart in Fig. 7.294b, numerical modeling starts with an analysis of the hydrogen concentration profile to evaluate the local hydrogen concentration near the crack tip. In the second step, the local mechanical load in terms of local strains or stresses is analyzed. The critical hydrogen concentration in the crack initiation range or near the crack tip, respectively, is then calculated from the crack criteria, usually given as a database or as a mathematical relation of the material properties dependent on the hydrogen concentration. Crack initiation or propagation, respectively, appears if the local hydrogen concentration at the crack tip exceeds the critical hydrogen concentration. After a respective time and crack increment, the procedure starts from the beginning and repeats. As particular advantages, in contrast to analytical models, such a numerical procedure allows exact calculations of the crack increment per time interval and also considers correctly the geometric effects of crack propagation on the hydrogen redistribution at the crack tip. Such numerical procedures generally require exact input data extracted from experimental results, like the diffusion coefficient and, in particular, hydrogen-dependent material properties.

As shown by Fig. 7.295, such numerical modeling has meanwhile been successfully applied to HASCC [7.336] as well as to HACC [7.338] in welds of supermartensitic stainless steels used for offshore pipeline applications. During recent failure cases, it turned out that HASCC in critical regions sometimes was associated with previously undetected HACC phenomena. Thus, more recent investigations have focused on the evaluation of hydrogen diffusion and cracking

in high-strength structural steel welds [7.339], first providing the respective crack criteria and then developing numerical modeling aimed at crack avoidance and lifetime assessments of such components.

Liquid–Solid Transformations A fundamental understanding of weld solidification has evolved over time, based upon the application of general solidification models to the conditions specific to welding [7.340–342]. Included among these weld-specific conditions are epitaxial nucleation on base metal grains, continuous advancement of a liquid–solid interface, variable temperature gradient/growth rate (G/R) conditions along the liquid–solid interface, and high-temperature gradients (G). Each of these conditions has a marked effect on weld solidification structure and the development of defects:

- Epitaxial nucleation results in continuous columnar grains.
- Irregular advancement of the liquid–solid interface results in banding.
- Low G/R at the weld centerline results in grain refinement.
- High G/R results in fine dendrite spacing.

Due to the rapid cooling rate associated with welding, there is only limited time for diffusion of solute in the solid. Thus, nonequilibrium conditions apply to weld solidification, which typically occurs in either a dendritic or columnar-dendritic mode. Dendrite spacing has been shown to vary inversely with the square root of cooling rate [7.343, 344], where the cooling rate can represented by G/R. Thus, the scale of dendrites and microsegregation tends to be an order of magnitude smaller for welds than for castings (approx. 10 μm versus 100 μm), because cooling rates are much higher (approx. 100°/s versus 1°/s).

Models and simulations regarding solidification grain structure and microsegregation are discussed below. Also addressed are weld solidification defects including liquation and solidification cracking (both sometimes referred to as hot cracking) and porosity. Additional aspects of weld solidification phenomena can be found in general reviews on the subject [7.345, 346].

Grain Structure. Weld metal grains tend to be columnar and smaller in diameter than those found in castings (approx. 100 μm versus 1000 μm), in part because of the epitaxial nucleation of weld metal grains on small base metal grains. Grain growth competition also plays a role in this, wherein grains not having a favorable orientation (i. e., with dendrites parallel to heat flow direction) must grow at a higher undercooling. Such grains will eventually become occluded, either from adjacent grains or from nucleation of a new grain [7.341]. Thus, competitive grain growth tends to limit the growth of most columnar grains, although this appears to not always be case (e.g., austenitic stainless steels and titanium alloys exhibit exceptionally large weld metal grains).

Columnar grains grow normal to the weld pool boundary, as this minimizes energy associated with grain boundaries. Thus, the shape of the weld pool determines the growth path of the columnar grains [7.340]. The development of weld metal grain structure has been modeled and simulated using a variety of methods including cellular automata [7.347, 348], grain boundary evolution [7.349–351], and Monte Carlo [7.352], imposing boundary conditions for epitaxial nucleation, weld pool shape, and competitive growth. These simulations have proven useful in predicting weld metal grain structure for a given weld pool shape, as demonstrated in Fig. 7.296 [7.351].

Of particular interest to weldability, for improved mechanical properties and resistance to solidification cracking, is the ability to grain refine, i. e., replace columnar grains with equiaxed grains. Grain refinement requires a combination of high undercooling

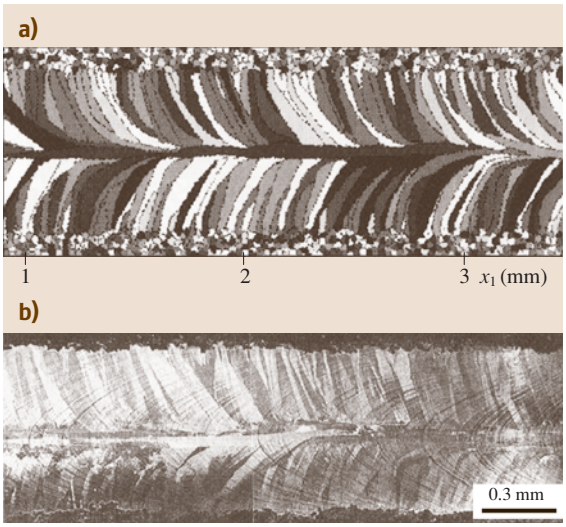

Fig. 7.296a,b Cellular automata simulation of weld grain structure **(a)** compared against actual weldment **(b)**, as viewed from top surface (after [7.351])

plus a substrate suitable for grain nucleation. Models used to predict the columnar-to-equiaxed transition (CET) must examine the undercooling ahead of dendrites in a columnar grain, which takes the following form [7.353]

$$\Delta T = \frac{GD}{R} + AR^{1/2}\,, \qquad (7.201)$$

where D is the solute diffusivity in the liquid and A is a material constant. Assuming site saturation for the nucleation of new grains ahead of the advancing columnar grains, equiaxed grains will nucleate at some critical undercooling, ΔT_N, and then grow until impingement by the columnar grains. CET can be achieved if these equiaxed grains have time to grow to sufficient size before impingement occurs [7.355]. This model has been applied to welding [7.356], where it has been shown that equiaxed grains can be expected at the weld center (high R) and along the fusion line (low R), i. e., locations of high undercooling.

Microsegregation. Modeling of microsegregation for nonequilibrium, dendritic solidification has been accomplished using the Scheil equation [7.357]

$$C_s = kC_0(1 - f_s)^{k-1}\,, \qquad (7.202)$$

where C_s is the solute concentration in the solid at the liquid–solid interface, k is the equilibrium partition coefficient, C_0 is the nominal solute concentration, and f_s is the solid fraction. When applied to a volume element oriented perpendicular to a cellular-dendrite axis (Fig. 7.297), this equation can be used to describe the distribution of solute across the core of the dendrite, assuming there is no diffusion in the solid.

In cases where corrections must be made for back-diffusion, a numerical finite difference solution becomes useful. An example of this is given in Fig. 7.298, showing the results of a numerical simulation using the Scheil equation, corrected for back-diffusion, for a Fe-21%Cr-14%Ni stainless steel alloy weld metal [7.354]. The nickel content is represented by various shades of gray and assuming solidification proceeds as either (a) primary austenite or (b) primary ferrite. In the case of primary ferrite, there is considerably more homogeneous distribution of nickel, due to a higher diffusivity.

Liquation Cracking. Liquation cracking, also known as microfissuring, occurs in the partially melted zone (PMZ) of the HAZ due to the separation of liquid films present in grain boundaries. Certain alloy systems are

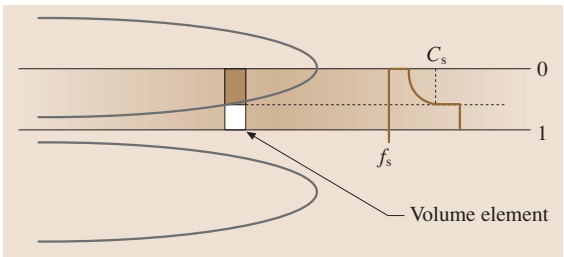

Fig. 7.297 Schematic of cellular-dendrite showing Scheil volume element and solute distribution within dendrite

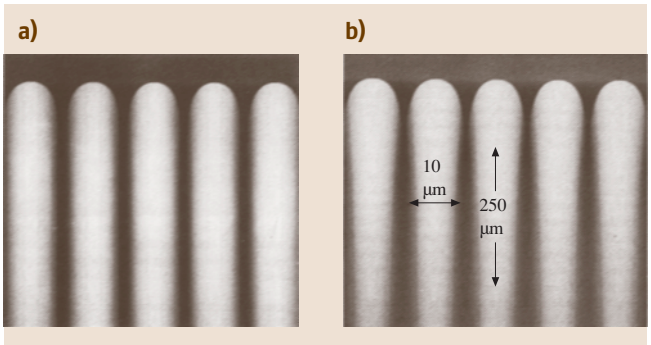

Fig. 7.298a,b Predicted distribution of nickel across cellular-dendrites in Fe-21%Cr-14%Ni solidifying as **(a)** austenite and **(b)** ferrite. Ni concentration increases with increasing darkness (after [7.354])

notably susceptible to this defect (e.g., nickel-based alloys and aluminum alloys). In nickel-based alloys (e.g., alloy 718), problems with liquation have been tied to the presence of niobium carbide (NbC) particles [7.358]. Aluminum alloys of the type Al-Mg-Si are known to be particularly problematic with regard to liquation [7.359, 360]. Even when there is insufficient strain to cause cracking, microstructural damage caused by liquation alone can impair joint performance.

One early model for liquation focused on nonequilibrium conditions, relating melting to the partial dissolution of residual eutectic particles present at grain boundaries, better known as constitutional liquation [7.362]. As solute diffuses from grain boundary particles into the matrix, melting will occur at a point where the eutectic composition is reached, provided the eutectic temperature has been exceeded. This assumes that the particle does not completely dissolve before the eutectic temperature is reached. The rapid heating and cooling rates associated with welding are particularly conducive to this mechanism as demonstrated in a coupled heat and mass flow model [7.363]. The liquid film produced during constitutional liquation can spread along grain boundaries and promote constitutional liquid film migration (CLFM) as observed in the nickel-based alloy 718 [7.358].

In more recent studies on aluminum-copper alloys [7.364], it has clearly been shown that equilibrium liquation is also possible whenever the solidus temperature is exceeded, although the kinetics of such reactions are not well established. It was demonstrated that cracking is likely to occur only under specific solidification conditions, where the weld metal fraction solid is consistently above the partially melted zone fraction solid [7.365]. This suggests that a strong weld metal, capable of resisting strain, will transfer strain to the HAZ where cracking can then initiate. Curves representing solid fraction were calculated based upon the Scheil equation (7.202).

Solidification Cracking. Solidification cracking involves the separation of liquid films present at grain boundaries in the mushy (liquid + solid) zone trailing the weld pool. Both thermal strains and solidification shrinkage act in conjunction to pull grains apart, initiating and sustaining crack growth. Certain alloys (e.g., fully austenitic stainless steels, steels having high sulfur or phosphorus impurity levels, and high-strength aluminum alloys) are known to be particularly susceptible to this type of cracking. A large solidification range and a continuous, columnar grain structure appear to favor cracking [7.366].

Numerous tests have been developed to asses cracking susceptibility, including Varestraint [7.367], circular patch [7.368], sigmajig [7.369], and PVR [7.370] tests. These tests rely upon large, reproducible, externally augmented strains (extrinsic type test) or internally generated strains (intrinsic type test) to generate extensive cracking for comparative purposes. These tests allow weldability to be quantified in terms of crack length and can thus be used to compare the cracking susceptibility of different base metals, filler alloys, and welding procedures. Cracking is often quantified in terms of total accumulated crack length (TCL), although the exact meaning and relevance of this value is questionable.

Most cracking models have centered on defining a brittle temperature range, and the maximum tolerable strain within this range, for predicting the behavior of a given alloy [7.371, 372]. At its extreme, this temperature range is bounded by the liquidus and solidus, but it has also been taken to be more restrictive, e.g., a coherent temperature range, whereby dendrites have interconnected and can resist strain. More recently, the maximum length of crack generated in a Varestraint test has been used to identify a critical temperature range for cracking, i. e., solidification cracking temperature range (SCTR), which may reflect more on an inherent propensity for cracking than TCL [7.373].

Other approaches have examined the conditions necessary for crack initiation based upon a drop in in-

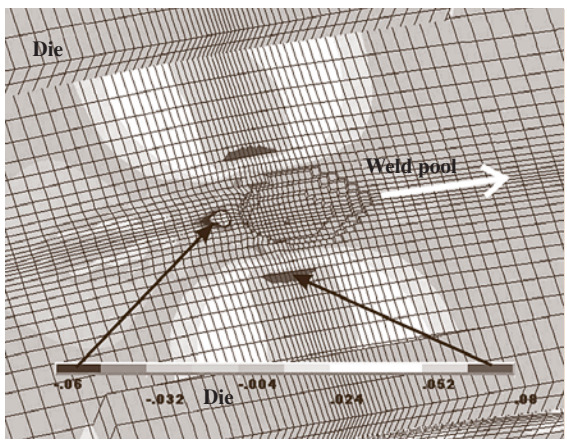

Fig. 7.299 Computer simulated strain distribution in a modified Varestraint test (strain in direction of welding) showing complex distribution of tensile and compressive strains beside and behind a moving weld pool after the test strain has been applied (after [7.361])

terdendritic liquid pressure, relating this to an inability to adequately feed solidification shrinkage and thermal contraction [7.374–376]. Although these models were developed for castings, they are equally applicable in principle to welding. Of particular importance to welding, however, is the influence of restraining conditions and their effect on local strain fields around a moving weld pool [7.377]. The ability to simulate these local stress/strain fields is of critical importance for predicting cracking, with several examples published [7.361, 378–380]. An example of one such simulation is given in Fig. 7.299, showing the strain distribution in a modified Varestraint test [7.361].

Porosity. Gas porosity in metals is usually associated with dissolved interstitial elements: H, N, and O, which form gas (diatomic molecules) during solidification. The conditions necessary for gas pore formation in molten metal have been modeled based upon a simple consideration of Gibbs free energy for nucleation [7.381]

$$\Delta G = \gamma A + P_e V - P_i V \,, \tag{7.203}$$

where ΔG is the change in free energy associated with pore formation, γA is the energy associated with the creation of gas/liquid interface of surface area A and surface tension γ, $P_e V$ is the positive work done forming a pore of volume V against an external pressure P_e, and $-P_i V$ is the negative work done with the aid of internal vapor pressure P_i. From this it follows that the critical radius needed for homogeneous nucleation of a spherical pore (i. e., r such that $\Delta G/\mathrm{d}r = 0$) takes the following form

$$r^* = -2\gamma/\Delta P \,, \tag{7.204}$$

where $\Delta P = (P_e - P_i)$. It follows that homogeneous nucleation is promoted by low surface tension, low external pressure, and high internal pressure (e.g., EB welding a nitrogen strengthened stainless steel in a vacuum). However, heterogeneous nucleation is even more likely to occur, allowing this critical radius to be achieved with a smaller volume of gas. Heterogeneous nucleation is favored by conditions where the liquid does not wet the substrate (e.g., oxide inclusions [7.382]).

ΔP can be considered as the driving force for nucleation and can thus be expressed in terms of a thermodynamic chemical potential [7.382]

$$\Delta P = -\frac{\mathrm{RT}}{\Omega} \ln \frac{p}{p_0} \,, \tag{7.205}$$

where R is the universal gas constant, T is absolute temperature, Ω is the molar volume, p is the interstitial partial pressure, and p_0 is the equilibrium interstitial partial pressure. It follows that there must be a condition of supersaturation (i. e., $p > p_0$) in order for nucleation to occur. Thus, in order to understand pore formation in a weld, one must first consider mechanisms to achieve supersaturation.

Pores can form in the weld pool if the liquid becomes supersaturated by picking up interstitials from the welding gas, directly under the arc (hot region), and then moving rapidly to cooler regions near the fusion line. The pickup of interstitials at the weld pool surface has been modeled, where it has been shown that dissolved interstitial concentrations exceed Sieverts' law predictions due to the dissociation of diatomic molecules in the arc plasma [7.383]. It is also possible to form porosity interdendritically, even when the weld pool has not become saturated, due to the partitioning of interstitial elements during solidification. The large drop in solubility between liquid and solid results in a buildup of interstitials in the interdendritic liquid, which leads to supersaturation. Simulations for interdendritic porosity have been used successfully to predict conditions favorable to pore formation in castings [7.384, 385].

Once nucleated, pores may grow, coalesce, become entrapped, or escape the weld pool, depending upon the welding conditions [7.382]. Slow welding speed allows time for pores to escape, aided by the buoyant force of gravity. The use of pool agitation (e.g., current pulsation) also helps in this regard. When welding in the overhead position, most pores become entrapped. Rapid travel speed limits the time available for pore nucleation and growth.

7.4.9 Fundamentals of Magnetic Pulse Welding for the Fabrication of Dissimilar Material Structures

One major challenge in welding is to develop fast, reliable, and cost-effective industrial processes to permanently join dissimilar materials, i. e., different metals (including alloys), or metals with plastics or ceramics. For these combinations of materials, the fusion welding processes are inapplicable, as the physicochemical properties of unlike materials are seldom similar or *compatible*. Alternatively, the *colder* and solid-state joining processes like magnetic pulse welding (MPW) offer the most potential, particularly for cylindrically symmetrical components including light and ductile

metals. MPW is straightforward and in many aspects similar to explosive bonding, except that it has for now only been applied to cylindrically symmetrical components. MPW utilizes the magnetic fields generated by heavy discharge currents into inductive coils. The resulting discharge is a dampened sine wave of consecutive *pulses*. In proximity to the coils are the components to be welded, or workpieces. The discharge current running through the coils induces Eddy currents in the nearby workpiece. The interactions between the magnetic fields of these two currents results in a strong repel force between coil and workpiece. By necessity, this workpiece must be electrically conductive as well as plastically deformable, and the repel forces must be such that a violent collision will occur, preferentially at a slight angle to form a jetting action similar to that in explosive welding. During MPW, the amount of heat produced is almost nonexistent since the process only lasts small fractions of a second. Parameters such as gap distance (between coil and workpiece, and between the two workpieces), material properties, thickness, as well as welder characteristics determine the properties of the final weld joint. Mechanical interlocking as well as thin and discontinuous intermetallic phases (all resulting from localized melting) will control the final properties of dissimilar-material welds, e.g., static strength, shock and vibration resistance, and vacuum tightness.

Magnetic pulse welding (MPW), also referred to as electromagnetic impulse joining or pulsed magnetic welding [7.386], is a four-decade-old process from the Cold War era [7.387]. Just like other governmental programs, the widely developed nuclear programs of the former Soviet Union, the United States, and other military and industrial powers spawned spinoff technologies that have found industrial and manufacturing applications. MPW is said to have been invented at the Kurchatov Institute of Nuclear Physics to seal metal canisters and nuclear fuel pins [7.387]. In the decade following its initial success until recently, the process only found military and aerospace applications, as for flight control rods, artillery shell casings, and bimetallic metal inserts [7.388, 389]. Almost 40 years after being invented, MPW has gained the attention of the private sector, in particular the transportation and refrigeration industries. With weight saving and improved vehicle safety driving the use of an increasing number of dissimilar materials' joints (e.g., aluminum with steel), the automotive community has emerged as the major player in further developing MPW technology. MPW is indeed one of the rare processes capable of joining dissimilar materials in high-volume production environment. The actual process lasts less than 100 ms, and the production rates may be readily customized (for instance, be as small as a few seconds).The process has not only been tested and applied to numerous combinations of metals and alloys [7.388–398], but also metals with ceramics or metal-matrix composites [7.399]. In the automotive industry, immediate potential applications for MPW include more conventional metallic materials for air conditioning tubings, tubular spaceframes, driveshafts, struts, shocks, and electrical connections. To date, any joints between round parts such as a tube-to-tube joint, a tube-to-end joint or a wire crimp joint are ideal candidates for magnetic pulse welding. In the near-future, it is conceivable to see magnetic pulse welding, alone or combined with other processes, applied to noncylindrical workpieces like flat sheets. MPW is an extension of magnetic pulse forming, or electromagnetic forming, a process that uses identical technology to manufacture complex shapes in fractions of a second.

Process Principles and Parameters

MPW can be applied to the same materials as explosive bonding, provided the hollow sections can be accelerated. MPW is identical to explosive bonding in the formation of the joint, but instead of the chemical explosive energy, magnetic fields are used to drive the materials together. In order to weld and in particular achieve a metallurgical bond wherein atoms of the two materials are brought into direct contact, a tremendous amount of energy must be compressed and discharged within an extremely short time. In some systems, the discharge is as high as 2 million amps and lasts less than 100 µs. As a result, the actual energy expenditure is exceptionally low and the components have no time to heat appreciably.

A schematic representation for a magnetic pulse welder is illustrated in Fig. 7.300. The welding unit, or welder, simply consists of an LC circuit (i. e., inductance–capacitance) with a high-voltage transformer and some impedance (not represented in Fig. 7.300) so that the discharge current waveform is a dampened sine wave. This discharge current runs through a coil, also called an inductor. This coil is usually positioned all around the workpieces to be welded, but not necessary as discussed later in this chapter. Figure 7.300 illustrates the situation where two concentric workpieces (i. e., an internal and an external workpiece) are welded. The workpieces are positioned coaxially inside the coil with gaps in between, a requirement to produce the Eddy currents and the magnetic force necessary for welding. The electrical currents in the coil

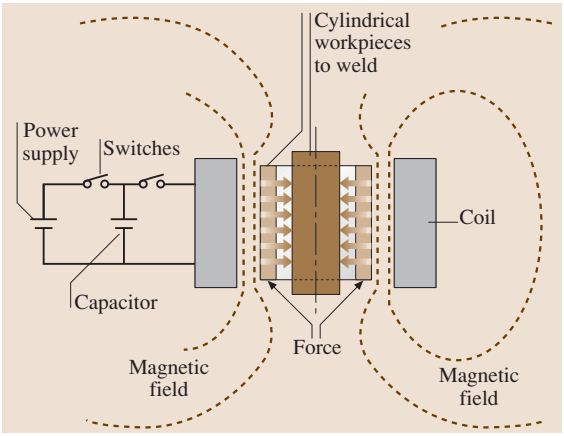

Fig. 7.300 Basic components and principle behind the magnetic pulse welding process

and workpiece (i. e., the inductive and the Eddy currents) naturally repel one another since the two currents, and their respective magnetic fields, are – as controlled by the laws of electromagnetism – flowing in opposite directions. This feature makes MPW comparable to what happens when two permanent magnets are held together, i. e., when like poles are brought to close distances they repel each other. Instead of expanding and penetrating each other, the two opposing magnetic fields develop a pressure that puts one of the workpieces into sudden motion. Once the distance separating the two workpieces, or gap, has been covered, the moving workpiece finally collides with the stationary workpiece (i. e., the inner workpiece in Fig. 7.300). The average velocity is typically on the order of 300 m/s [7.392, 393], but the local velocity can be significantly higher (e.g., greater than 1000 m/s) [7.388]. Later, we will discover that conversion of this kinetic energy to plastic deformation often results in local heating; as a result, magnetic pulse welds may develop a variety of characteristics depending upon the materials and established conditions of collision.

To create conditions for welding, two conflicting machine characteristics are required: a large energy storage, which usually means a high capacitance (produced by a bank of capacitors), and a high frequency, which means a low inductance. The energy storage E and the frequency of an LC circuit are given by [7.386]

$$E = \frac{1}{2} C U^2 \,, \tag{7.206}$$

$$f = \frac{1}{2\pi\sqrt{LC}} \,, \tag{7.207}$$

where C is the capacitance (in F), U is the charging voltage (in V), and L is the total inductance of the unit (in H). Since frequencies for MPW are usually on the order of 10–200 kHz, the magnetic field produced by the inductive coil only diffuses through the skin of the nearer workpiece, a phenomenon sometimes referred to as the Kelvin effect [7.400]. The higher the resistivity of the material and the lower the frequency, the more penetrating the induced current and the less effective the induced magnetic field. For the situation described in Fig. 7.300, the induced current will result in a high magnetic field on the outer surface of the exterior workpiece and little or no magnetic field on its interior surface, an imbalance that will cause the collapse of the external workpiece. The velocity when this workpiece impacts the stationary workpiece depends on the magnetic pressure, the mass of the accelerated workpiece, its material properties, and the initial gap between the two workpieces. The magnetic pressure, created by the inductive current pulses or oscillations, can be approximated as [7.398, 401]

$$P = \frac{\mu_0 K^2 n^2 U^2 C \sin^2(\omega t) \exp(-Rt/L)}{2 L I_\mathrm{w}^2} \,, \tag{7.208}$$

where μ_0 is the magnetic permeability (in H/m), K is a coefficient depending upon the physical dimensions of the coil, n is the number of windings of the coil, ω is the LC oscillation frequency associated to (7.207), R is the total resistance of the discharge circuit (in Ω), I is the working coil length (in m), and t is the time (in seconds). Because current and pressure rapidly dampen, the collision between the two workpieces must take place in about half the period of current oscillation to maximize the process efficiency, in particular the collision velocity.

To illustrate the effects of the various process parameters, a simplified description of the process can be made by combining several equations, starting with Newton's second law, which is applied to describe workpiece motion as a function of the time and the various forces developing during the process

$$m \frac{\mathrm{d}^2 h}{\mathrm{d}t} = F_\mathrm{m} - F_\sigma \,. \tag{7.209}$$

In (7.209), m is the mass of the moving workpiece (in kg), h is the gap separating the two workpieces (in m), F_m is the induced magnetic force (in N), which can be approximated by multiplying magnetic pressure (7.208) by external area of the outer workpiece (for the configuration illustrated in Fig. 7.300), and F_σ is the force

induced by the accelerated workpiece as it resists deformation (in N). This force may be described as [7.398]

$$F_\sigma = \sigma 2n l_w r \,, \tag{7.210}$$

where σ is the plastic flow stress of the moving workpiece material (i. e., its strength in N/m^2 or Pa), l is the length of its deformed area (in m), and r is either the outer radius or inner radius (in m) of the moving workpiece (whichever applies best). In (7.210), σ not only represents the strength of the moving material under uniaxial conditions (a simplification), but it is also taken independently of the developing microstructures, i. e., strain hardening and strain-rate dependence must be neglected. Equations (7.208–7.210) infer that the magnetic force must first overcome the resistance of material and force it to plastically deform. Although not represented by any equation here, the magnetic force must also remain below a critical value, above which too much of the work produced by the magnetic pressure will result in heat generation during the collision, a situation that would eventually cause interfacial melting and cracking, as discussed in several publications [7.394, 395, 397] and later in this chapter. Equations (7.206) and (7.208) indicate that the charging voltage must also be high to increase the amount of stored energy in the capacitance, and thus produce the adequate magnetic pressures for welding. Typically, given the fixed design of a magnetic pulse welder, a major factor influencing the quality of a weld assembly is the geometry or design of the weld joint. Equation (7.209) suggests that the gap between the coil and the workpiece and between the workpieces (represented by h in (7.209)) is a key parameter. Wider gaps will provide the time to accelerate the moving workpiece and thus create the high collision velocities that are needed for welding.

Process Requirements

MPW requires a lap joint configuration with several important characteristics in order for high-quality joints to be achieved. Herein, we will define high-quality joints as those that satisfy a set of desired properties. While mechanical strength (static, dynamic, i. e., under impact conditions, or fatigue) is always important for product reliability and durability, other properties may be equally important in certain applications. For instance, when excellent electrical and thermal conductors like aluminum and copper are bonded, conductance may be primary, and the detailed characteristics of the weld (described later in this chapter) may then become important to consider. For MPW, the workpieces may be of a variety of sizes. They may be as small as a few millimeters in diameter, but not excessively small to prevent the magnetic fields from interacting with each other. Workpieces can be as large as the application requires and the magnetic pulse welder allows. Workpieces in excess of 100 mm are not yet common but are weldable by magnetic pulse technology with the appropriate equipment and joint design.

As discussed earlier, the gap that initially separates the moving workpiece from the stationary workpiece directly affects the collision velocity (in (7.209) dh/dt represents the velocity). This gap can be either constant or variable, as in the cases of tapered workpieces. Figure 7.301 depicts a variety of magnetic pulse weld joints. The configurations with tapers offer considerable advantages, especially in producing the jetting described in the next section. Figure 7.301 also reveals that the coils can be placed either on the inside or on the outside of the workpieces. With external coils, the moving workpiece collapses onto the inside stationary workpiece. For an inside or internal coil, the inner workpiece will expand radially and collide with the inside of the wider and peripheral workpiece. The choice of coils, internal or external, depends on the dimensions of the assembly, as well as on the materials and weld properties that must be achieved. External coils can be provided to weld outside diameters between ≈ 2 and 100 mm. Internal coils are typically used for diameters between 100 and 250 mm.

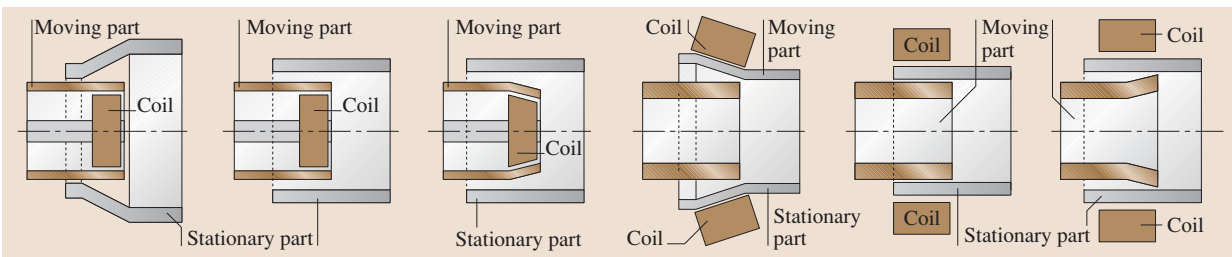

Fig. 7.301 Magnetic pulse weld configurations with corresponding positioning for the inductive coil (after [7.398])

The properties of the workpieces will affect the design of the joint. For instance, the workpiece that is to be accelerated must be made of a good electrical conductor. The higher its electrical conductivity, the easier it can be moved provided its section is relatively thin and deformable at high strain rates. Ideally, the more conductive material is also the least strong and most ductile. Metallic materials that have an electrical resistivity of 15 μΩ/cm or less lend themselves well to magnetic pulse welding. Some of these materials include alloys of aluminum, copper, and the precious metals. When welding electrically resistive materials, the more conductive of the two should preferentially be placed near the coil and this coil may be located on the outside to yield the necessary magnetic forces. This situation describes, for instance, the welding of an aluminum tube over a copper, titanium, or steel workpiece. In Fig. 7.302 are depicted several such weld joints before and after peel testing (peeling is used as a simple destructive test to assess joint strength) [7.395]. Aluminum-to-copper and aluminum-to-stainless-steel joints involving tubes of comparable wall thickness are shown. Because stainless steel's plastic flow stresses are significantly greater than that of aluminum and its alloys, the inner tube does not collapse on itself during the collision. With steel on the inside, the final component is undistorted and generally within the dimensional tolerance imposed by the design. Characteristics of several of the joints of Fig. 7.302 will be revisited later in this chapter. As can be seen in Fig. 7.301, the workpiece in close vicinity to the coil will often be forced to stretch before contacting the stationary workpiece. As a result, MPW inherently involves a significant amount of plastic deformation prior to bonding. While many metals and alloys are highly deformable, especially in the high strain rate and adiabatic conditions created by the process, it is clear that hard and very brittle materials may be unsuitable (e.g., tungsten).

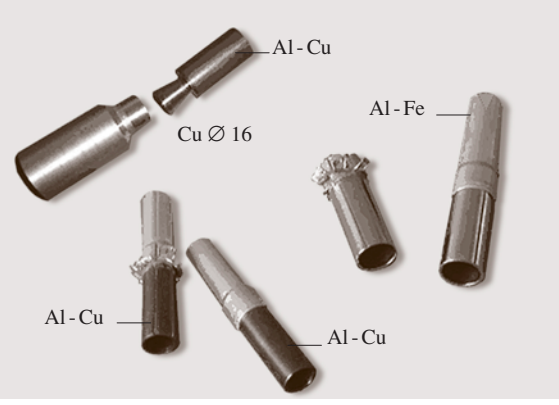

Fig. 7.302 Examples of hybrid structures of aluminum fabricated by magnetic pulse welding

In developing MPW technology, the electrical conductivity of metals and alloys has imposed severe requirements on the capacitor bank, the load inductor, and the tooling [7.402]. For welding, electrically resistive metals such as stainless steel, titanium, or nickel alloys necessitate a high ringing frequency (and consequently a low inductance is required). Less electrically resistive metals like aluminum and copper can be welded satisfactorily with lower frequency and lower current machines. Of primary importance, the coils for a magnetic pulse welder must be significantly stronger than the workpiece to be projected in order for them to be reusable. Many of components must also be electrically isolated so that the fields generated by the coil do not interact with any adjacent components. Because of the close tolerances required between the coil and the workpieces, and in between the workpieces, coils are frequently designed unique to their applications, i. e., tube size, rigidity, and materials.

While a thinner moving workpiece is preferred for a rapid acceleration before collision, a thicker stationary workpiece is often necessary to avoid distortions on the inner workpiece and keep the entire assembly within the imposed geometrical tolerance. MPW of thin-walled tubes on other thin-walled tubes is therefore difficult, unless a mandrel is used to back up the inner workpiece. Since magnetic pulse welds are lap welds, the length of the overlap is a critical parameter to achieve high strengths, particularly high tensile-shear strengths. Difficult-to-bond materials will require longer overlaps than easier-to-bond materials. Also, for the long welds sometimes needed by products, split coils may be designed to allow easy loading and removal of long components.

Characteristics of Magnetic Pulse Welds

Jetting. Welding may be attributed to two major mechanisms. In order to produce strong welds, the two workpieces must be brought close to each other at the atomic level, i. e., the two materials must at least be allowed to diffuse into each other [7.392–398]. In a normal atmospheric environment, in which MPW is usually conducted, the metallic surfaces are covered with thin films of oxides, nitrides, and other adsorbed gaseous elements. For instance, aluminum is covered with alumina and copper with a variety of oxides with

compositions and crystallographic structures that depend upon prior thermal exposures. These surface films are diffusion barriers and will prevent materials from the two workpieces from exchanging atoms and thus create a true metallurgical bond. Fortunately, with a few exceptions, these films do not have to be removed before welding because of the phenomenon known as jetting [7.403]. Jetting occurs when the two workpiece collide. As one strikes the other, a high pressure is generated ahead of the collision and the metal in the vicinity is largely swept away, giving rise to this scouring jet of semimolten materials. As illustrated in Fig. 7.303, the jet contains fragments of the surfaces from both workpieces and leaves a virgin metal in close contact under very high pressure. As also depicted in Fig. 7.303, the materials also become severely plastically deformed along the weld interface. The interface of a magnetic pulse weld will often contain large numbers of projections and depressions with more or less periodicity, depending upon prior surface preparation and variations in gap distance [7.404]. These irregularities contribute to the high strength (i. e., fracture forces) of magnetic pulse welds. They not only increase the effective area of the joint, but also interlock the two surfaces, thus providing another bonding mechanism that will contribute to the high strength of many magnetic pulse welds.

The major parameters that determine whether a high-quality joint, preceded by the jetting phenomenon, will occur are the collision angle and the collision velocity, which are both dependent upon the magnetic field strength, the workpiece thickness, and its characteristics. With materials of relatively low plastic flow stresses and high ductility, the collision angle does not need to be as high as with strong and less ductile materials. Equation (7.211) relates collision angle with a material's hardness and collision velocity. Although (7.211) was initially developed for explosive bonding

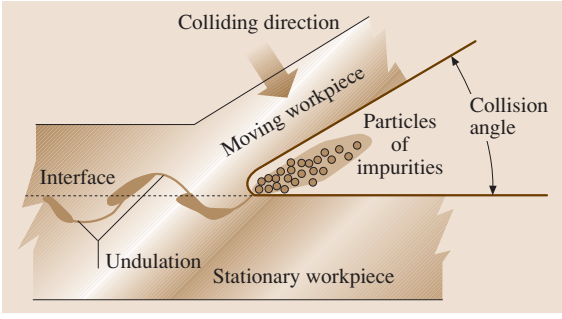

Fig. 7.303 Schematic representation of the jetting process for two workpieces entered in contact

to select the appropriate collision angle for jetting and bonding conditions, the same equation can be applied to MPW. Equation (7.211) indicates that the minimum angle for jetting to occur increases with the hardness of the moving workpiece H_v and decreases as its density ρ and its collision velocity V_c decrease [7.404]

$$\beta_{\min} = K\left(\frac{H_v}{\rho V_c^2}\right) . \qquad (7.211)$$

In order to improve jetting and bonding, many workpieces are machined to provide such a minimum collision angle, as shown in Figs. 7.302 and 7.303. Typical collision angles are in the vicinity of 8–12°. For difficult-to-weld combinations of materials like those between transition metals, surface preparation prior to cleaning may be recommended in order to lower the velocity for jetting. Surface roughening by mechanical or chemical means (i. e., etching) may be employed, as are a few commercial chemical agents designed for explosive bonding.

Weld Characteristics. Up to this point, we have emphasized that MPW applies best to dissimilar metals and alloys that (1) are good electrical conductors and (2) exhibit measurable differences in plastic flow stress. Light metals (e.g., aluminum, magnesium, etc.) are therefore most appropriate for welding with transition metals (e.g., steel, titanium, etc.) despite oxides and the fact that brittle intermetallic phases form when these metals are in contact at elevated temperatures. As discussed earlier, the quality of the weld depends on process parameters and material properties and can be evaluated through various techniques, detailed later in this chapter. Of all these techniques, visual examination of a weld interface from cross-sections is particularly useful for determining whether a true metallurgical bond has formed. When examining dissimilar material welds from polished cross-sections, the interface between the workpieces can take one of three appearances: straight with direct metal-to-metal contact, straight with a continuous layer between the workpieces, or wavy [7.395–404]. These three morphologies are often present in the same weld joint, especially when one of the workpieces is tapered and a gradient of collision velocities is consequently established.

Figure 7.304 presents a set of optical micrographs along the interface of a magnetic pulse weld between aluminum and titanium. From left to right, the gap that initially separated the aluminum and titanium workpieces gradually increased and therefore created greater and greater collision velocities. As seen in Fig. 7.304,

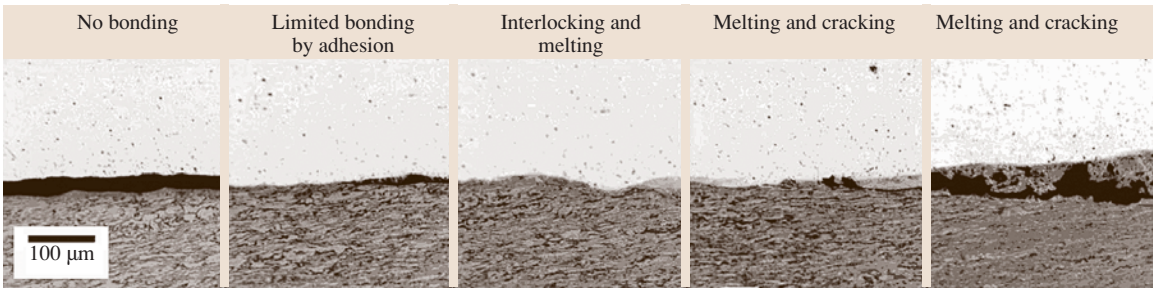

Fig. 7.304 Set of optical micrographs showing various interfaces at aluminum-titanium magnetic pulse welds. Collision velocity increased from left to right (after [7.395])

the narrower gaps of the left images produced no or only a limited bonding (attributed to adhesion), as can be seen in the first two images. As the distance between the workpieces increased, the two materials became slightly interlocked. To increase mechanical interlocking, larger, more penetrating, and more frequent surface irregularities would be necessary, as promoted for instance with surface roughening prior to welding. As the gap further widened, an interfacial microconstituent formed, exactly as seen in other dissimilar metal welds (e.g., aluminum with copper or steel) [7.388–390, 393, 394]. With the widest gaps, the interfacial microconstituent thickened, and cracking eventually developed all along the observed weld interface, as seen on the right-hand images of Fig. 7.304. Among the micrographs of Fig. 7.304, the conditions associated to the third image are best for the fabrication of high-quality aluminum-titanium welds. The ideal weld would be one with a high density of undulations for interlocking and with the thinnest interfacial microconstituent. This condition, although established by a narrow process window, has been observed to generally promote the highest mechanical strength and, if electrical and thermal conductivity are of concern, also the least resistance for current or heat to flow. The presence of an interfacial microconstituent is not preferred, but it guarantees that the two materials have truly created a metallurgical bond.

The presence of a new microconstituent, as illustrated in Fig. 7.304, is characteristic of many welds between dissimilar metals and alloys [7.387–398]. Figure 7.305 shows compositional maps captured at the cracked region of several dissimilar-metal welds. In the first, second, and third rows are backscattered electron images and compositional maps for an aluminum-low-carbon-steel weld, an aluminum-stainless-steel weld, and an aluminum-titanium weld, respectively. The aluminum maps are shown in the second column, and in the third column are the maps for iron and titanium. Using a particular colorscale, each of these maps represents element concentrations over a predetermined area, the brightest colors depicting the regions with highest concentrations. It is seen in Fig. 7.305 that the presence of a thick microconstituent is also associated with cracking. All the images of Fig. 7.305 also demonstrate that the various interfacial microconstituents are composed of at least one new intermetallic phase, perhaps more.

Line-scan results across the interfacial microconstituent of Fig. 7.304 (also represented in the third row of Fig. 7.305) are shown in Fig. 7.306. The first and last 40 µm on Fig. 7.306 indicate the chemical compositions of the two base materials, both expressed in

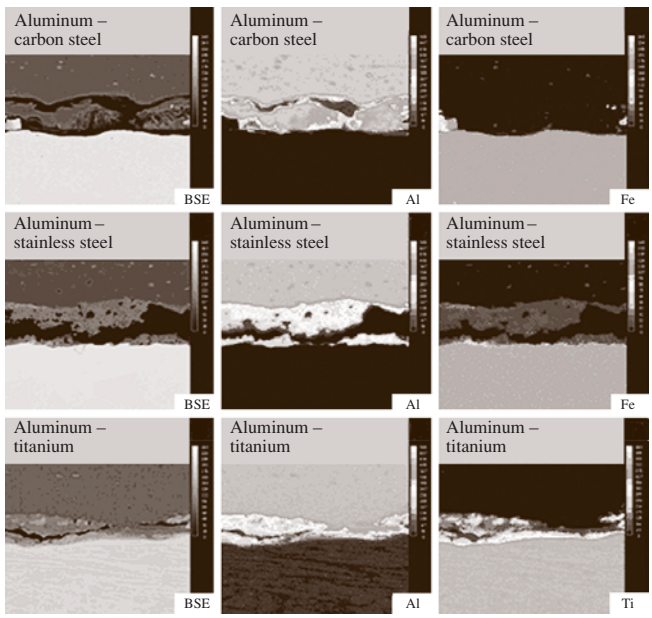

Fig. 7.305 Set of compositional maps reveling new phases at magnetic pulse welds between dissimilar materials

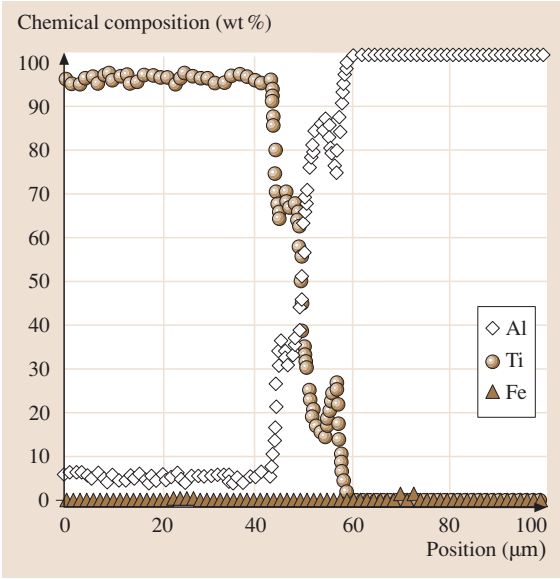

Fig. 7.306 line scan results showing the chemical composition across the interfacial microconstituent seen in aluminum-titanium magnetic pulse welds

weight percent. The chemical compositions of the interfacial microconstituent are found at distances between 40 and 60 μm on the *x*-axis. In this region, steep compositional gradients prevailed, except near 45 and 55 μm, where the compositional gradients changed sign and zeroed, thereby indicating the absence of a chemical driving for diffusion. In two narrow zones, aluminum and titanium have reached a local equilibrium and have therefore formed new phases. Figure 7.306 reveals that compositions of these two new phases were approximately 62–70 wt % titanium (i. e., 30–38 wt % aluminum) for the phase seen at a distance of 45 μm, and 15–25 wt % titanium (75–85 wt % aluminum) for the phase at a distance of 55 μm. It is here confirmed that the chemical elements of different workpieces do not participate equally in formation of the joint. It is also shown that the two new phase compositions match two intermetallic phases on the equilibrium phase diagram between aluminum and titanium [7.403]. This phase diagram is reproduced in Fig. 7.307. It shows that up to four equilibrium intermetallic phases can coexist between aluminum and titanium at temperatures less than 500 °C. They are $TiAl_3$, $TiAl_2$, TiAl, and Ti_3Al, several of which can be stabilized over a significant range of composition. As a consequence of four intermetallic phases, five ranges of compositions are available to produce dual-phase microstructures, i. e., microstructures with two phases (in Fig. 7.306, these dual-phase microstructures were found in a region of compositional gradients). The binary-phase diagram of Fig. 7.307 for titanium and aluminum resembles many other binary-phase diagrams between aluminum and a transition metal element, like iron (steel) for instance. As a result of such similarities in the phase equilibria, interfacial microstructures in aluminum-carbon steel or aluminum-stainless steel welds are not profoundly different from aluminum-titanium welds, and thin layers of intermetallic phases are produced, as demonstrated in Fig. 7.305.

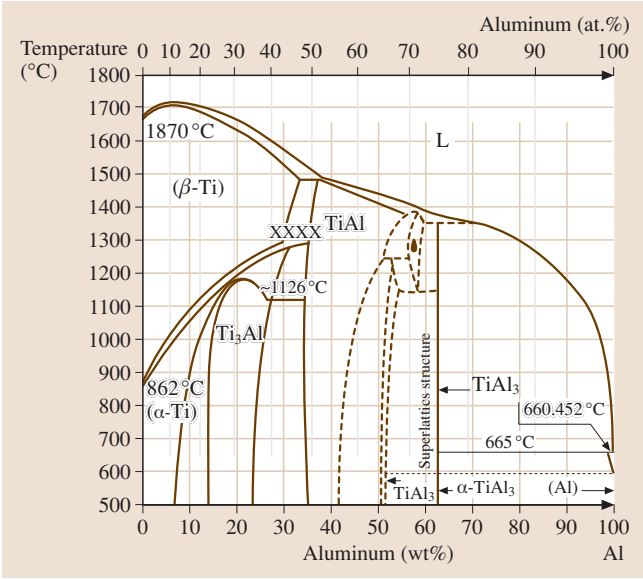

Fig. 7.307 Titanium-aluminum equilibrium phase diagram (after [7.403])

Given the short duration of the process, the temperatures necessary for the formation of intermetallic phases through atomic diffusion cannot be other than extremely high. In fact, melting provides the only explanation for the results in Figs. 7.304–7.306. Using the phase diagram of Fig. 7.307, it can be seen that the titanium-rich phase identified in Fig. 7.306 has a composition matching TiAl. Note that TiAl forms directly from the liquid phase near 1350 °C; a characteristic that strongly suggests very high interfacial heating. Similarly, the aluminum-rich phase found in Fig. 7.306 may be identified as $TiAl_3$ in the phase diagram of Fig. 7.307. This phase also possesses a particularly high melting temperature. The strongest evidence that melting occurs in magnetic pulse welds made with high collision velocities is shown in Fig. 7.308. In Fig. 7.308a are presented

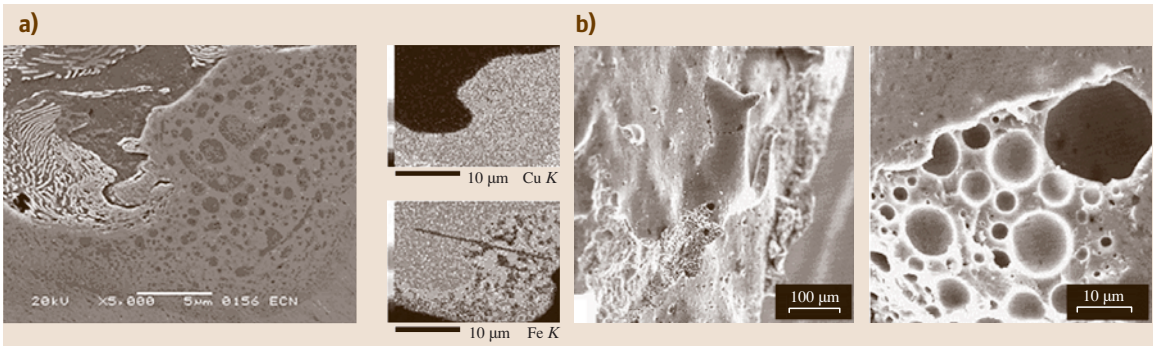

Fig. 7.308 **(a)** Secondary electron image of a low carbon steel-copper weld interface with compositional maps. **(b)** Images at the aluminum side of an aluminum-copper weld.

a secondary electron image of the weld interface between a low-carbon steel and pure copper, as well as corresponding compositional maps for aluminum and iron. Note the presence of a lamellar constituent in the upper left of Fig. 7.308a. This lamellar constituent is known as pearlite [7.405]. Pearlite is a mixture of two equilibrium phases, ferrite and cementite (e.g., Fe_3C), that both form during the slow cooling of low-carbon steel from the decomposition of the high-temperature austenite phase (another stable phase of iron, but found only at high temperatures in the absence of substantial alloying elements). In Fig. 7.308a, the pearlite is also found to disappear in the weld region, a proof that pearlite has been dissolved by a combination of high temperatures and rapid cooling. In addition to the disappearance of pearlite, dark clusters can be detected at what appear to be random locations. As validated by the compositional maps, these clusters are, as seen earlier, also evidence of the presence of new phases. Unlike previous maps, however, the results of Fig. 7.308a can hardly be explained by solid-state diffusion. Diffusion in the solid state would not produce this seemingly random clustering, but a layering of phases. The compositional maps of Fig. 7.308a reveal that the two materials, steel and copper, melted and strongly resisted mixing, as would be seen when oil and water coexist in the same medium. The two images of Fig. 7.308b present additional evidence of the occurrence of melting. In Fig. 7.308b are shown microvoids that were encountered in aluminum-copper welds. These voids were found exclusively in the regions with thick interfacial microconstituents. Once again, melting provides the sole explanation for the array of spherical voids seen in Fig. 7.308b. For the great majority of metallic materials, solidification is accompanied by a volumetric shrinkage. These voids are associated with the volumetric contraction of a new liquid phase in between the aluminum and copper workpieces.

In typical magnetic pulse welds between dissimilar materials [7.388, 393–395, 398], the intermetallic microconstituents are harder than any of the two original materials, despite adjacent strain hardening or fine-grain recrystallization that often occurs in the softest material [7.396]. Figure 7.309 shows for the aluminum-titanium weld of Fig. 7.304 that the Vickers hardness number of the microconstituent is ≈ 100. The hardness of the aluminum (initially 30) is also considerably changed. Although not represented, hardness changes in the stronger and harder titanium were unnotice-

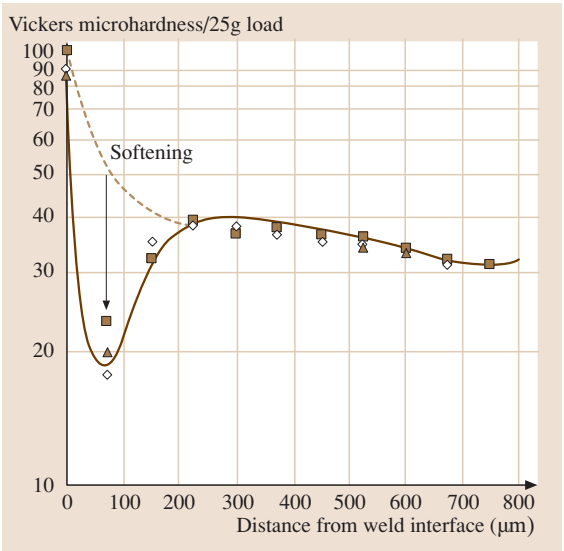

Fig. 7.309 Microhardness profile in the aluminum, as measured normal to the interface between aluminum and titanium (log scale for the microhardness)

able. These microhardness changes in the aluminum workpiece can be correlated to microstructural transformations. Because hardness variations were not monotonic, as could have been expected by strain hardening (i. e., materials strengthened as they were deformed), two competing mechanisms acted in the vicinity of the weld interface. Strain hardening clearly occurred further away from the interface, where hardness gradually increased closer to the weld. In sections of the welds where interfacial microconstituents were not seen, the hardening of the aluminum was also greater, and hardness variation was monotonic all through the aluminum wall thickness. Hardening is also greatest when the intermetallic constituents are thin [7.395]. The softening immediately adjacent to the interface, also observed in aluminum-copper welds [7.393–395], indicates that the interfacial heating was simply enough to oppose the hardening due to plastic strains. Figure 7.309 shows that the aluminum softening near the microconstituent could be as high as 30 kg/mm^2 (see arrow in Fig. 7.309). As depicted in Fig. 7.309, this decrease in hardness therefore appears to represent as much as 50% of the material initial hardness (thus strength).

While eliminating totally the intermetallic phases may reveal difficult in the case of dissimilar joints treated here, magnetic pulse welding more than any other process allows to reduce their thickness. Strengths, especially in the tensile-shear mode of aluminum-copper, aluminum-steel, and aluminum-titanium joints – among other dissimilar-metal joints – have proven to be exceptionally high [7.395]. Welds are often so strong that no other process can outperform MPW. In fact, magnetic pulse welds are often associated with weight reduction, in part because the overlaps do not have to be as long as with other processes (e.g., brazing, adhesive bonding). Since the moving workpiece is usually thin and only accounts for a small cross-sectional area relative to the area associated with the overlap, this workpiece normally fails, in many occasions leaving the joint undisturbed during testing. In applications involving tube-to-tube joints, where fluids flow on the inside of the assembly, resistance to high internal pressures is primary. A variety of tests, including hydrostatic pressure tests and helium leak tests, may be applied to measure weld quality. In some cases (e.g., heat exchanger tubes), weld joints can also be subjected to thermal cycles within a wide range of compositions at the same time they are tested for leaks. Frequently, the quality of magnetic pulse welds is proven, and magnetic pulse welding provides a hard-to-beat cost-effective engineering solution to large-scale manufacture of tubular structures.

Conclusions and Summary

MPW is a suitable process for dissimilar materials, particularly metals (including alloys) since they are electrically conductive and Eddy currents can flow in them. The moving workpiece, i. e., the one with Eddy currents, collides with the stationary workpiece with such force that both mechanical interlocking and atomic interactions occur between the two materials. Surfaces of the workpieces do not have to be cleared of surface contaminants because of the phenomenon of jetting. Magnetic pulse weld interfaces are similar to those produced by explosion welding and their properties mainly depend on the collision velocity and the collision angle. MPW possesses numerous advantages and a few disadvantages.

Several advantages of MPW are largely tied to the fact that the process can be electrically controlled from the power supply. The parameters are therefore easily controlled, adjusted, and set. This results in a highly repeatable process, which, because of the rapid discharge, is extremely fast. Other advantages of the MPW process are linked to the fact that the process is energy efficient and melting is either absent or localized to a narrow skin. As a result, the materials are not heat affected dramatically, i. e., annealed, oxidized, and residual stresses are deeply reduced compared to many other processes, as are the intermetallic phases that form between dissimilar metals.

The disadvantages of MPW are mainly related to the cost and workpiece geometry. MPW is initially more expensive than other types of welding technologies (small machines begin around $100 000), but, once up and running, it has a much lower cost than most other processes. The coils are extremely important and for optimal process performance have to be specially designed and manufactured for each application. In addition, there are high voltage and current levels in the operation of the machine that may present a safety hazard when working on the machine. Coaxial positioning of the parts to be welded is also critical, as is the angle of impact and gap. Efforts are under way to refine the MPW process and extend the process for the joining of noncylindrical components. Nonclosed coils are being developed to allow increasing part accessibility.

7.5 Rapid Prototyping and Advanced Manufacturing

This section presents basic technologies of rapid prototyping and their application in the development and functional verification of market products. Time to market is a very important factor determining the final success. The verification of virtual prototypes, while significant for the project executors, is not always sufficient for evaluation of a new product by future customers. An important argument for creating a physical prototype is the possibility of carrying out complex investigations on a tangible object. In order to accelerate the product development and evaluation, a number of so-called rapid prototyping (RP) technologies have been developed. They are also more generally called time compression technologies (TCT). A characteristic feature of RP technologies is their *additivity* – a physical object is built by *adding* material, usually in the form of layers (slices), instead of *subtracting*, as is the case in traditional manufacturing. An exception, sometimes also classified as an RP technology, is high-speed cutting (HSC) or high-speed machining (HSM).

Like virtual prototyping methods, RP technologies require a complete geometric computer model of a 3-D object to be manufactured. Various materials can be used as the construction material, e.g., photopolymers, thermoplastics, plastic films, paper and organic, ceramic or metallic powders. The material applied determines (affects, influences) mechanical and aesthetic properties of created models.

The group of TCTs also includes rapid tooling techniques that allow for building a tool to manufacture a short series of a new product (from 5 up to 100 pieces) and reverse engineering methods that allow for digitizing the geometry of an existing object, which is then processed in a CAD environment as (part of) the design of a new product.

Parts manufactured with rapid prototyping technologies still need postprocessing with specialized machining technologies for manufacturing on micro- and nanoscales. These are often called advanced manufacturing technologies.

RP technologies are especially important in developing market products since their life cycle is getting shorter and shorter and demand for new products and market competitiveness is still increasing.

Manufacture in a Competitive Market

The purpose of every manufacturer's technological activity is to process materials by means of various technologies in such a way that as a result of specific processes they become marketable products. The business purpose, however, is to configure those processes in such a way that the income resulting from the sale of the manufactured products, aimed at covering production costs and supporting design of new products and new technologies, is as high as possible. The new concepts usually have an increasing, cyclically changing nature, i. e., a step forward in technological growth happens when existing technologies and manufacturing processes do not assure superiority or at least a technological balance of a manufacturer in the marketplace.

The innovative technologies and organisational production aspects are considered to be the most important development factors of present-day production enterprises. This is especially important in long-term perspective, which usually means perfect prosperity of a company, as well as further development of innovative technologies and products. Innovative technologies create the most important indices of competitive production, namely [7.406, 407]:

- Cost reduction up to 70%
- Quality improvement up to 25%
- Increase in production flexibility up to 89.5%
- Product innovativeness up to 100%
- Technology innovativeness up to 70.6%
- Productivity increase and product line extension up to 64.7%
- Improvement of external economical indexes effect up to 44.4%
- Penetration of the international market up to 58.8%

The above data make a sufficient argument for using the newest methods, technologies, and tools in all production types, irrespective of the production scale and the company size. This is all the more important as it is possible to determine a great many variability indices of characteristic features and criteria of manufacturing systems [7.408] (Fig. 7.310).

They can be subdivided into several categories: technical, organizational, market-related, cost-related, local, and global. Of course, different criteria may also be formulated for classifying conditions, requirements, and development tendencies related to manufacturing systems. The tendencies of change will be different for different manufacturing areas, company sizes, environments, markets, or product lines.

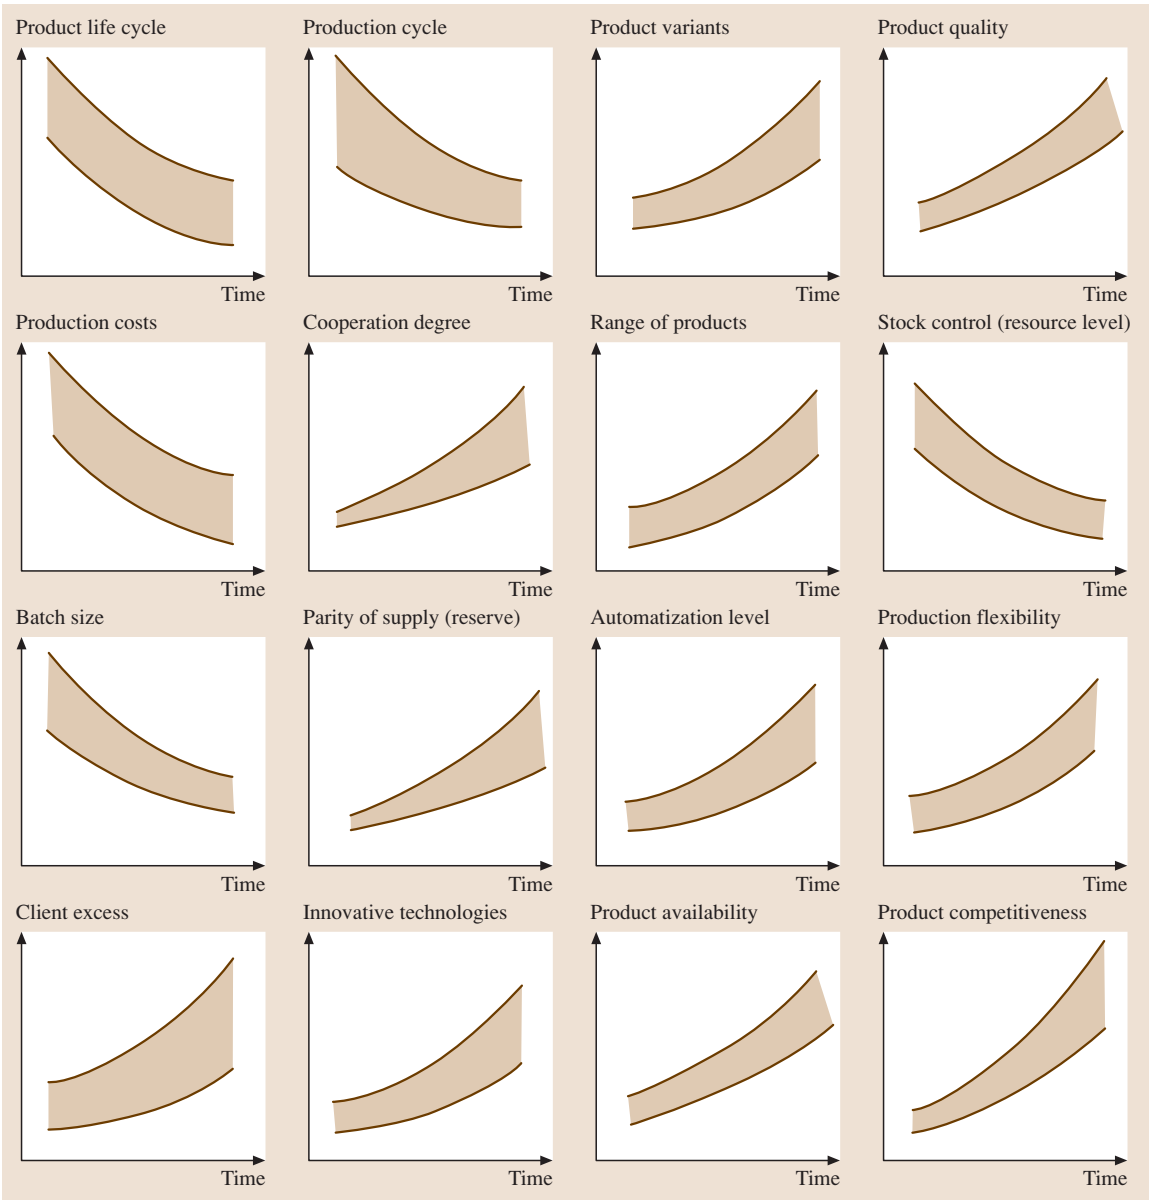

Fig. 7.310 Changes occurring in manufacturing systems

7.5.1 Product Life Cycle

The product life cycle should be defined with its determined technical, aesthetic, usability, cultural, environmental, and other functions that, as a result of operation or the passage of time, can be treated as stable, i. e., those that have not lost the value measures and criteria assigned to them as early as at the preliminary development stages.

The issue of methodological description of the product life cycle can be reduced to two important areas:

1. The basic phases of development:

- Marketing design that covers the most important features of a future product, laying the groundwork for marketing research to define its functional features with the customer's participation.

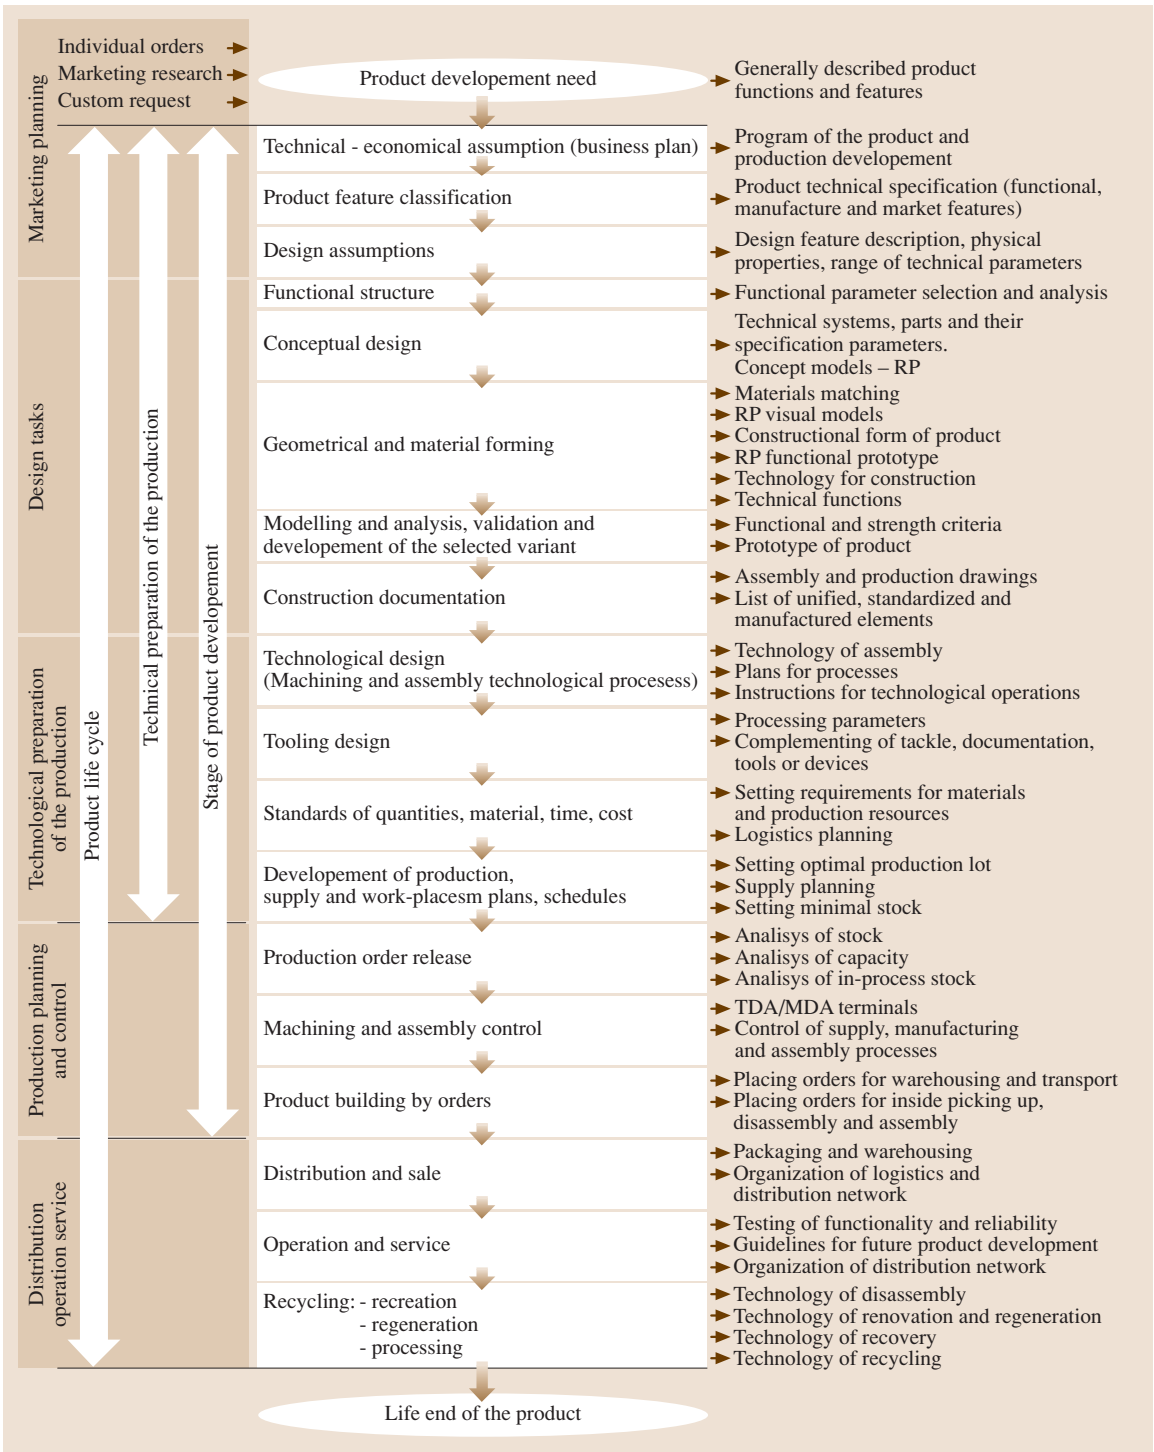

Fig. 7.311 Areas and phases of product lifecycle (after [7.408])

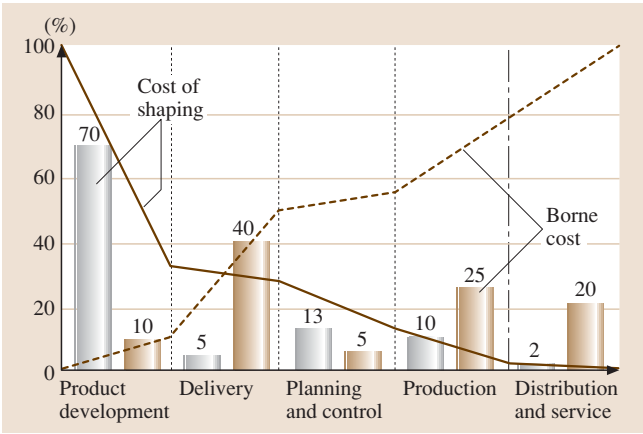

Fig. 7.312 Determined costs and costs borne at various stages of product lifecycle

- Constructional design that covers giving functions and constructional form to the new product, with special regard to geometric and material forming;
- Technological design aimed at determining technological processes together with their parameters and necessary auxiliary processes;
- Planning of manufacturing processes, considering normative planning of necessary resources and requested realization times as well as securing the production infrastructure.

2. The basic phases of manufacture and operation:

- Processing and forming of the material to the features of the product or its components;
- Assembling components and finished products manufactured to an individual customer's needs or to stock;
- Operation, servicing, and product recycling.

The basic phases of the product life cycle are shown in Fig. 7.311.

For realization and evaluation of each product's life cycle, very important are the evaluation criteria. They express not only the degree of fulfilment of functional, material-related, geometrical, ergonomic, and other requirements, but they also imply specific technological solutions. So it is a continuously challenging and inventive development and implementation process. In large enterprises, this means continuous development of one's own products, technologies, and production processes.

Costs in the Product Life Cycle

The cost of making a product is a very important factor that determines the product's price and thus its position in the marketplace. In any enterprise the development of a new product is especially dependent on the imposed functional and technical-economic requirements, formulated evaluation criteria, and market conditions. Research shows that in a product development the highest attention should be paid to the preliminary, conceptional assumptions that define the above-mentioned requirements. During new-product development, all technical aspects are determined, including the material and geometry, which in turn determine technological and process-related solutions. This proves that solutions accepted at this stage (can) influence the product's manufacturing costs up to 70% (Fig. 7.312) [7.410]. For mass-produced market products this is therefore a crucial stage since the enterprise's profitability and market position can be significantly influenced here.

Time in the Product Development

Of the general triad of antagonistic conditions and requirements imposed on today's manufacturing systems, besides cost and quality, it is time that becomes the most important. This parameter is strictly connected with flexible reactions to market demands and is a very strong factor in competitiveness, especially in distributed manufacturing systems. Globalization, using economies of scale in the manufacturing process, has contributed to the increase in production lots and distributed manufacturing, as well as forced a radical reduction in production cycles. An example is shown in Fig. 7.313.

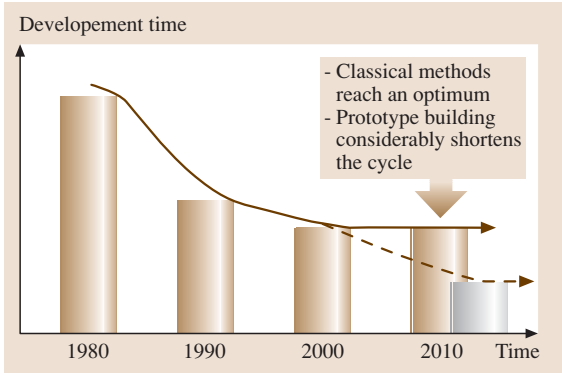

Fig. 7.313 Tendencies of reducing the product development time (after [7.409])

It is estimated that the year 2000 was a turning point for classical methods of product development and creation of new product prototypes. The market pressure on new products and more and more frequent customization require new methods and technologies. One should expect a dynamic technological development that can be seen even in rapid prototyping technologies.

The most susceptible to those changes are basic market sectors that include innovative products with a high level of application of mechatronics and IT systems as well as automotive and machine building industries. However, the contribution of information exchange and communication has increased significantly as a result of introducing the latest organizational solutions in design work – namely, concurrent engineering and collaborative engineering (simultaneous engineering). In such an organization of design work, designers spend a significant portion of their time on data search and interchange. A common concept has become that of *e-manufacturing* – completely integrated and synchronized design, manufacture, project management, etc..

Objectives of Technological Development in Manufacturing

The global economy has brought rapid development to many fields by finding new markets and using economies of scale that allow for a reduction in production costs (Fig. 7.314).

This is the current model of global objective realization by global manufacturers. The model is stable enough but not very innovative. The purpose of all manufacturers is to introduce their products to zones 3 and 4, which means dynamic technological development resulting in introducing to current and new markets new products representing new functions and usable features and generating the highest added value with not necessarily large production volume.

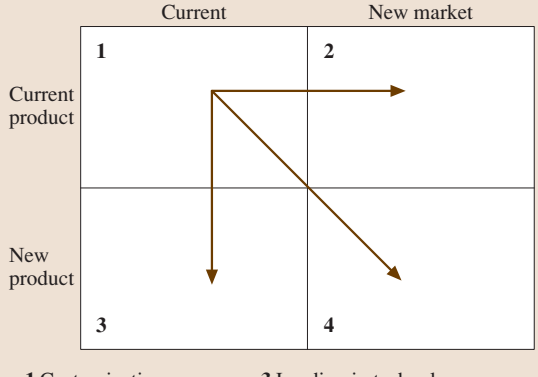

Fig. 7.314 Objectives of development in manufacture (after [7.411])

7.5.2 Rapid Prototyping Technologies

An important stage of new product development is the manufacture and evaluation of its prototype. In many applications a virtual model does not allow for a full verification of a new product and it is necessary to make a physical prototype, e.g., using a technology from a group called rapid prototyping (RP), also called more generally time compression technologies (TCT).

Rapid technologies usually form a smooth transition in a product's development (cycle) between a virtual model and the series production [7.412–414]. Mechanical properties of RP models are, from the point of view of their applications in subsequent stages of product development, important features that are the prerequisite of effectiveness of a given method for designing properties of the planned product.

Basic Knowledge on RP Technologies

A characteristic feature of RP technologies is a shorter time to obtain fully valuable prototypes of new products or their components owing to the elimination of tools required in traditional mechanical technologies (dies in casting, cutters in machining, electrodes in spark erosion, etc.). Another feature is that the processes are based on 3-D computer models of the parts to be manufactured [7.408, 412–416].

The third attribute of RP technologies is their *additivity* – a physical object is built by *adding* material, usually layerwise, instead of *subtracting* it, as in traditional manufacturing. Depending on the RP technology, prototypes are manufactured by an additive method in computer-controlled machines and can be built from paper laminated object manufacturing (LOM), laser-hardened resin (stereolithography), plaster powder (3-D printing), sintered powders of plastics or metals (selective laser sintering), etc. (Fig. 7.315).

As an exception to building with a laminar growth of material there are technologies of HSC or HSM, sometimes also classified in the RP group, where a laminar loss of constructional material is realized by machining. The use of modern tool materials and designs, the progress in machining technology, and advanced constructional solutions in high-speed milling machines allow for obtaining high productivity and very high

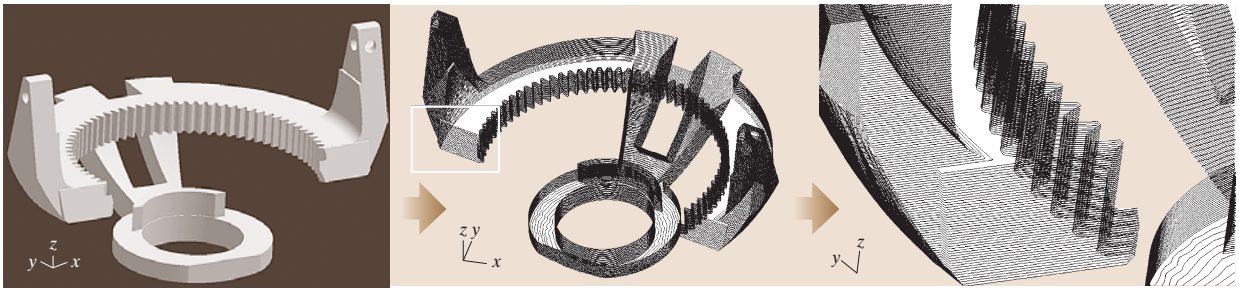

Fig. 7.315 Idea of slicing process in layer additive technologies

machining precision in processing metals and other materials. Therefore, the manufactured objects can be pattern models, prototypes, tools for shaping (dies, stamps), molds for injection forming of plastics, or molds for metal casting. Direct application of HSM for manufacture of finished products in one-off or series production is an example of so-called rapid manufacturing (RM).

Most frequently, the selection of a traditional, an RP, or HSM technology is determined by the time and costs of manufacturing a physical model (a pattern or a prototype). These quantities are shown in Fig. 7.316 [7.417].

The technology of additive manufacture of physical objects is more effective than machining (realized by the HSM or the more conventional milling on NC machine tools). The time and cost of additive manufacturing are only slightly dependent on a model's degree of geometrical complexity. The values shown above will soon change as a result of quick development of both methods. During the last few years, for example, the rate of physical model creation with RP methods has increased several dozen times due to the application of:

- Multiplying the number of laser systems building the same object in a machine
- Higher power lasers allowing faster scanning of a layer being built
- Faster drives and control systems of laser beam deflection systems
- New organization of the manufacturing process

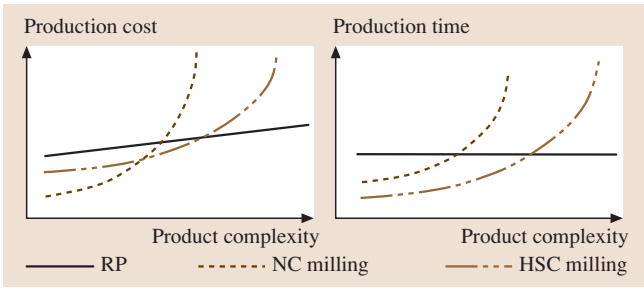

Fig. 7.316 Comparison of time and production costs of prototype models made by the RP and RM-HSC methods

Additive Technologies in Rapid Prototyping

RP describes the generating methods used for laminar creation of components and prototypes with a high degree of geometric complexity. Various technologies are based on one basic principle: 3-D geometrical models created in 3-D CAD systems are *sliced* into layers and in this way reduced to a 2-D form. Such prepared *flat* objects are bonded together to create a 3-D physical model. In many RP methods materials are spot hardened with laser beams (photochemical methods). This process is repeated for all layers of the object being created. Alternative methods are based on laminar cutting out of the contours with a laser beam or on bonding the powdered material with a binder into laminar structures. Since implementing stereolithography as the first commercial RP method in 1987, many other methods have been developed that use the same principle of laminar object structure [7.412, 418, 419]. Classification of RP methods based on applied and processed materials is shown in Fig. 7.317 [7.420].

The necessary condition and the starting point for application of all RP methods is the existence of a complete 3-D geometrical description of the component being prepared. The object geometry, described in a CAD system, is simplified for further mathematical processing by approximating the object's surfaces with triangle meshes and transformed into a data exchange format standard for most RP methods – stereolithography language (STL). Very important is setting the proper number of triangulation parameters (*chord height, angle control*), since they largely determine the quality of the obtained approximation. The maximum

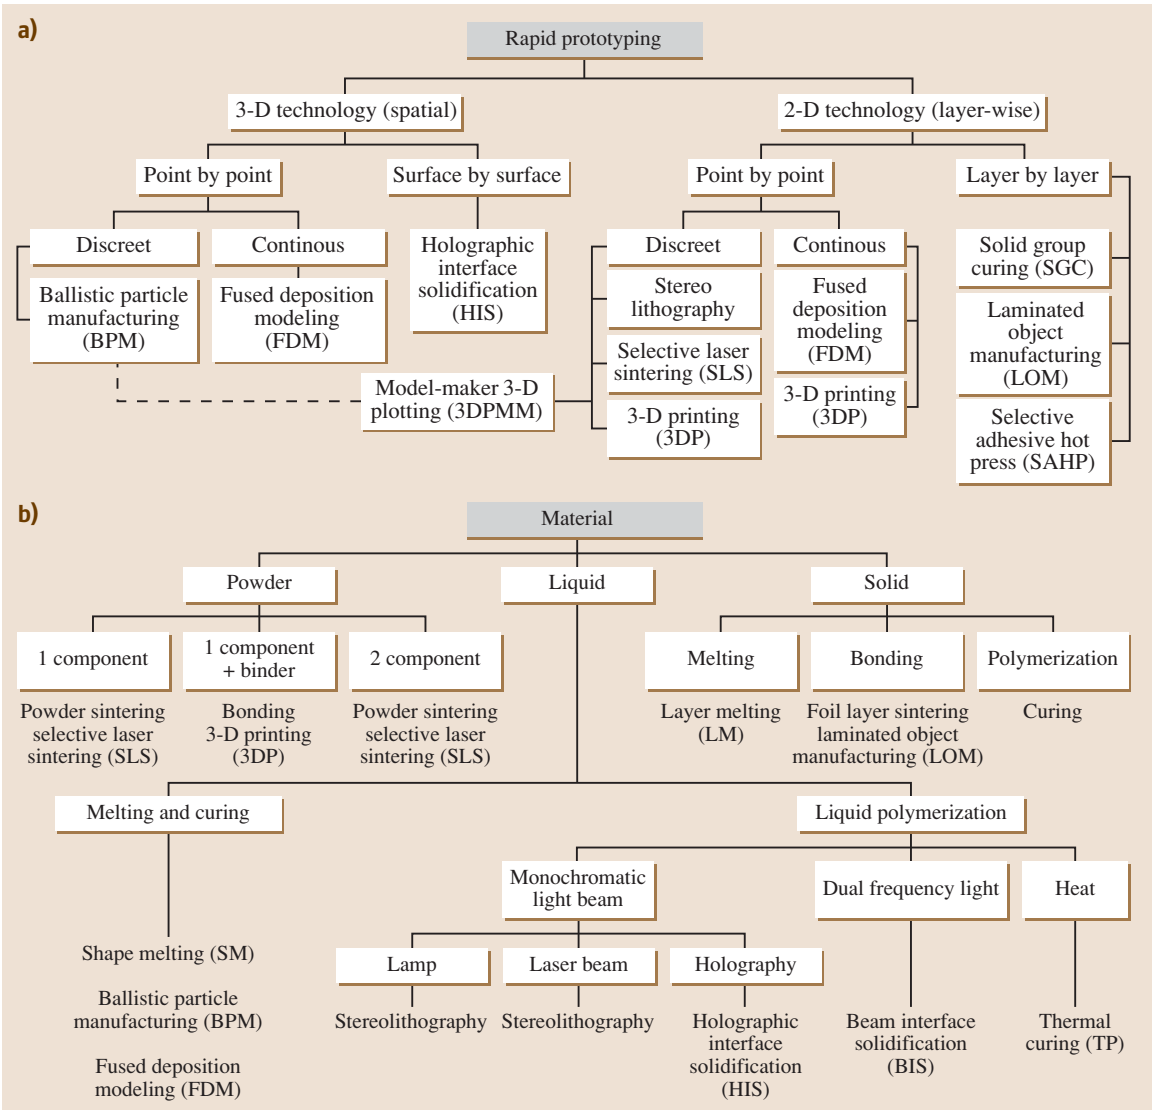

Fig. 7.317a,b Classification of RP methods based on building method **(a)** and based on applied materials and processes **(b)**

permissible chord error (in millimeters) is set by the *chord height* value, and the *angle control* value determines the maximum permissible angle between two triangles. The STL data of an object are further processed in such a way that the 3-D geometry is broken into individual sections (layers) with a defined height (SLI format). Usually, those layers are 0.1–0.2 mm thick.

Classification of RP Technologies. The wide range of solutions in the field of incremental laminar technologies, also referred to as *layer manufacturing* (LM), uses three basic principles of bonding material: chemical bonding, sintering, and gluing. They also include materials in the form of epoxy and acrylic resins, metal and plastic powders, ceramics, and paper. The main laminar methods are shown in Fig. 7.318 [7.421].

Abbreviations (names of developers in brackets): FDM – fused deposition modeling (Stratasys), CC – contour crafting (University of Southern California), SMM – Sanders model maker (Sanders prototype), DMD – direct metal deposition (University of Michi-

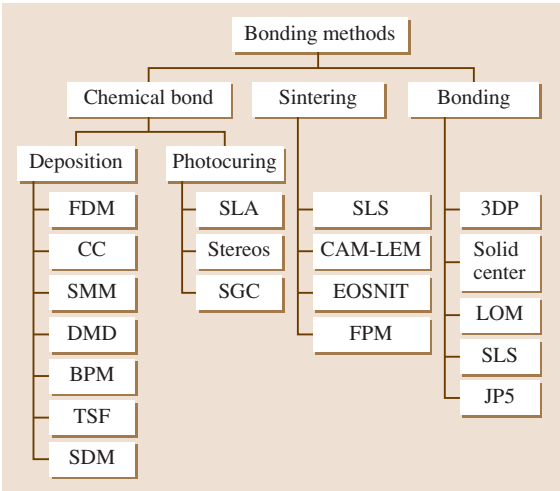

Fig. 7.318 Classification of RP technologies based on the commercial names

gan), BPM – ballistic particle manufacturing (BPM, Inc.), TSF – topographic shell fabrication (Formus), SDM – shape deposition manufacturing (Stanford University), SLA – stereolithography (3-D Systems, Inc.), SGC – solid ground curing (Cubital), SLS – selective laser sintering (University of Texas and DTM), FPM – freeform powder molding (RPI), 3DP – 3-D printing (Massachusetts Institute of Technology and Z-Corp.), LOM – laminated object manufacturing (Helisys), JP5 – JP5 system (Schroff), CAM-LEM – computer aided manufacturing of laminated engineering materials (Case Western Reserve University and CAM-LEM Inc.), EOSINT – laser sintering (EOS GmbH), STEREOS – laser photolithography (EOS GmbH), solid center – paper lamination (Kira Corp.)

Some of the methods, like stereolithography, require adding to the model some supporting structures to enable removing the prepared part from the supporting platform in the machine, and to protect the model against deformation during the building process. The basic advantages and disadvantages of RP techniques are given in Table 7.56 [7.412].

Models and prototypes made with RP techniques can be classified in the following way (slightly modified definitions given in [7.412]):

- The *conceptual model* describes the main geometric and dimensional proportions in a simplified way that allows clear and persuasive presentation of the design solution idea. Detail minuteness of the solution – low.
- The *ergonomic model* determines the boundary conditions of the solution with respect to safety and comfort of the product operation by the future user. Detail minuteness of the solution – medium.
- The *geometrical model* fully reflects the geometrical features of the 3-D CAD model. Often called a visual prototype (model). Detail minuteness of the solution – high.
- The *constructional model* is a synthesis of the above-mentioned models. Detail minuteness of the solution – high.
- The *functional model* has features of the constructional model but also allows for testing performance and basic functions of a product. It is the final stage

Table 7.56 Main advantages and disadvantages of the RP techniques

Advantages	Disadvantages
• Rapid creation of physical patterns • Pattern component at the disposal as early as during the structure development • Especially suitable for – parts with complex geometry (first of all outlines), – free-shaped surfaces • Low manufacturing costs in comparison to other methods (milling, turning, electromachining etc.), mainly for small number of pieces • Possible application of different methods within the whole chain of processes (rapid engineering)	• Limited dimensions of the created objects • Limited range of materials • Components meet the requirements to a limited extent only • Limited exactness (ca. ±0.1 mm), surface quality conditioned by the applied manufacturing technique • Additional smoothing often necessary

of the product design. Detail minuteness of the solution – high.

- A *functional prototype* permits evaluation of the main functions of the solution in close-to-reality conditions, with limited operational parameters.
- A *technical prototype* has all the functionality and aesthetic features of a mass product that allow subjecting it to examination and evaluation within the whole range of operational parameters. It is used for examination and determination of allowed operational parameters. After evaluation by potential users and possible corrections (usually in ergonomic and functional models), it is moved on to series production.

The classification given above is not explicit and, depending on the type of product, features of some models can be synthesized or be absent entirely. They will be understood in different ways in manufacturing processes of cars, home appliances, TV sets, table lamps, or perfume bottles.

Typical application areas of these techniques are:

- Design and ergonomic studies
- Examination and evaluation of design solutions on the basis of physical models and research methods from the scope of photoelasticity, thermovision, X-ray radiography, flow modeling, etc.
- Analysis and evaluation of manufacturing processes, especially assembly processes
- Examination and modeling of flows in plastics forming
- Marketing examination and evaluation of new products
- Testing multifunctional models in casting and plastic working
- Modeling and manufacture of osseous and *soft* implants in medicine

Owing to the application of these methods it is possible to significantly reduce the product life cycle as well as reduce the costs and risk of its development and implementation. The possibility of manufacturing objects without any special tools, molds, or dies has undoubtedly become the decisive factor in the increasing interest in these methods to minimize investment risk. The range of materials used in RP technologies is still growing and includes metals, polymers, ceramics, timber, fiber-reinforced materials, and various metal- or polymer-matrix composites.

In RP processes some problems occur related to the quality of the obtained objects. Besides the stepwise appearance of inclined surfaces, resulting from laminar object preparation, there are also problems related to material shrinkage during processing (e.g., in stereolithography) and with porosity (SLS). Therefore, efforts are being made to develop materials with lower shrinkage and to formulate suitable strategies of manufacturing processes [7.413, 415, 416, 422–424].

RP Technology Application Areas. RP technologies are especially useful in these industrial sectors and these fields where it is necessary to create physical models and respond quickly to market demands. The main application areas of the RP techniques are as follows [7.412]:

- Prototype building for:
  - Verification of design solutions
  - Analysis and evaluation of design solutions
  - Examination of flows
  - Research in wind tunnels
  - Selection of construction materials
- Physical model building for:
  - Searching for design solution ideas
  - Building design and industrial design
  - Marketing presentations for customers
  - Problem solving by the *case study* technique
- Manufacture of components for:
  - Production of tooling and accessories
  - Production of auxiliary means of production
  - Marketing research with a trial lot
- Design and manufacture of tooling for:
  - Planning of production processes, especially assembly processes
  - Design and manufacture of prototype tooling, especially for sheet metal forming
- Design and manufacture of patterns and models for:
  - Casting technologies, including sand casting and lost-model processes
  - Vacuum forming
  - Hydro- and thermoforming
  - Forming by metal spraying on a pattern
  - Epoxy techniques and materials

As determined by research in companies using RP technologies, the most important and largest area of RP application is in the manufacture of functional prototypes subject to constructional analysis in working conditions of finished products and their manufacturability analysis. Figure 7.319 shows the shares of application areas of models made by rapid prototyping techniques, obtained on the basis of data acquired in

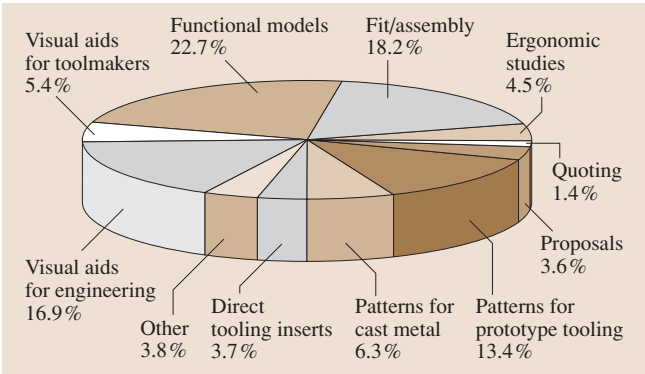

Fig. 7.319 Application of RP technology in industry

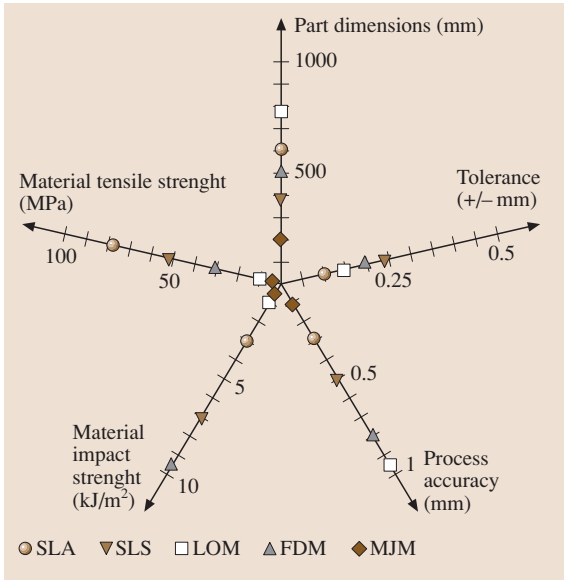

Fig. 7.320 Mechanical properties of materials applied in RP technologies (after [7.426])

2001 from 57 companies (14 users of RP systems and 43 suppliers of RP services), based on industrial data from their customers and their applications [7.423,425].

The data show that 41% of all models were used for analysis of assembly processes and functional examination. About 27% of the models were used as visual aids at the stages of design, making tools, and analyzing orders and offers. Over 23% of the RP models were used as patterns in the manufacture of prototype tooling such as casting patterns as well as for the manufacture of cores and inserts.

The application range and frequency of RP methods depends on the properties of the processed materials and their condition after process termination. Figure 7.320 illustrates the basic mechanical properties of materials processed in RP processes, durably formed in the manufactured products.

It can be seen from the above specification that the largest application field of RP models is the analysis of constructional solutions, assembly, and functional examination. These applications require that prototype models be very precise and represent geometrical features, which in turn implies usable properties of prototype components.

Review of Selected RP Technologies

Stereolithography. The oldest, most popular, and best known RP technology is *stereolithography* (SL). It was first presented by 3-D Systems Inc. in 1987 at the AUTOFACT Fair in Detroit. In this method master objects (physical models) may be manufactured without casting molds or tools. The first realization stage is geometric modeling of an object in a 3-D CAD system. At the next stage geometrical data of the object are processed by a special program that splits the 3-D model in the *X*/*Y* plane into layers usually 0.1 mm thick. As a result, a set of layers is obtained that allows for a suitable program to control a UV laser beam (He-Cd laser, with the power ranging from 20 mW to 1 W). The software controls the beam movements in such a way that by scanning it exposures a section of the 3-D model on the surface of liquid polymer. In the exposed place photopolymerization occurs, i. e., the polymer is transformed from liquid to solid state [7.427]. In this way a fragment of the physical 3-D model is created (Fig. 7.321).

The material out of which a model is made is a liquid plastic hardened (polymerized) with a laser light of a suitable wavelength. The object created in this process, immersed in liquid polymer, is gradually moved down (along the *z*-axis) in such a way that the subsequently hardened layer is connected with the previous one, making a uniform body. Before each stage of exposing a new layer, the polymer level is evened, so that the exposed layer height is identical on the whole surface. After the object creation process is terminated, the object is removed from the liquid polymer and additionally hardened by exposure to UV light. Since the part is built in a liquid environment, in some cases like long, flat, irregular objects etc., it is necessary to complete the model structure with proper supporting elements in order to make it more rigid. The time of the object surface scanning with a laser beam depends on the complexity of individual layers, the velocity of the laser beam movement, and the time of polymer harden-

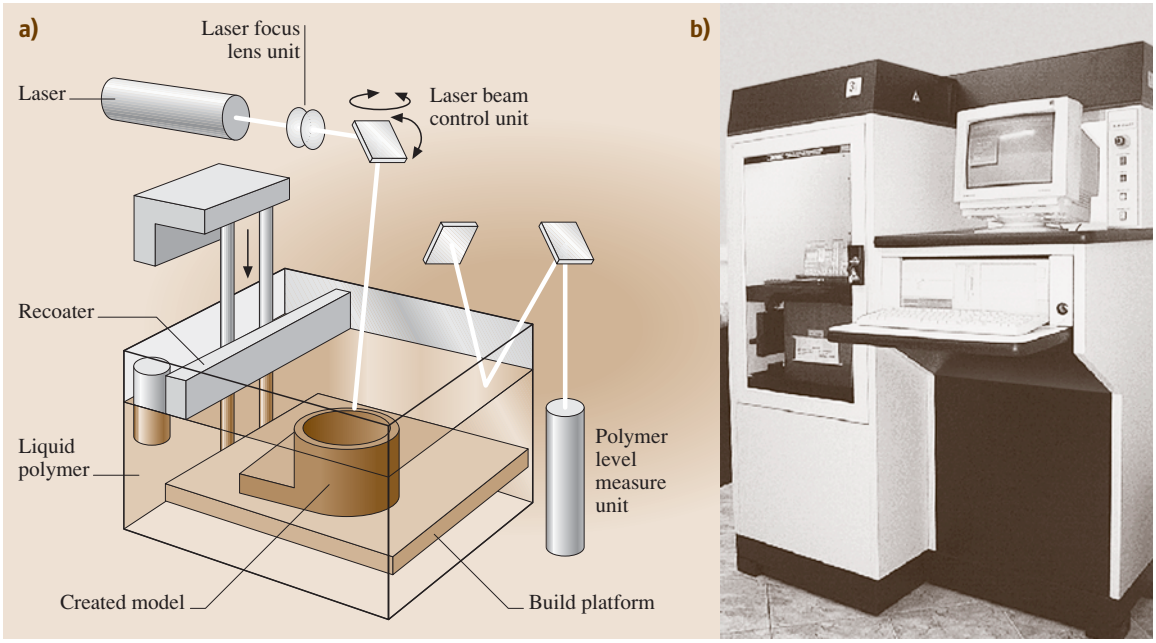

Fig. 7.321a,b Diagram of model creation by stereolithography **(a)** and a stereolithography machine SLA-250 **(b)**

ing and bonding with the preceding layer. Thus, SL is based on achievements in such fields as polymer chemistry, CAD/CAM systems, and laser technology.

The main stages of a stereolithographic model creation are:

- Building a model in a 3-D CAD system
- Exporting the model in the STL format
- Designing the position and geometry of supporting elements (new 3-D model)
- Setting the model-building parameters in a SL machine
- Dividing the 3-D model into layers according to the set parameters of the physical model creation
- Building the physical model in the photopolymerization process

At the time of building a model, a so-called *recoating* system ensures a constant thickness of the layers. The system skims needless polymer allowance from the last,

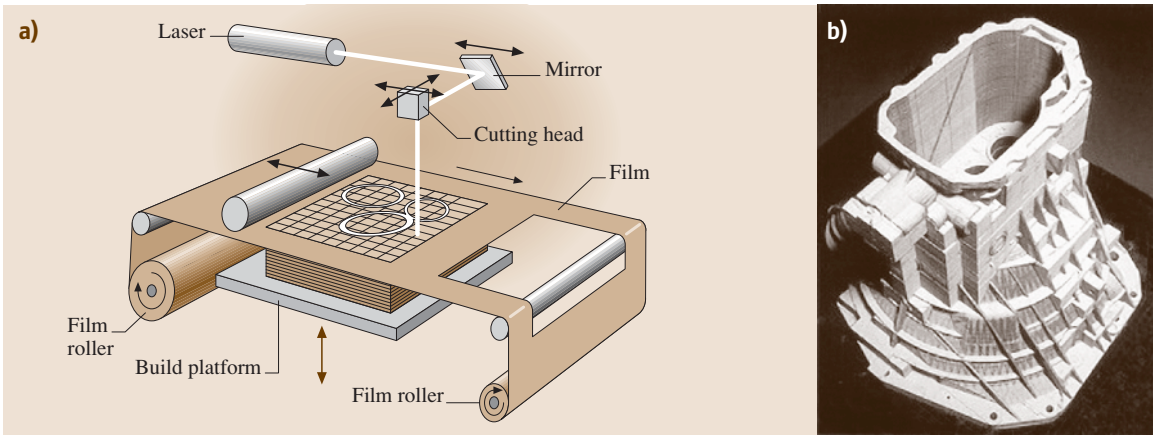

Fig. 7.322a,b Diagram of model manufacturing by LOM method **(a)** and a model prepared this way **(b)**

hardened layer of the photopolymer. When relatively large layers are scanned and hardened, it is necessary to apply an additional liquid layer to ensure constant thickness of the subsequent hardened layer.

SL is widely used in building models and prototypes of products and usable objects in many fields such as industrial design, automobile manufacturing, and home appliances, as well as medicine and architecture. To obtain specific properties of models and prototypes, some additional processes are often required that give the object suitable, required features.

Solid Ground Curing Technology. The method of direct substrate hardening *solid ground curing* (SGC) was developed by an Israeli company called Cubital Ltd. and is realized in the form of the SOLIDER system. The principle is similar to that of the SL method, but there are several significant differences [7.428].

In this case the model is also built layer by layer by hardening a photopolymer. However, the UV light source is not a laser but a UV lamp. Moreover, individual model layers are created generally by exposure of a previously prepared mask of the given layer on a glass plate. This mask is made using a technique similar to that used in a laser printer, although a negative image of a model's layer is created. This means that in the places where the object outline is to be created (exposed), the mask surface is transparent and can transmit UV light, but in other places a nontransparent toner is deposited on the plate. The glass plate, after cleaning, can be repeatedly used for mask making. The pot with the created object moves not only vertically (consecutive model layers) but also horizontally as it is necessary to perform subsequent stages of object creation on individual stations of the SGC machine. When consecutive model layers are created, the nonhardened polymer is collected and free space in the object is filled with wax. This makes it possible for the created model to stiffen and no special supporting elements are required. A cold metal plate is used for wax hardening. Each created model layer is leveled to proper height by milling, which makes it possible to *undo* operations, i. e., to cancel results of previous actions. Next, a subsequent layer of polymer is applied on a smooth and even surface of the created object.

Laminated Object Manufacturing Technology. The method of *laminated object manufacturing* (LOM) was developed by the American company HELISYS.

In this method an object is created by cutting out outlines of individual layers of a model with a laser (with power from a few dozen to a few hundreds watts) and sticking consecutive layers of a film moving by means of rollers over the model being built [7.413]. The model is located on a platform that, along with the model creation, is gradually lowered down by a thickness of consecutive model layers. The film is coated underneath with special glue and the cut-out layer is stuck to the previous one by means of a hot roll that melts the glue and presses and levels the surface of the object being created. As the thickness of the film is not exactly constant, a special sensor is used for measurement of the model height. Plastic, ceramic, and metal films can be used. To facilitate removing the excess material from the finished model, especially if it is not prismatic and has complex internal spaces, the laser beam cuts characteristic squares on the film areas not used for the model creation. After pressure welding, the squares make prisms that are easily removed from the model body. This part of the material is waste. However, this material cannot be removed from completely or partially closed internal spaces of the model. This is a disadvantage of the method that can be omitted by subdividing the model into several parts.

3-D Printing Technology. A simple and cheap method of manufacturing conceptual models is *3-D printing* (3DP), developed at the Massachusetts Institute of Technology [7.424, 429, 430]. The principle is based on laminar bonding of powdered material with a binder applied by a printing head. A diagram of the 3-D printer operation is shown in Fig. 7.323 and exemplary model in Fig. 7.324.

Models manufactured with this type printer are made of powdered starch or powdered plaster. The building process is as follows:

1. The printer applies a powder layer from a container to cover the surface on the molding platform.
2. The binder is overprinted on the prepared substrate to form the first layer of the object cross-section. In overprinted places, the powder is bonded (glued) with the binder. The remaining unbounded powder, in unchanged form, serves to support the physical model.
3. After a layer is completed, the platform with the model is slowly lowered down by a distance equal to the layer thickness.

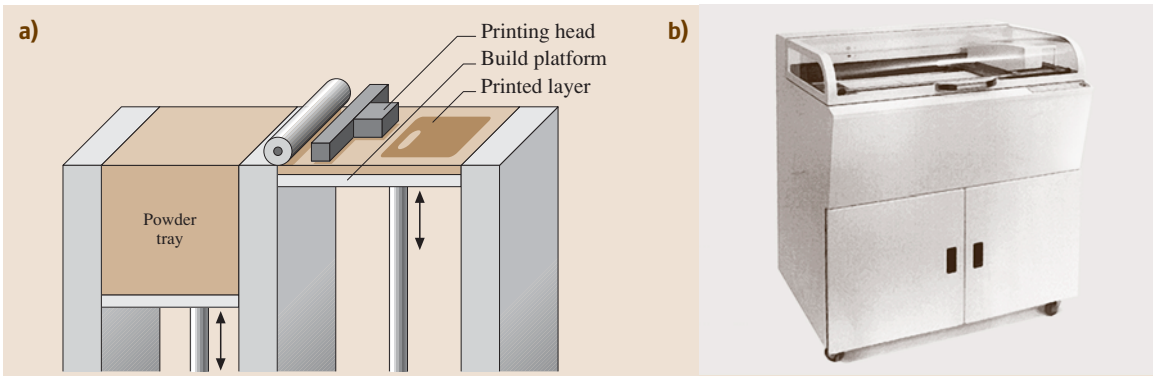

Fig. 7.323a,b Functional diagram of a 3-D printer Z400 made by Z Corporation (**a**) and view of the equipment Z400 (**b**)

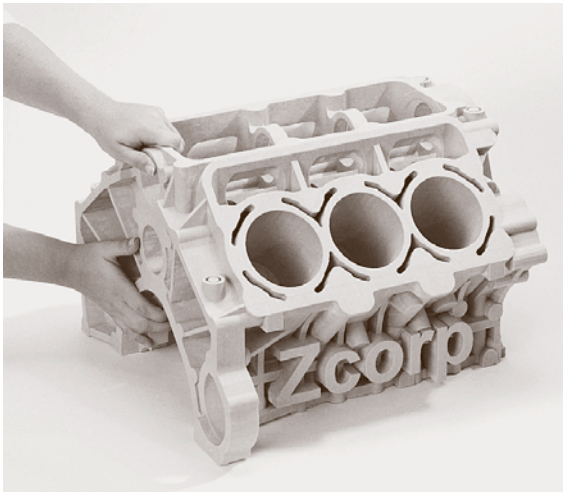

Fig. 7.324 Exemplary model made in 3DP technique

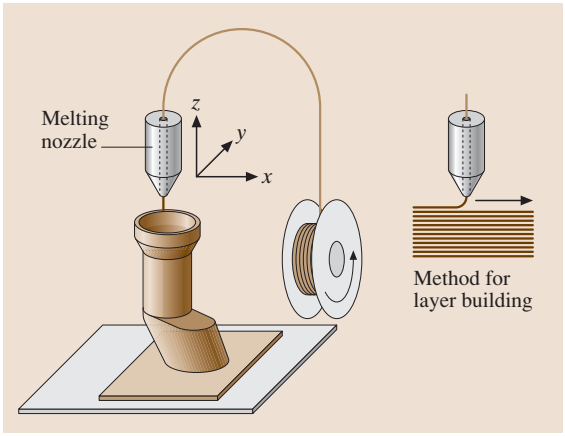

Fig. 7.325 Diagram of model manufacture by FDM technique

4. A subsequent powder layer is applied and the binder overprinting process is repeated.

This cycle is repeated until the whole physical prototype is completed. When building is terminated, the platform with the model is raised and the free, unbound powder is sucked off. The part prepared in the 3-D printer can be impregnated with various materials to increase its strength or flexibility.

Fused Deposition Modeling Technology. In the *fused deposition modeling* (FDM) method, developed by Stratasys, the physical object is built incrementally by applying layers of a material melted by means of a properly controlled nozzle [7.431]. The operating principle is shown in Fig. 7.325.

Direct Laser Sintering and Melting Technologies. A laser beam causes the sintering of determined areas of the powder layer, which sticks to the previously applied layer to provide a uniform structure of the model being created. This method, unlike the previously described RP methods where the material was transformed from the liquid into the solid state, is characterized by material transition from the solid (powder), through the liquid, and again to the solid state (sintered). The technology allows for manufacturing all kinds of models, but also high value tools for series production, like dies, stamps, casting molds, or injection molds for plastics, as well as finished products manufactured in single pieces or small lots.

Selective Laser Sintering Technology. The *selective laser sintering* (SLS) method was developed at the

University of Texas in Austin, USA. In this method a special roll spreads on the working platform a powder layer that is then locally sintered with a laser beam (with power up to several hundred watts and even several kilowatts) (Fig. 7.326).

The SLS method uses such materials as plastics, wax, metal powders (Fe-Cu), and mixtures of metallic and ceramic powders. An advantage of this method is that, like the 3DP and SGC technologies, it does not require any supporting elements when the model is asymmetrical and not too large. However, in very complex and large models it can be necessary to use such stiffening supports. At the final stage of model creation, the nonsintered powder is removed [7.427, 432].

In the SLS process metal powder grains coated by polymer binder are joined by laser power. The disadvantage of SLS is the necessity of removing the binder and infiltration of the product with bronze.

DLF/DLM Technolgies. *Direct laser fabrication* (DLF) is a new technology of rapid prototyping or even rapid manufacturing, developed at Birmingham University [7.433]. It is a modification of the SLS method; like SLS, it is based on laser sintering of consecutive powder layers, but, unlike SLS, it concerns exclusively metal powders and does not require adding polymers or resins that maintain the solidity of the created 3-D ob-

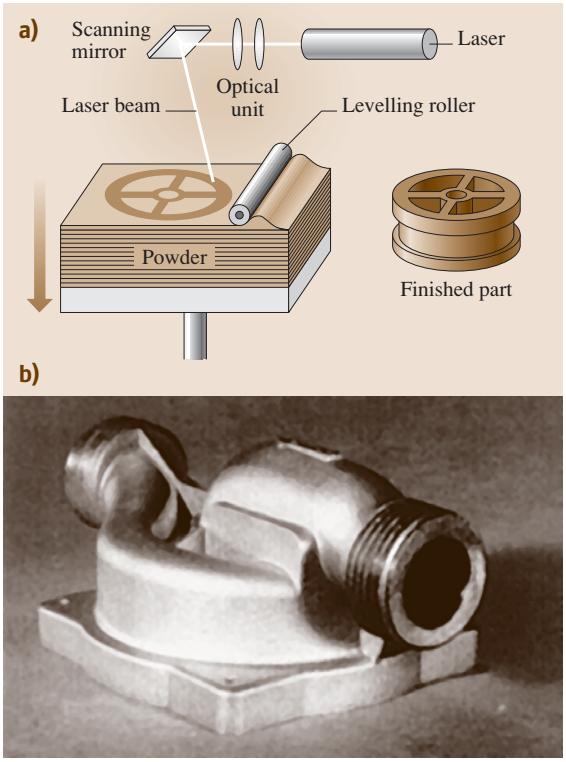

Fig. 7.326a,b Diagram of model manufacture by SLS method (a) and a model prepared this way (b)

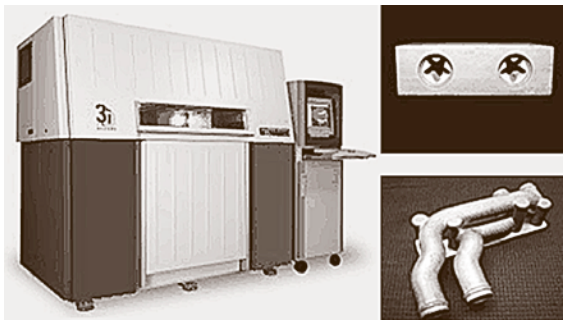

Fig. 7.327 Sinterstation HiQ System of 3-D Systems. Technical characteristics: materials: steels ST100, ST200 and A6; no full melting, infiltration required; layer thickness 70 μm; accuracy 0.05–0.1 mm; build volume 330 × 380 × 457 mm; speed 50–80 cm^3/h

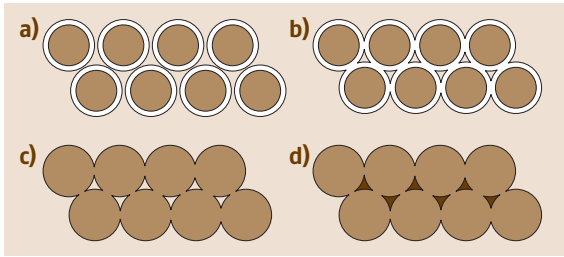

Fig. 7.328a–d SLS process: (a) Loose powder grains before sintering, (b) sintered grains (c), grains without melted binder (d), infiltrated grains

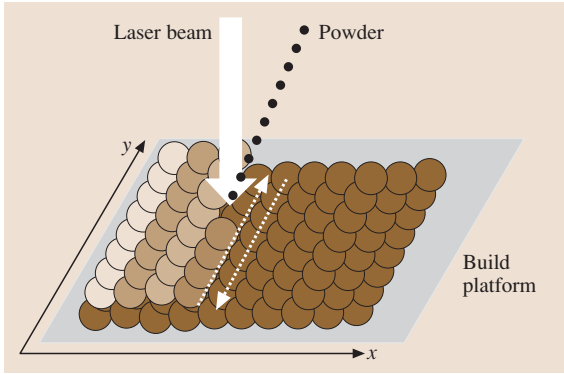

Fig. 7.329 Operating principle of DLF method

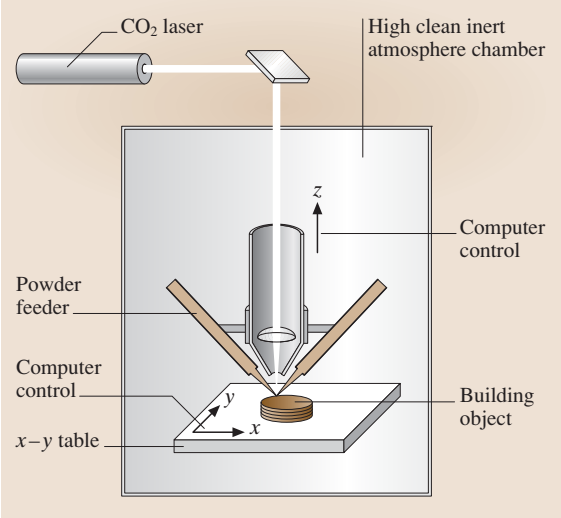

Fig. 7.330 Layout of a DLF machine

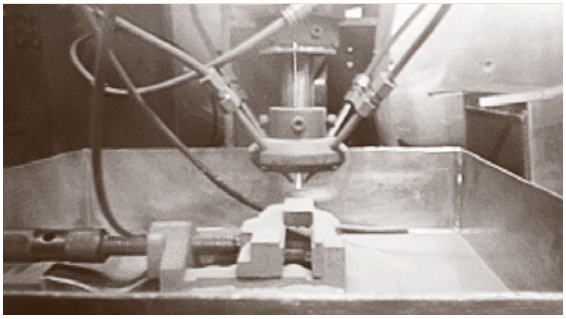

Fig. 7.331 Inside of a DLF chamber

ject and must be later baked and impregnated to reduce the material porosity.

In the DLF method the laser beam (CO_2, 200–1000 W) is focused on a determined point of the created object, which permits temperature increase in the working point up to ca. 1000 °C. A powder is also supplied to the focal point. Owing to that, the obtained object is characterized by almost full density with no necessity to infiltrate it after removal from a DLF machine.

It is possible to control the DLF process parameters in order to obtain objects with various porosities. In this way, one can manufacture objects with controlled porosity, e.g., for medical applications or for the production of filters.

The material structure of a created model is significantly affected by thermal conditions, depending on, among other things, laser power, scanning speed, and

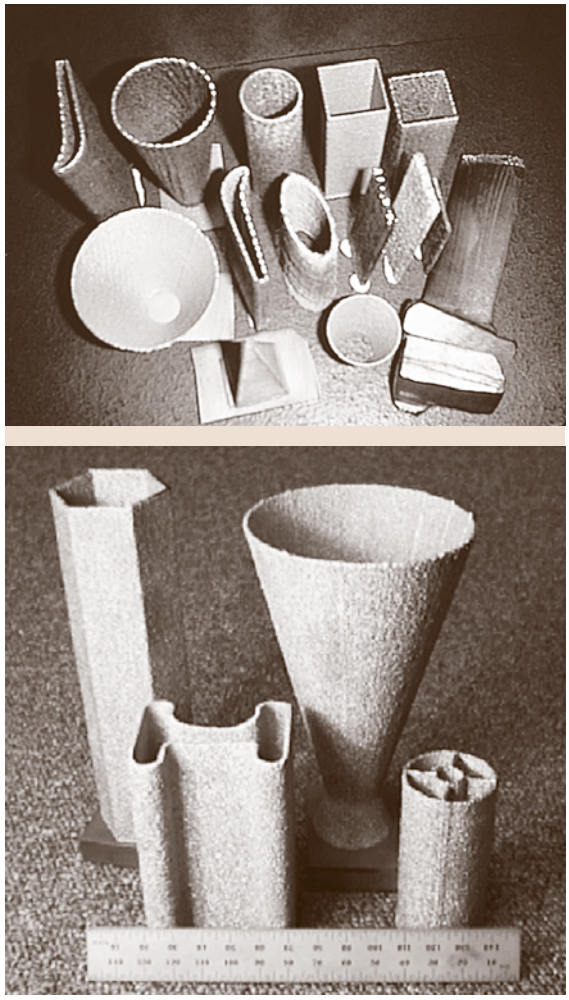

Fig. 7.332 Parts made with the DLF technology from steel and titanium alloy

the quantity and composition of the powder applied. Thanks to the *DLF* technology it is possible to manufacture easily and quickly parts of materials difficult for casting and other more traditional processing. The metal powder fused into a finished product is completely free of pores and its strength is equal to that of a solid material.

Direct Metal Laser Sintering Technology. The direct metal laser sintering (DMLS) process was developed by the EOS company for the equipment EOSINT M (Fig. 7.335) [7.434, 435]. This technology uses a mixture of bronze and nickel powders without additional bonding components. The powders are characterized by

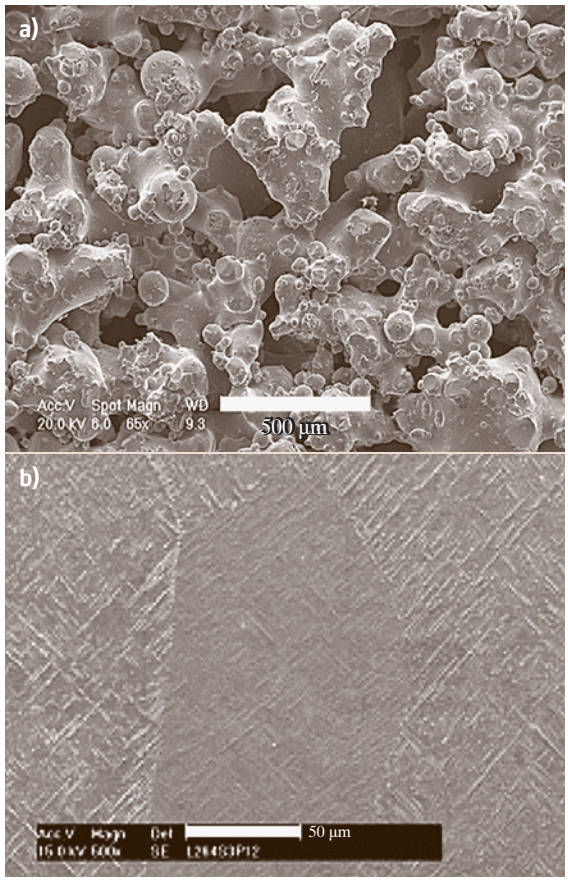

Fig. 7.333a,b Effect of laser power on model structure: laser power 180 W: **(a)** Porous material, laser power 264 W, **(b)** completely fused material

different melting temperatures, which meets the SLS principle based on the fact that the absorbed laser energy melts the low-melting phase (bronze) and wets the high-melting phase (nickel) that remains solid and develops by irreversible change of the crystal lattice. This ensures constant volume during sintering and thus results in high exactness of geometrical representation of the part. The occurring porosity within 25–45% is removed by infiltration of the mold surface with epoxy resin. The application range of this method can be expanded by use of powdered steel materials. This group includes DirectSteel 50-V1, the material developed by EOS for the equipment EOSINT M 250 Xtended. Steel powder with a grain size of 50 µm permits obtaining steel forming inserts of injection molds and thus producing series even up to 100 000 pieces. This technique

Fig. 7.334 EOSINT M270 – EOS device. Technical characteristics: materials: tool steel H20, steel DS20,Ti6AL4V, stainless steel EOS 17-4 PH, bronze DM20; full melting; layer thickness 20–100 µm; accuracy 0.05–0.1 mm; build volume 250×250×215 mm; speed 5–70 cm^3/h

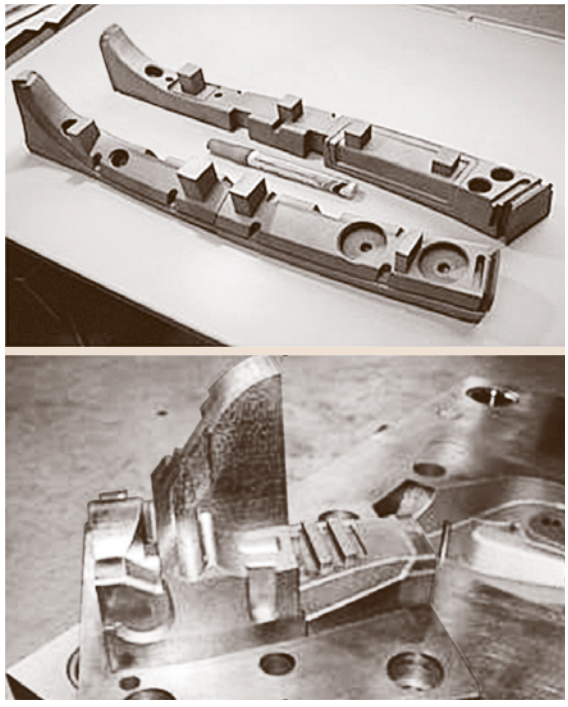

Fig. 7.335 Tools manufactured by DMLS

can also be applied for pressure die casting of highly abrasive plastics to obtain series of molding up to several hundred pieces.

SLM Technology. Since 1995 SLM technology has developed in close cooperation between F&S and the Fraunhofer Institut für Lasertechnik (ILT, Aachen). SLM is a rapid tooling method that uses commercially available one-component pure metal powders (with no binders) with a corn size of 10 to 30 µm for the production of 100% dense parts. To date powders from stainless steel, tool steel, and aluminum can be processed. Currently it is marketed by MCP [7.436, 437].

Especially by the usage of tool steel the produced SLM parts reach a new dimension with respect to maximum load and wear resistance. Right after the production process tool steel SLM parts show a hardness of ≈ 550 HV. Already in 1997 mold inserts for plastic injection molding and aluminum die casting were built and tested by industrial partners. The potential application spectrum of such parts reaches beyond usage as a tool prototype for small series up to ready-for-use series production.

Postprocessing known from the methods of SLS to increase density and strength is unnecessary in SLM.

The characteristics of the MCP Realizer II are as follows:

- Many different materials may be used to build parts from almost all metal powders (e.g., titanium, steel, Co-Cr).

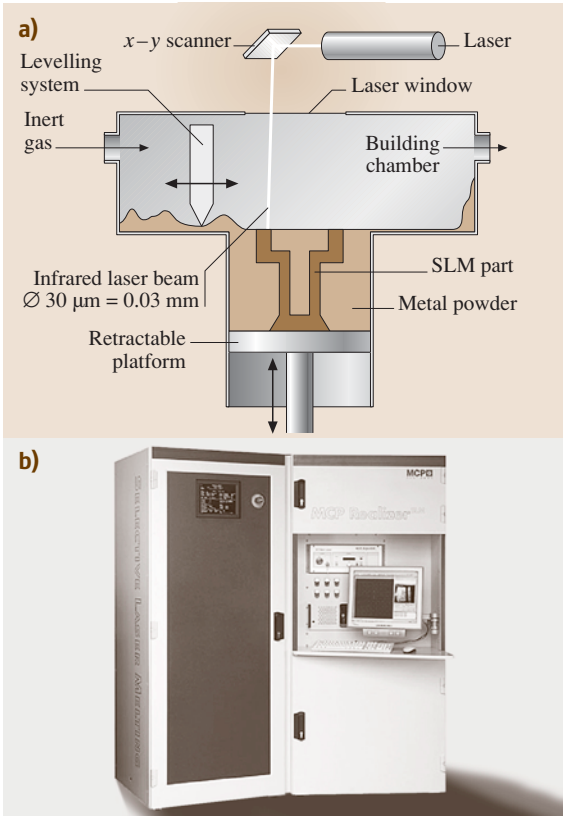

Fig. 7.336a,b SLM: (a) process principle, and (b) example of SLM machine – MCP Realizer II

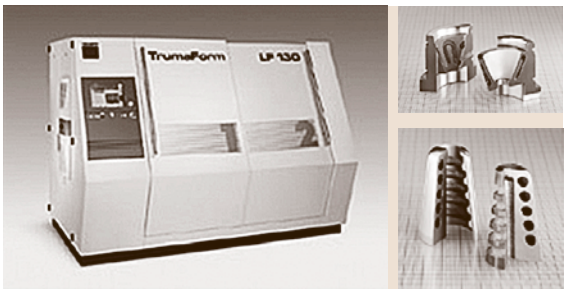

Fig. 7.337 TrumaForm LF 250 from Trumpf. Technical characteristics: full melting; layer thickness 50–200 µm; accuracy 0.1 mm; build volume ∅ × 130 × 160 mm or ∅ × 250 × 160 mm; speed 3–12 cm^3/h

Fig. 7.338 Phenix PM250 equipment

Fig. 7.339 M3 Linear from Concept Laser

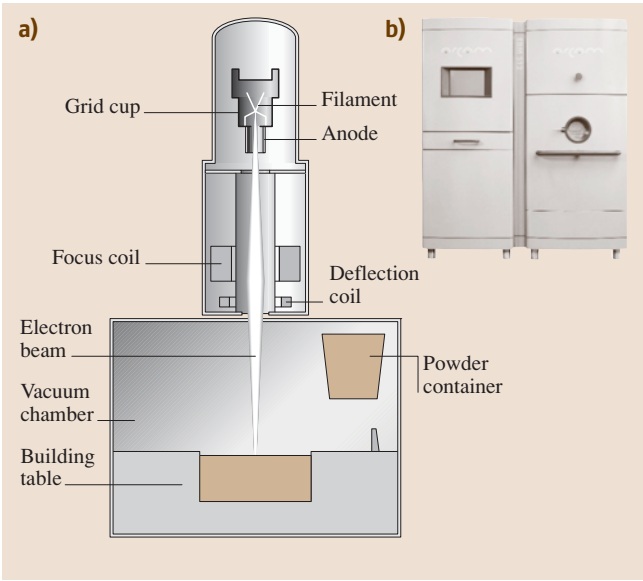

Fig. 7.340 (a) The EBM scheme and (b) the machine from Arcam

- Homogeneous components build up with up to 100% density.
- No necessity of postprocessing (heat treatment, infiltration).
- Fully automated process.
- Possibility of producing internal undercuts or conformal cooling channels.
- High process resolution and accuracy, low heat production.

Technical characteristics:

- Materals: stainless steel 1.4404 (316L), tool steel 1.2344 (H13), titanium (cp-titanium) and titanium alloys (TiAl6V4, TiAl6Nb7), aluminum (AlSi12, AlSi10 Mg), Cobalt-Chrome (CoCr ASTM F75)
- Full melting
- Layer thickness: 30, 50, 75, (optional 100) µm
- Accuracy (material depending): 0.1–0.2 mm
- Building volume: 250 × 250 × 250 mm
- Building speed (material depending): 5–7 cm^3/h

Direct Laser Forming Technology. In the direct laser forming (DLF) process metal powder is melted and homogeneous parts are produced without any binder. DLF allows for producing casting molds and tools that are impossible or very difficult to manufacture in the traditional way. This technology enables creating internal conformal cooling channels, offers the possibility of creating molds, saving materials and functional details.

The dual-chamber idea increases the TrumaForm's versatility [7.438]. During the cooling process in one chamber, the next job can be started in the second chamber with different powder.

Laser Sintering Phenix Systems Technology. The company PHENIX SYSTEMS has developed a rapid prototyping and manufacturing process using laser sintering that represents a true alternative at times when the performances of conventional manufacturing means can no longer meet the technical or economic requirements for product development [7.439].

Manufacturing volume is made up of a cylinder 250 mm in diameter and a height of 300 mm.

The standard materials used are metallic (stainless steel, tool steel, nickel, etc.) and ceramic powders (alumina, mullite, zirconia, etc.), which can be found on the powder metallurgy market.

Common characteristics of metallic parts:

- Accuracy of the produced parts: ±50 µm per 120 mm

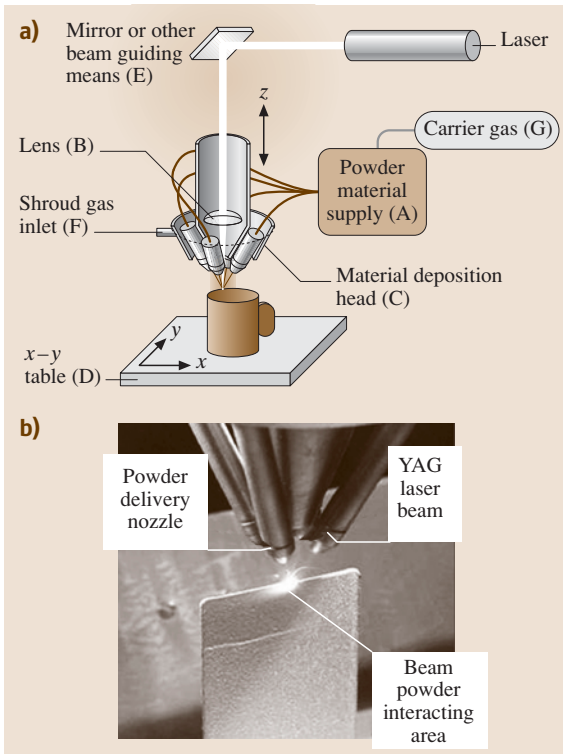

Fig. 7.341 (a) The LENS scheme and (b) realistic process

- Level of detail: 150 μm
- Postprocessing: polishing

Common characteristics of ceramic parts:

- Accuracy of the produced parts: ±50 μm per 120 mm
- Level of detail 300 μm
- Postprocessing: postsintering in the furnace

Technological characteristics:

- Fiber laser 50 or 100 W (high absorption of IR light)
- PM 100: diam. = 100 mm, H = 100 mm
- PM 250: diam. = 250 mm, H = 300 mm
- Building in a furnace: $T_{max} = 900\,°C$ with controlled atm.
- Building speed: 3–30 cm^3/h
- Layer thickness: 20–30 μm

Concept Laser. The M3 Linear is a modular system [7.440]. Apart from the additive manufacturing module it offers an erosion processing module and a marking module in one system.

Module 1 (laser cusing): the module for producing parts from metallic powders. It allows for building parts layer by layer from many materials (e.g., stainless steel and hot work steel). Metallic powder is melted to produce 100% component density. The exposure strategy allows for producing large-volume parts without deformations. A patented surface postprocessing ensures good surface quality and hardness.

Module 2 (3-D erosion module): the module for 3-D material erosion by a laser. It allows for erosion on free-form surfaces. The depth of the erosion process may be individually set by a laser-measuring sensor integrated with the machine software.

Module 3 (marking module): the module for creating signs on plastic or metal elements. It allows for laser marking and engraving on a wide variety of materials.

Technical characteristics:

- Materials: tool steel CL50WS I CL60DG, stainless steel CL20ES, titanium
- Full melting
- Layer thickness: 20 μm
- Accuracy: 0.1 mm
- Build volume: 250 × 250 × 170 mm
- Speed: 5 cm^3/h

Electron Beam Melting – EBM Technology. Arcam AB (Sweden) provides CAD to Metal® technology based on the electron beam melting (EBM) process originally developed at Chalmers University [7.441]. It is a powder-based method having a lot in common with selective laser sintering (SLS), but replaces the laser with a scanned 4 kW electron beam that produces fully dense parts. Materials available at present include H13 tool steel, Arcam low alloy steel, titanium alloy (Ti6Al4V), and pure titanium. Arcam low alloy steel is an easy-to-machine material for prototyping applications.

Parts are fabricated in a vacuum and at about 1000 °C to limit internal stresses and enhance material properties. The cooling process is also controlled to produce well-defined hardening. As with other processes, the parts require some final machining after fabrication, although the company indicates they feel their finishes might be somewhat better than those available from laser powder forming and other competitive processes. Arcam also says that processing in a vacuum provides a clean environment that improves metal characteristics. The EBM process may ultimately be applicable to a wider range of materials than competitive processes and also has the potential to offer much better energy efficiency.

Technical characteristics:

- Materials: steel A6 and H13, Ti6Al4V, Co-Cr
- Full melting
- Layer thickness: 50–200 μm
- Accuracy: 0.2–0.4 mm
- Build volume: 250 × 250 × 195 mm
- Speed: 10–60 cm^3/h

Laser Engineering Net Shape – LENS Technology. Laser engineered net shaping (LENS) technology developed by Sandia National Labs has been commercialized by Optomec [7.442].

This process is similar to other rapid prototyping technologies in its approach to fabricating a solid component by layer additive methods. However, the LENS technology is unique in that fully dense metal components are fabricated directly from raw materials, bypassing initial forming operations such as casting, forging, and rough machining. Parts have been fabricated from stainless steel alloys, nickel-based alloys, tool steel alloys, titanium alloys, and other specialty materials; as well as composite and functionally graded material deposition. Microscopy studies show the LENS parts to be fully dense with no compositional degradation. Mechanical testing reveals outstanding as-fabricated mechanical properties.

Other RP Technologies

Apart from the technologies described above there is a multitude of methods and machines from other suppliers. Below, example technologies are classified with their industrial and research applications. More information on the world market may be found in reports published annually by Wohlers Associates.

There are more and more solutions and suppliers emerging apart from the technologies and machines shown above (Fig. 7.342). Fast progress in this area is to be expected because the issues of rapid manufacturing and customization are growing in importance. Better efficiency, accuracy, surface quality, and new materials will soon cause wider acceptance of these technologies and more industrial applications.

7.5.3 Reverse Engineering Technologies

Digitizing of 3-D Geometry

Digitizing means numerical notation, converting analog data into a digital form that can be saved in a computer's memory. The variability range of the analog data is subdivided into intervals (so-called quanta) and each interval is given a constant, averaged numerical value. The smaller interval, the higher the digitizing resolution and, at the same time, the higher memory consumption for storing the results. Spatial digitizing means numerical notation of a spatial, geometrical model shape in the form of coordinates of points located on its surface in a generalized coordinate system.

Two groups of methods of spatial digitization can be distinguished [7.443].

- *Contact* methods, which use a movable probe acquiring information in the form of coordinates of points on the examined surface, defined in a 3-D coordinate system. Data saving and processing are performed in a computer's memory. In these methods a coordinate measuring machine (CMM) can be used.
- *Noncontact* methods, where a physical model is scanned layer by layer, e.g., by means of a laser beam or X-rays. By converting the acquired contours and surfaces, a 3-D computer model is obtained, designed for further processing in a RE process.

In combination with the modern CAD systems and rapid prototyping technologies, digitizing has given a new meaning to such terms as *rapid product development* or *prototyping*, and in the complete cycle it can be called reverse engineering (RE) (Fig. 7.343) [7.444].

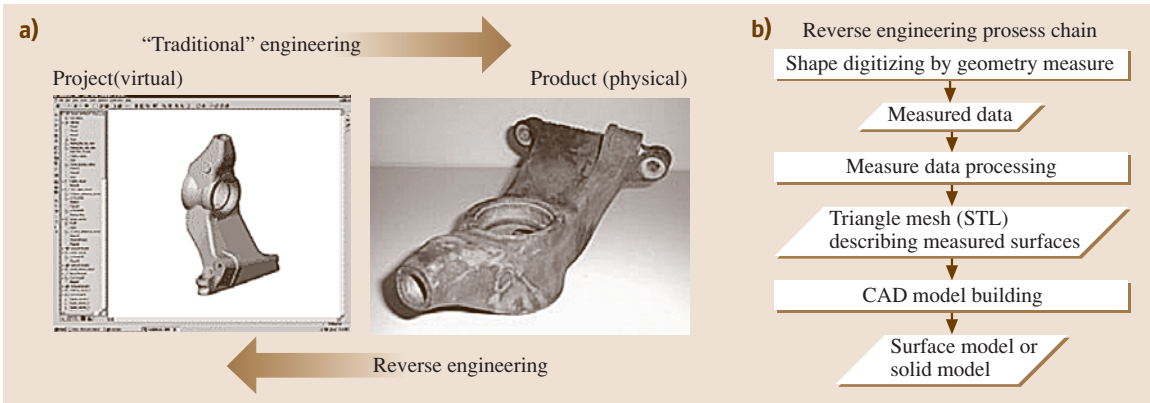

Fig. 7.343 (a) Reverse engineering idea and (b) basic operations at creating a 3-D CAD model

Basic digitizing methods and their application range with regard to their accuracy are shown in Fig. 7.344

Digitizing has created and is still creating new possibilities and its application range is still developing. Its dynamic development results simply from growing demand.

As a result of digitizing, spatial positions of a number of points located on the surface of an object are obtained, based on which a 3-D surface model is created in a CAD system environment [7.414].

The application software associated with machines for spatial digitizing allows exporting data in the most popular formats:

- DXF (points, polylines, polygon meshes)
- IBL (polylines)
- IGES (points, polylines, spline)
- OBJ (polygon meshes)
- STL (polygon meshes)
- VDA (polylines)
- XYZ (point coordinates)

Application of Reverse Engineering Techniques

The importance of numerical notation combined with the above-mentioned rapid prototyping techniques has immensely affected development of the RE that finds application in many fields, among others in:

- Reproducing technical documentation
- Building object models for repair or recovery
- Building a technological model on the ground of an industrial designer's pattern
- Analyzing competitive products in CAE systems
- Designing the shape of an object interfacing with existing objects

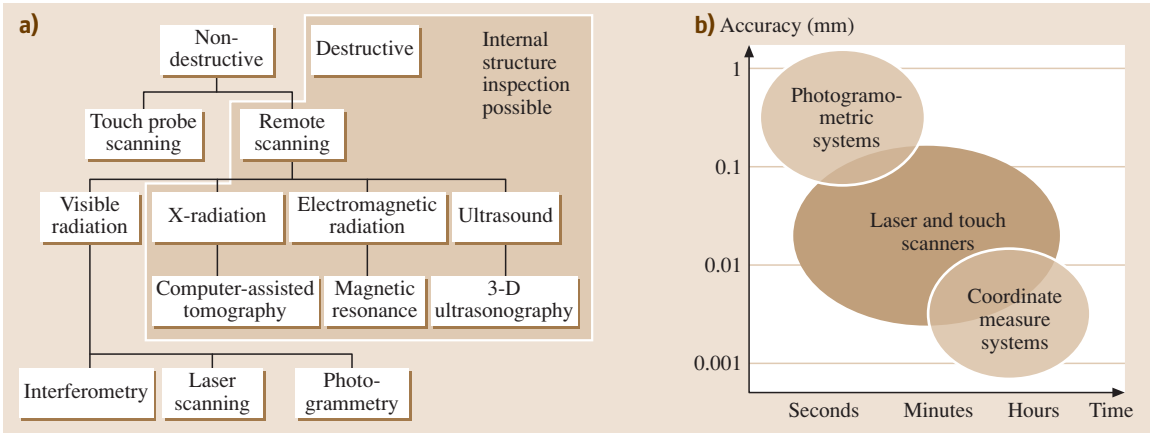

Fig. 7.344 (a) Methods of geometry digitizing; (b) exactness and time-consumption of digitizing methods (after [7.445])

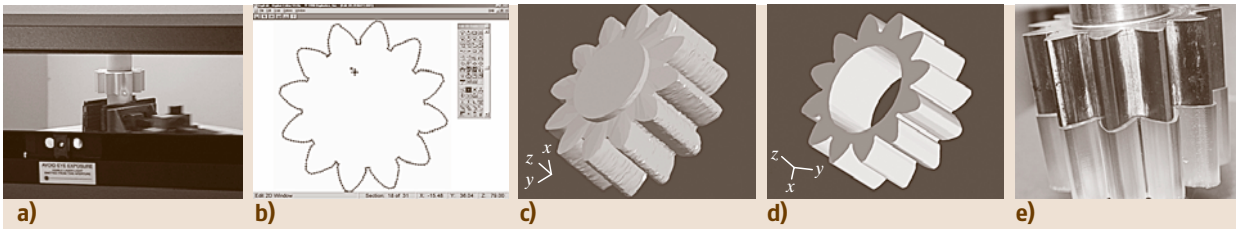

Fig. 7.345a–e Digitizing phases of a gear wheel: **(a)** placing on the scanner table and starting the digitizing process, **(b)** single contour obtained from the measurement, **(c)** geometrical STL model, **(d)** 3-D CAD model, **(e)** digitized gear and the gear made by SLA method after digitizing

- Updating design documentation after optimizing tests on a physical prototype
- Quality control – *first article inspection* aimed at evaluation of manufacturing processes
- Machine building, especially the automotive industry in the early development stages and in tool repair, quality inspection, reproduction of documentation, etc.
- Manufacture of packaging for new products of various, sometimes nontypical, shapes, designed by stylists
- Medal engraving and numismatics (shape reconstruction of coins and medals)
- Footwear and clothing industry (digitizing patterns and molds of footwear components, especially of customized products)
- Jewellery and souvenir industry (copying patterns and natural objects)
- Toy industry (making molds of the ground of artists' designs)q
- Art history (archiving and copying objects – sculptures, buildings etc.)
- New product development by means of rapid prototyping and rapid tooling technologies

A separate field of RE application is medicine, especially biomedical engineering. Owing to such equipment as a tomograph (computed tomography, CT) it is possible to record a 3-D geometry of a living organism or its internal organs [7.444, 446, 447]. Doctors and particularly surgeons have joined engineers who use the 3-D modeling. By means of models created on the ground of tomographic pictures they are able to prepare better for treatments or surgeries [7.414].

Here are some examples:

- Building a 3-D model from a series of flat sections of an object, obtained through computed tomography or magnetic resonance imaging (MRI) (Fig. 7.346)
- Planning complex surgical operations with the use of precise anatomic models built by rapid prototyping methods
- Designing an individual implant for a specific patient
- Reconstructing the geometry of biomedical objects for numerical analysis of their properties

Digitizing Techniques

Coordinate Measuring Machine (CMM). CMMs play an important role in precision measurements since, unlike in traditional measurements, they allow for

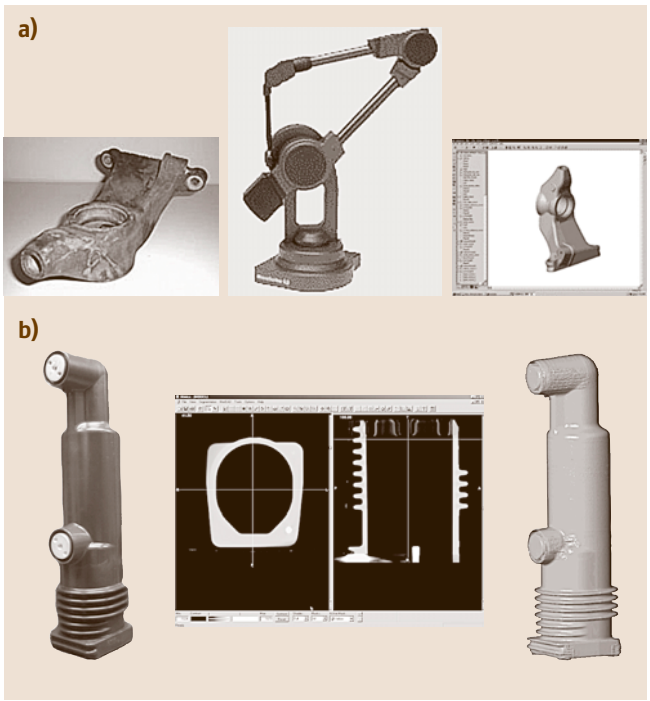

Fig. 7.346 **(a)** 3-D model of a digitized automotive part and **(b)** geometry of an insulator determined by computer tomography

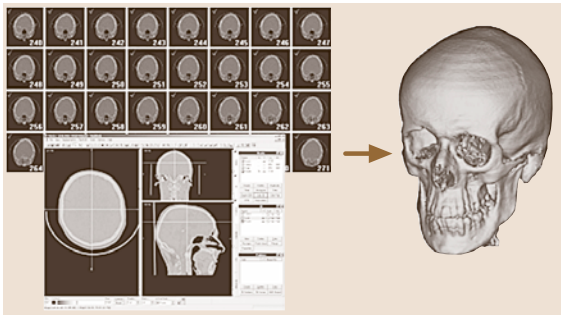

Fig. 7.347 Skull reconstruction on the ground of a set of CT pictures

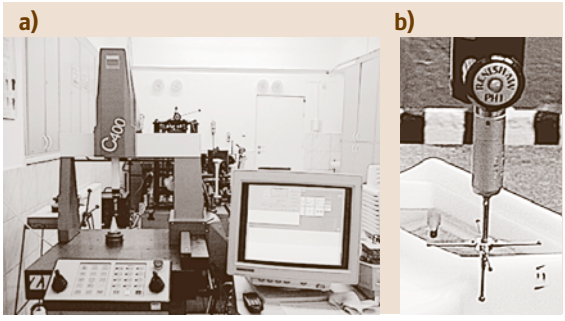

Fig. 7.348 **(a)** Coordinate measuring machine ZEISS C400 and **(b)** a measuring head, magnified

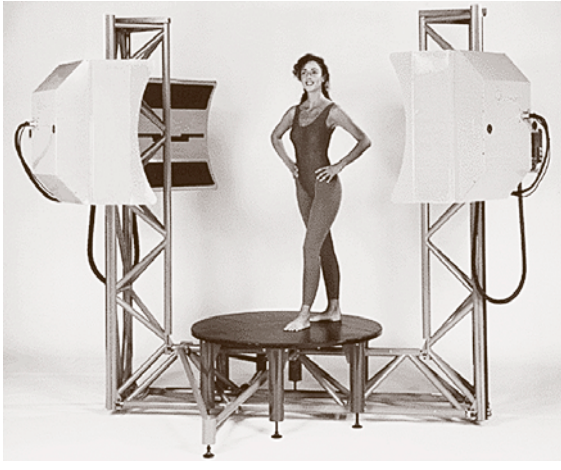

Fig. 7.349 Use of a three-dimensional scanner for clothing design (after [7.449])

quick, precise, and convenient, complex measurements of an object's geometry. Two basic methods of controlling those machines are available: manual (using a manipulator) and automatic (NC) supported by

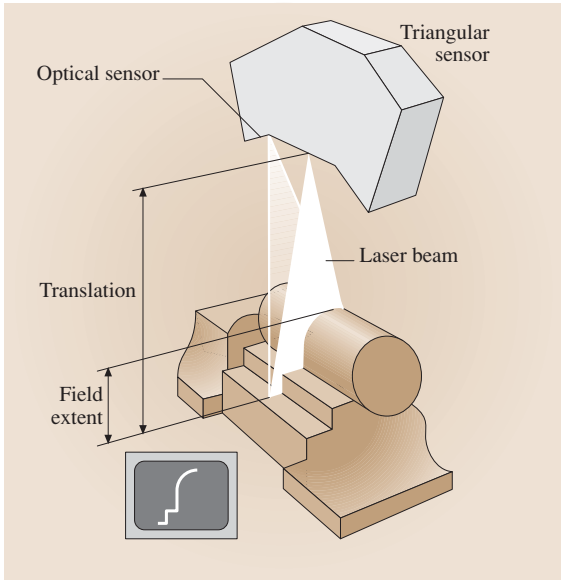

Fig. 7.350 Triangulation sensor used in laser scanners (after [7.450])

a computer program. The correct position of a measuring probe depends on the exactness of manufacture of the machine and its precise mechanisms [7.448]. Typical measurement accuracy is in the range of 0.005–0.0005 mm.

Digitizing of an object or its parts on a CMM is performed in the following way:

- The object is located on a table, the probe is selected, and the machine calibrated.
- The reference plane is determined.
- Characteristic points are indicated on the examined surface (using manipulators) as the basis for the measurement point mesh.
- The measurement step is defined, i. e., the distance between two consecutive measured points (the smaller the step the higher the accuracy)
- The manual or automatic digitizing procedure is started

Depending on the software, the results are processed by the machine controlling computer or exported to an external computer with suitable software, generally in IGES or XYZ formats.

The operation with the manual control is based on a *manually* indicated set of characteristic points of an object, i. e., the points that create simple geometric features adequate for reproducing the object by creating it in a CAD program in a 3-D space. This mode involves

an operator who sets the machine in motion by means of a control desk.

The operation in the NC mode does not require an operator after it is started. Such measurements are made by the machine executing a previously prepared program. The program includes data on the coordinate system, distribution of measuring points, sequence of measurement tasks, machine movement trajectories, calculations, and the form of result presentation. An NC program can be prepared in two ways:

- Teaching programming: the operator carries out all necessary measurements, considering the intermediate points that inform the machine of the idle movement trajectory. The machine saves the data and converts them in an NC programming language.
- OFFLINE programming: The program is created without the machine, in an NC programming language. The programmer inputs data and commands from the keyboard, in any text editor, and the instructions inform the machine of the courses and measuring tasks. The program can also be generated by a CMM module in a CAD system.

Laser Scanners. Three-dimensional scanners create computer models of existing objects. From among numerous developed variations of 3-D scanners and digitizers, the most popular use lasers [7.451]. They can automatically register shapes and colors of scanned surfaces with an accuracy reaching 0.125 mm, in a non-contact way, by means of an optical system consisting of a laser, movable mirror, and a sensor or video camera. The high quality, reliability, and operating speed of this type of equipment are reflected in their high prices.

Designers of 3-D laser scanners with video cameras use low-power lasers emitting orange-red or infrared light, revolving mirrors to deflect the laser beam and high-resolution CCD converters similar to those used in video cameras. The laser beam is deflected by means of a computer-controlled mirror. Image of the laser-illuminated place is recorded by a black-and-white or color video camera.

The scanning process runs automatically in one of three modes offered by the control program:

- Translation mode – the laser with the sensor moves along the arm, the model is fixed
- Rotation mode – the model rotates with the table, the laser head is fixed, and only the sensors move
- Adaptive mode – the laser head and the sensors move along the arm, the model is rotated to acquire the best *view* of the laser beam spot on the object's surface

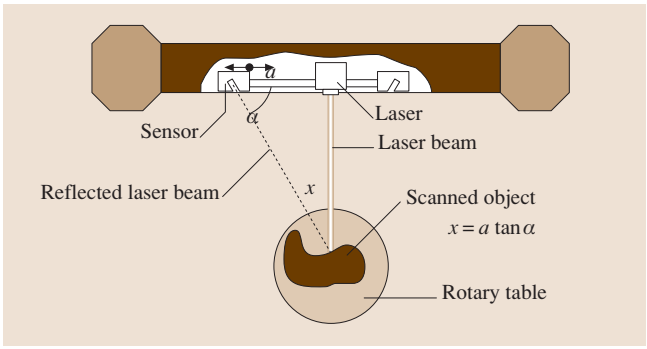

Fig. 7.351 Triangulation on the example of the Digibot II scanner

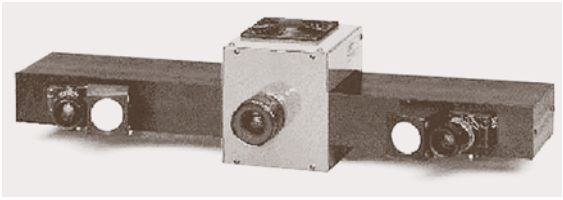

Fig. 7.352 White light scanner

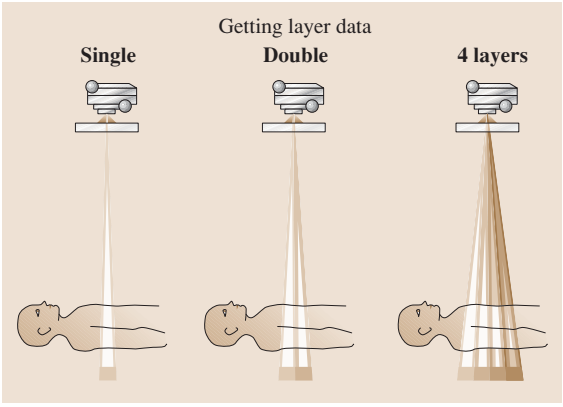

Fig. 7.353 Multilayer technology of computer tomography

In each of those modes the operator can set distances between individual layers (z axis) and numbers of points on each layer, determining the scanning resolution.

Scanners with White Light Triangulation (WLT). This method is an optical technique based on stereovision. In its function it is very close to the operation principle of laser scanners – the measurement data are calculated from the incident ray angle, intercepted reflected ray

angle, and locations of the light source and the recording camera. While laser scanners use a laser beam, WLT scanners use white light [7.451].

The main advantage of the process is that during the scanning process a mesh of measured points is recorded in the form of parallel layers. The laser scanners acquire the point data from one layer only. Image read-outs at various angles are combined and transformed into a 3-D cloud of points.

Computed Tomography. Computed tomography (CT) is a radiographic imaging method that uses a computer to reconstruct images from parallel cross-sections of an object. The 3-D object *image* is created from individual scans (slices of radiographic information) calculated for the analyzed object. The resulting image precisely represents the internal and external geometry of the object (Fig. 7.346). The distance between individual slices is selected by the machine operator depending on the object's degree of complexity. A single slice consists of a large number of points (pixels) in a 2-D image. Computer 3-D CAD models may be built by stacking the consecutive slices.

This method allows for measuring objects with complex shapes without physical access to their insides. It is a nondestructive method. Outside and inside dimensions can be measured with the accuracy of 0.002 mm. CT also delivers information on the density and composition of analyzed objects.

Apart from the original medical applications, CT is also playing an increasingly important role in industry. With equipment shown in Fig. 7.354 it is possible to transfer images of machine parts to virtual space with very high accuracy. A perfect example is the project conducted at the University of Munich [7.452].

The university undertook a project aimed at producing a casting mold for engine heads of an old car made in 1937 [7.453]. The first stage was to scan an existing, well-preserved head using CT. The 550 mm long

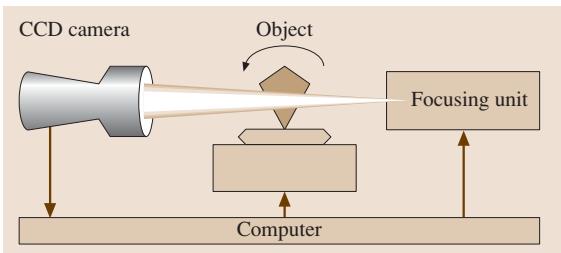

Fig. 7.354 Layout of a microtomograph used in industrial applications

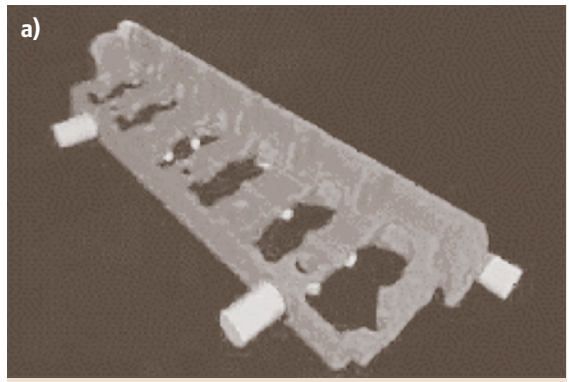

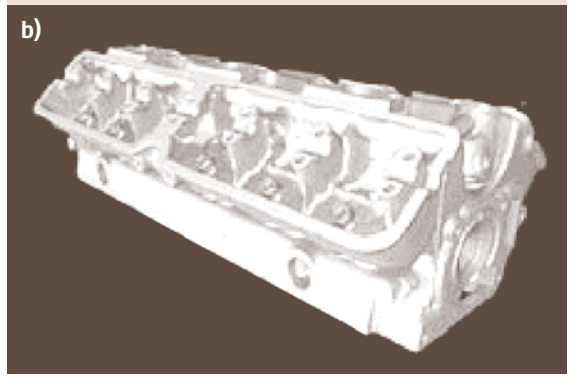

Fig. 7.355a,b Virtual 3-D models generated on the ground of CT scanning: **(a)** core and **(b)** head body

object was *sliced* into 1080 layers with a resolution of 1024 × 1024 each.

From those data the next step was to reconstruct the head body and with an array of internal passages. Both models were saved in the STL format; the first one was used for generating the mold model and the second for the core model. Both the mold and the core were made of sand in a laser sintering technique (SLS).

The finished mold was used to make a casting of an aluminum alloy. The cast body was subject to finishing on a five-axis milling machine. The final result is shown in Fig. 7.356.

Moiré Interferometry. Moiré interferometry (MI) is an optical method that has been used for many years in 3-D applications. It is a very exact tool (accuracy on the order of single micrometers) that determines surface profiles of objects as large as telescope lenses, car dashboards, or other difficult-to-measure components. This technique is based on illuminating the examined object with the Moiré light pattern and acquiring the reflected image by high-resolution CCD cameras. At

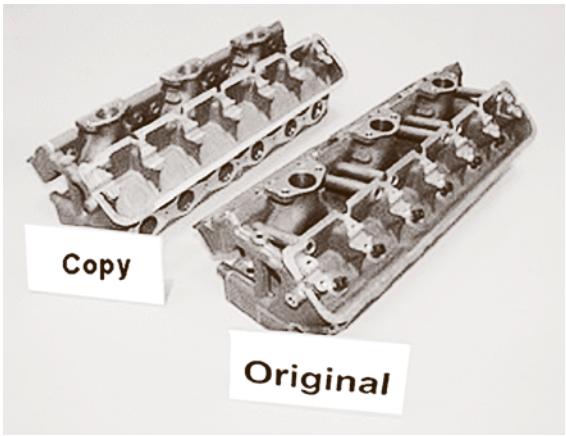

Fig. 7.356 Original head body and a copy based on CT pictures

present traditional MI has been developed into a scanning method.

Traditional MI consists of the following stages [7.454]:

- Illuminating the object surface with Moiré's pattern light
- Saving data from a CCD camera
- Shifting the pattern, very precisely, by a few micrometers
- Repeated saving data from the CCD camera
- Repeated shifting of the pattern by the same distance
- Finally, saving data from the CCD camera
- Reproducing the object topography with calculations based on the obtained picture

As a result of these steps each single point of the object surface has three pictures taken at three different light intensities. In this way, by simple computer calculations, an exact point location is obtained. The high costs and low capacity resulting from the long digitizing process (very precise shift of the pattern) did not allow this technique to be used on a large scale.

A solution is scanning Moiré interferometry (SMI), which has overcome the disadvantages of the traditional technique. The difference between the two concerns the procedure of acquiring points from the surface. Instead of a high-resolution 2-D CCD camera, the new process uses three-line scanning. Now the point-acquiring process is as follows:

- The CCD camera and the Moiré light pattern emitter are combined to create a special compact sensor.
- The object is moved in front or behind the sensor that reads the light intensity for each point.
- The object topography is created on the ground of calculated luminous intensity of each acquired point.
- The scanning process is continuous.

The following advantages were thus obtained:

- The linear CCD camera eliminates laborious picture taking for three subsequent positions.
- In combination with a movable manipulator, it is possible to process the acquired data continuously, at a speed equal to the recording speed on the video camera.

However, this has not changed the fact that this technique is useful for static objects only. Application of the SMI technique allows for digitizing objects with the same accuracy as the original MI but at a higher speed and with lower costs.

Reconstructions Based on a Set of Photographs (Photogrammetry). Photogrammetry is a technique of measuring 3-D objects from 2-D photograms. The term *photogram* covers both ordinary paper photos and images recorded with digital cameras or X-ray equipment. The results of photogrammetry may be:

- Models in the form of point coordinates
- Topographic and subject maps

Photogrammetry is a noncontact technique. It is popular in two application areas:

- Aerial photogrammetry used for building maps and digital land models
- Close-range photogrammetry used by architects (to check the condition of buildings and to determine their deformations and damage), archaeologists, and surgeons

In the photogrammetry technique three methods may be distinguished to obtain models and maps: from a single picture, from a series of pictures, and from stereophotogrammetry. All these methods involve using very expensive equipment like a metric or stereometric

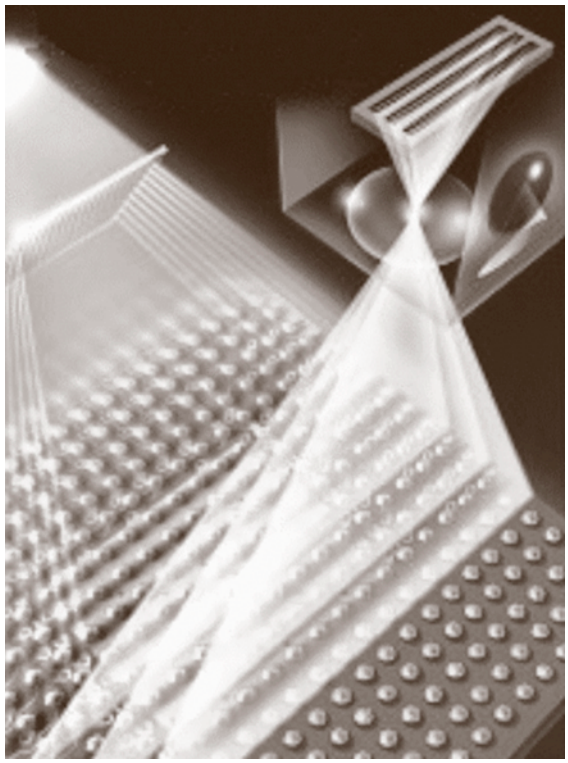

Fig. 7.357 SMI sensor in the three-line scanning process

camera. The acquired image is converted through complicated operations and computer calculations until the final results are obtained [7.455].

Black & White Scanning. Another digitizing method is used by Align Technology, USA. Since 1997 the company has been manufacturing orthodontic equipment in the system invented by them, Invisalign [7.456].

The manufacture of their teeth aligner starts from an impression of a patient's jaw, which is then used to make a plaster cast. Several such models are submerged into a block of a thermosetting plastic.

The hardened resin/plaster block is placed on a basic digitizing stage. On a device that could be called a *scano-milling machine* the block is repeatedly milled and then photographed. In each pass its height is reduced by 0.001 in. (Fig. 7.358).

A *stack* of black-and-white images of all layers is transferred to a computer, where, using a program developed by Align, a digital model of the jaw is built in 3-D space.

The computer models of patients' teeth are used by an orthodontist to generate series of aligners to be worn

Fig. 7.358 View at a single layer of a block

by patients to gradually correct the position of their teeth. The patterns for aligner manufacture are built in stereolithography.

7.5.4 Rapid Tooling Technologies

The pattern models and prototypes obtained with rapid prototyping methods are usually manufactured in small series for marketing and exhibition purposes or for experimental and service research. At this stage of product and manufacturing process development materials (or equivalents) and colors prescribed by the designer are used and the product is given suitable aesthetic features that should fully meet the features of series production. There are several commonly used rapid tooling (RT) technologies. They aim at providing tools (molds, dies) for manufacturing shorter or longer series of products in either specific processes or standard processes common in the production environment. The term rapid tooling covers various techniques of tool manufacturing, including forming inserts of injection molds from plastics, low-temperature melting metal alloys, or metallic powders.

Depending on the strength of the applied materials and their durability and application range, the subgroups of *rapid soft tools* and *rapid hard tools* can be distinguished among the tools manufactured by RT methods. The latter subgroup is characterized by higher durability and wider application range, and the properties close to those of molds manufactured by traditional machining technologies.

The techniques used in the manufacture of tools for mass production are based on highly efficient lost material machining called *high-speed cutting* (HSC),

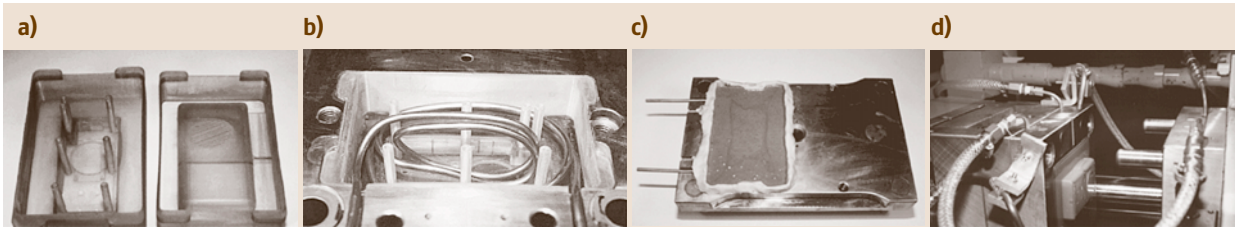

Fig. 7.359a–d Stages of creating an injection mold with cavities made by Direct AIM method: **(a)** stereolithographic forming inserts, **(b)** insert with cooling channels placed in the mold frame, **(c)** sealing the cooling channels in resin filler, **(d)** mold ready to be installed on an injection machine

high-speed milling, and *high-speed machining* (HSM). These technologies, whose development was prompted by new machine tools and machining strategies, allow for quick manufacture of dies and molds with complicated shapes from various materials, including hardened steels.

Direct Rapid Tooling Methods

Direct AIM. One of the direct manufacturing technologies of forming inserts is *direct AIM* (AIM = *ACES injection molding*), where forming elements are manufactured from epoxy resin hardened in a stereolithographic (SLA) process [7.412, 427].

The method was developed by 3-D Systems on the basis of model-building technology *accurate clear epoxy solid* (ACES). Injection molds made by this method are characterized by sufficient thermal and mechanical strength. The glassy temperature of such inserts is about 75 °C, which allows for obtaining 20 to 100 moldings of materials at forming temperatures of up to 300 °C. Here, the precondition is using a proper cooling system. An example of forming inserts made using *direct AIM* technology, including the mold-building stages, is shown in Fig. 7.359.

Direct Metal Laser Sintering. The direct metal laser sintering (DMLS) process, based on the SLS method, was developed by EOS GmbH and is marketed with the EOSINT M 250 machine (Fig. 7.360) [7.435]. This technology uses a mixture of bronze and nickel powders without additional bonding components. The powders have different melting temperatures, which fulfills the SLS principle based on the fact that the absorbed laser energy melts the low-melting phase (bronze) and wets the high-melting phase (nickel) that remains solid and develops as a result of an irreversible change in the crystal lattice. This ensures constant volume during sintering and thus results in high exactness of geometrical representation of the part. The occurring porosity within 25–45% is removed by infiltration of the mold with epoxy resin. The application range of this method can be expanded by the use of powdered steel materials. This group includes DirectSteel 50-V1, the material developed by EOS for the EOSINT M 250 Xtended machine. Steel powder with a grain size of 50 μm permits obtaining steel-forming inserts of injection molds for

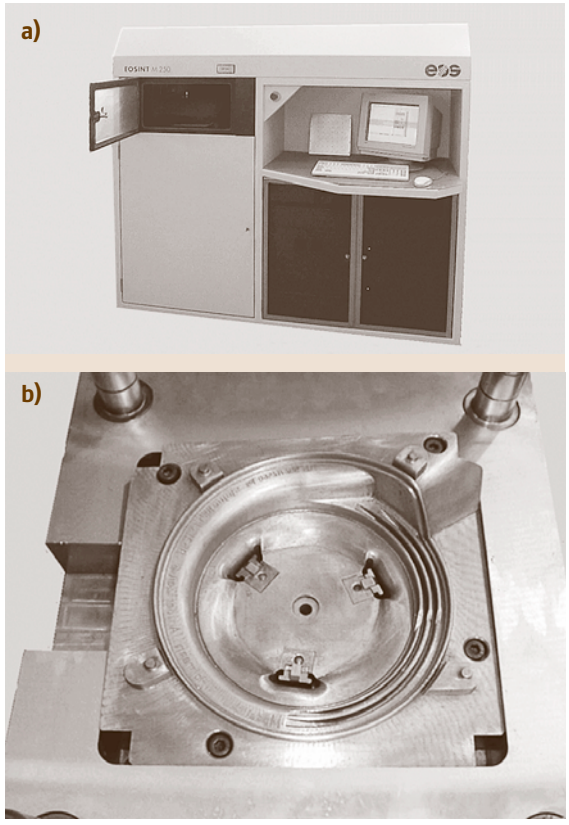

Fig. 7.360 **(a)** View of the equipment for laser sintering of metal powders EOSINT M 250 Xtended and **(b)** a prepared mold cavity

producing series of up to 100 000 pieces. This technique can also be applied for pressure die casting of highly abrasive plastics to obtain series of moldings of up to several hundred pieces.

Indirect Rapid Tooling Methods

Indirect RT methods use positive geometries of base models, created in rapid prototyping processes, to form *negative* mold cavities and dies. These technologies are applied in precision casting, vacuum molding, or in preparing mold cavities and dies by metal spraying.

The group of indirect RT technologies includes, among others [7.437]:

- Vacuum molding in silicone molds (*vacuum casting*)
- Building injection mold cavities by metal spraying (*metal spray*)
- Building molds of composite materials (*epoxy tooling*)

With regard to the different materials used in these technologies, they can be included in the *rapid soft tools* group in the case of vacuum molding and in the *rapid hard tools* group in the case of metal spraying and epoxy tooling. Vacuum molding is used for short prototype series, but metal spraying and epoxy tooling may be used for manufacturing longer series.

Vacuum Molding in Silicone Molds – Vacuum Casting. *Vacuum casting* (VC) is a technology that uses the environment and physical properties of a vacuum, both in the tool-preparing process and in the manufacture of prototype series [7.414, 437, 457]. The mold is made from two-component silicone resins that fill the space around a pattern model in the molding box. The entire tool-forming process runs in a vacuum, securing very accurate representations of the macro- and microstructure geometry of the pattern model. During the process, maximum negative pressure in the vacuum chamber reaches 0.5 mbar. All manufacturing stages of this technology are shown in Fig. 7.361.

The cycle, beginning from pouring into a mold, is repeated for each piece of the product manufactured. This technique allows for manufacturing of 5 to 30 pieces of a prototype product. The number depends on the product's degree of complexity. With very geometrically complex, thin-walled products, this number will always be smaller. The basic advantage of this tech-

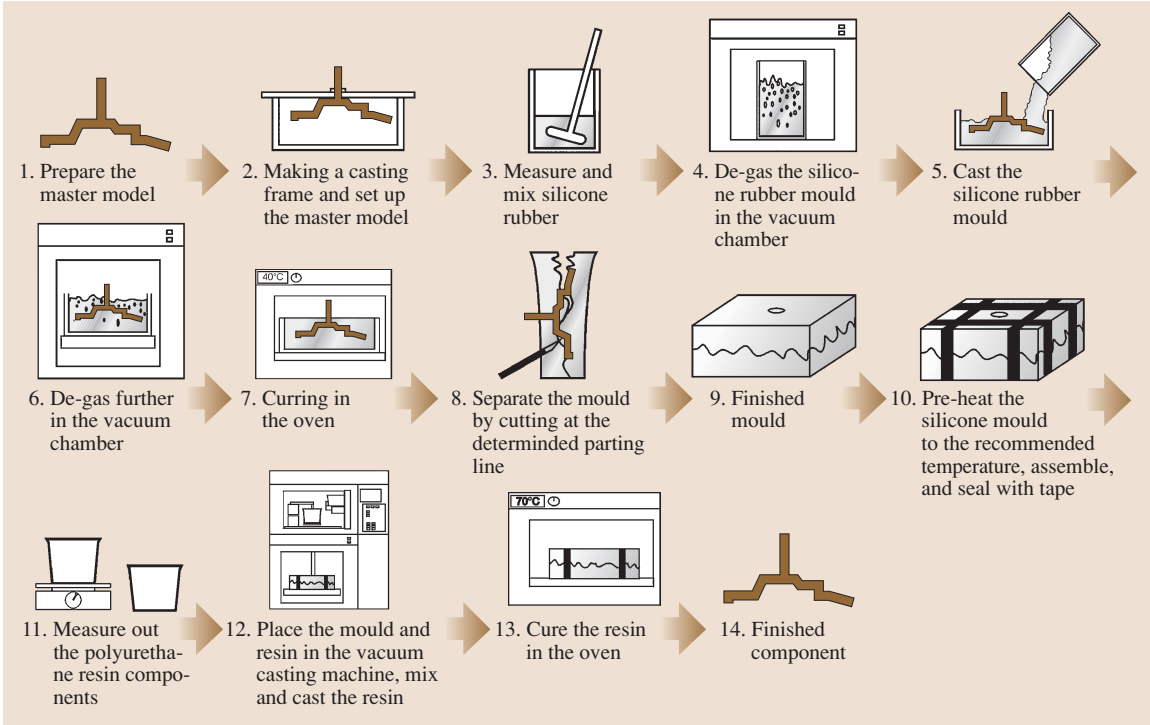

Fig. 7.361 Stages of vacuum molding in silicone molds

Fig. 7.362a–c Examples of vacuum casting application: **(a)** prototype products, **(b)** equipment for vacuum molding and **(c)** silicone molds

nology is its low cost, being about 3–6% of the cost of traditional technologies used in injection molding, and short production cycle counted in hours instead of months (about 3% of the time required in traditional technologies).

The cavities of silicone molds are used for gravity casting of prototype series products. The materials used for prototypes in this technology are two-component epoxy and polyurethane resins. They allow for obtaining prototype models with mechanical properties close to those of parts manufactured with injection molding. The resins used in VC imitate properties of typical thermoplastics used in plastics processing.

The equipment used in VC technology is shown in Fig. 7.363.

Characteristic features of silicone resins for molds in VC technology are presented in Table 7.57 [7.437, 458]

These materials, with their properties close to the thermoplastics family used in plastics processing, e.g., ABS, polyethylene, or polyvinyl acetal, allow for manufacturing a variety of prototype parts with a wide range of design and mechanical properties at full color scale [7.437].

Fig. 7.363 Equipment for vacuum molding 001ST made by MCP-HEK

With regard to the reaction of the mold material with the cast resins resulting in surface brittleness of mold cavities, the durability of the molds is limited to 20–30 cycles; however, the series repeatability is guaranteed for the first 10 pieces.

Figure 7.364 shows an example of an SL model with VC made in a silicone mold.

Metal Spray Technology. Another representative of the indirect *rapid tooling* techniques, of the *rapid hard tools* group, is *metal spray* technology. It allows one to prepare injection mold cavities, dies, and stamps for plastic forming of sheet metal [7.437].

Table 7.57 Parameters of two-component resins used in tool manufacture by VC processes

Component Property	ESSIL 241	ESSIL 244	VTV750/ CAT750	VTV800/ CAT800
Manufacturer	AXSON	AXSON	MCP-HEK	MCP-HEK
Setting time at 25 °C (min)	90–120	ca. 105	100	120
Density after hardening	1.10–1.14	1.10	1.2	1.2
Shore hardness	40 A	40 A	40 A	38 A

Linear shrinkage (%)	< 0.1	< 0.1	< 0.1	< 0.1

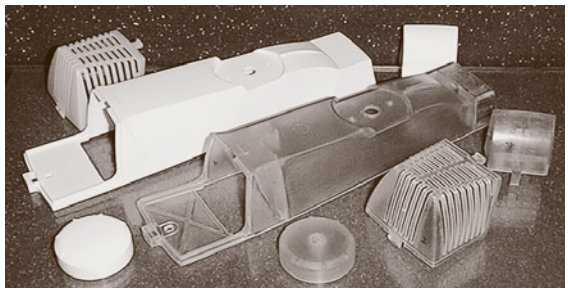

Fig. 7.364 Element of a prototype series with the original SL prototypes

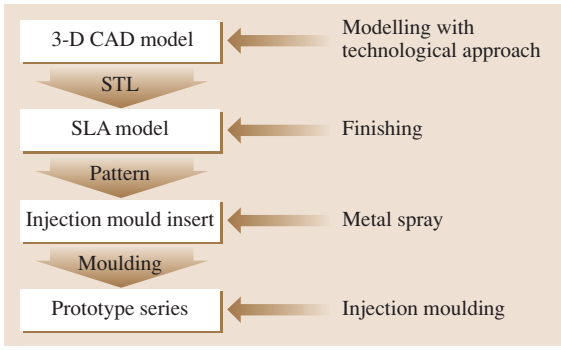

Fig. 7.365 Diagram of the process of prototype series manufacture by means of an injection mold made by metal spraying

The main advantage of this technology is that it allows for very quick preparation of mold inserts and dies based on a shell mold obtained by metal spraying of the pattern model previously prepared by, e.g., RP methods. The mold prepared by spraying the pattern model fully represents all the details of the model, with respect to both geometry and surface structure. The individual stages of this technology for injection mold building are shown in Fig. 7.366. Tools for mechanical working of sheets are manufactured in a similar way. The durability of a mold is estimated for 2000 to 10 000 pieces of finished product, depending on their geometrical complexity, applied materials, and process parameters. The typical time needed for mold preparation is 1 to 2 d, and costs do not exceed 15% of those estimated for mold manufacture by machining or electromachining.

When this method is used to manufacture dies and stamps for mechanical working of sheets, the processing sequences are similar, except that the process should consider the properties and thickness of the sheet to be processed [7.437].

Application of this technology is especially effective in both the initial and final stages of product prototyping, even including cars.

The range of materials that can be used with this method includes low-melting alloys of zinc, copper,

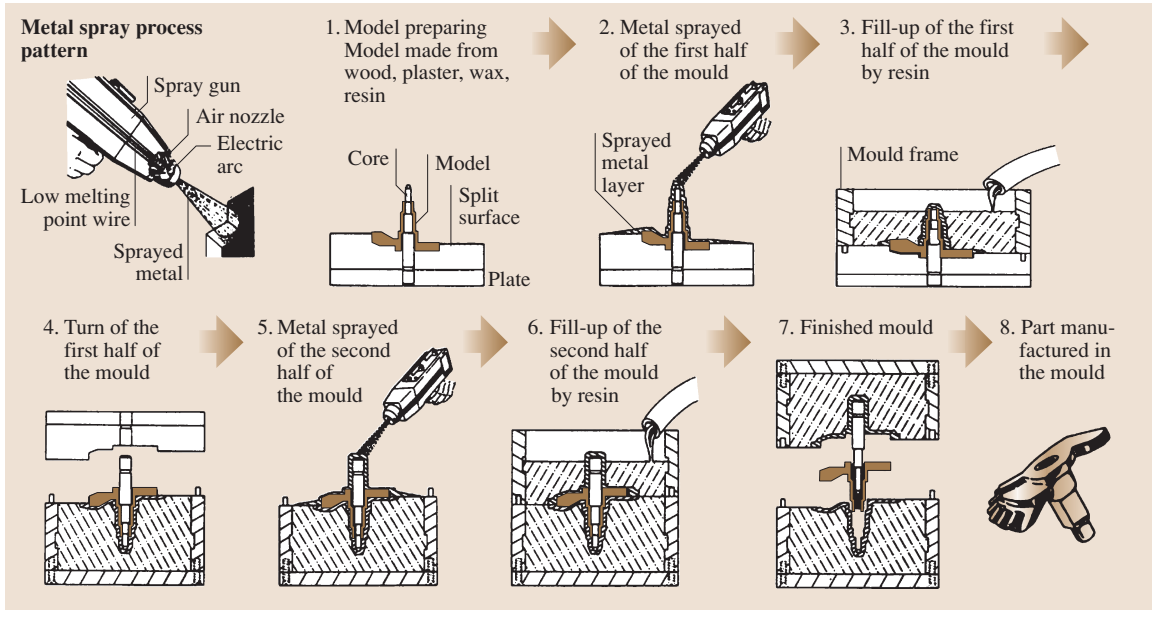

Fig. 7.366 Application of RT technology for preparing an injection mold cavity

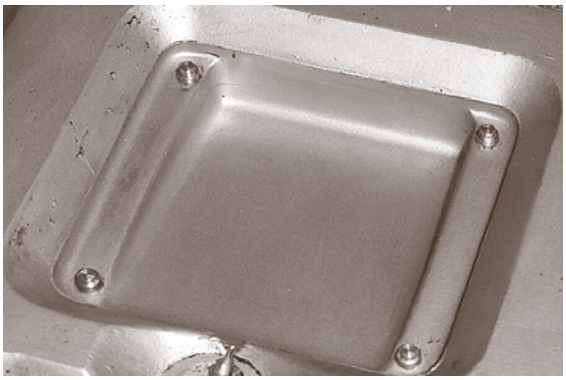

Fig. 7.367 mold cavity made by metal spray technique with brass inserts (after [7.414])

and aluminum, as well as steel. In the case of steel, it is necessary to prepare ceramic heat-resisting pattern models, which makes the tool-creation process more complicated. However, this method is applied in cases requiring higher heat resistance and mold durability. These features represent an advantage in tool preparation in comparison to the nonferrous metals molds.

An example of a mold cavity with brass inserts is shown in Fig. 7.367.

The metal spray technology based on low-melting alloys of tin and zinc was developed by the MCP-TAFA company. The method of building shell cavities of injection molds, stamping dies, and stamps for sheet processing was developed on the basis of the arc spraying machine TAFA-8830.

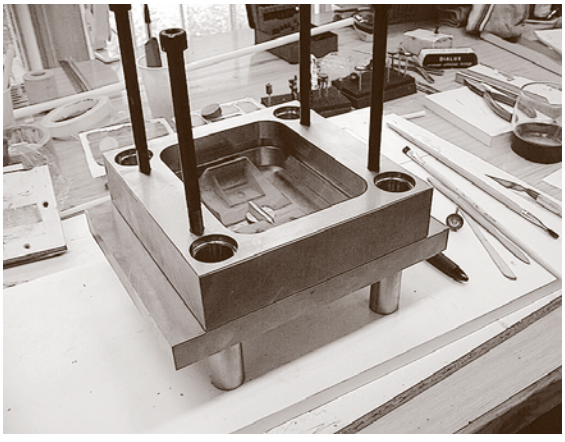

Fig. 7.368 View of a model with shaped parting plane, fixed in the mold frame

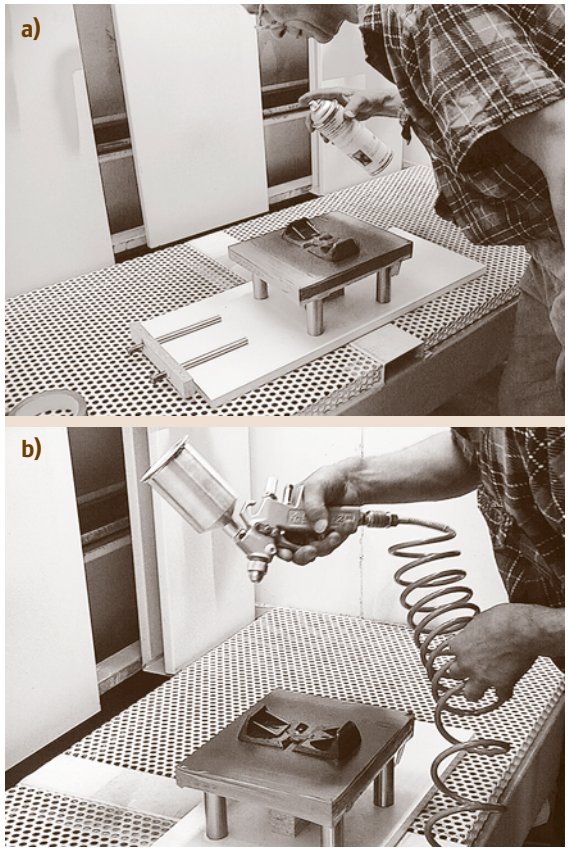

Fig. 7.369 **(a)** Stages of applying layers of graphite and **(b)** glassy separator

Apart from low-melting alloys developed for RT technologies, the spray gun TAFA 8830 also permits spraying such materials as copper alloys or steel. The process of pattern model preparation to be covered with an alloy layer includes the following stages:

- Giving the model the required properties of surface micro- and macrostructure, like roughness and surface quality.
- Fixing and shaping the parting planes.
- Covering the model with separators to enable dismembering the mold and removing the pattern model. Models with shaped parting planes are first covered with a graphite-based agent and next with a thin layer of another separator.

The spraying process (Fig. 7.370) should be continued until the shell is 3 to 5 mm thick.

Materials used in this method include, among others, low-melting tin and zinc alloys like MCP 200,

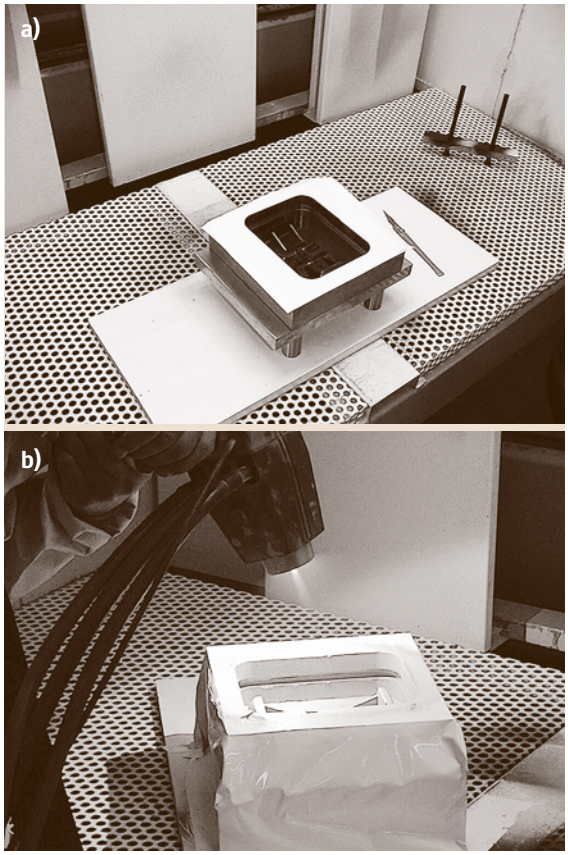

Fig. 7.370 (a) Metal spray of mold cavities prepared for spraying. (b) Course of the spraying process

TAFA 204M (MCP 400), and TAFA205. A view of a model with a shaped parting plane, covered with a separator and ready for spraying the cavity of the first half of the mold, is shown in Fig. 7.371.

The Costs of molds manufactured by RT techniques are much lower and, in the case of the technology developed by MCP-TAFA, comprise ca. 23% of the costs of molds prepared by traditional machining. Owing to this difference and to the time of mold preparation, the RT techniques are an effective tool in the initial stages of product development, significantly reducing the cost and time of new product implementation.

Epoxy Tooling, Composite Tooling. Another one of the *rapid hard tooling* technologies is a method of forming injection mold cavities, based on applying composites of epoxy resins and metal powders, usually aluminum [7.437]. This method permits reducing by ca. eight- to tenfold the time required to prepare process

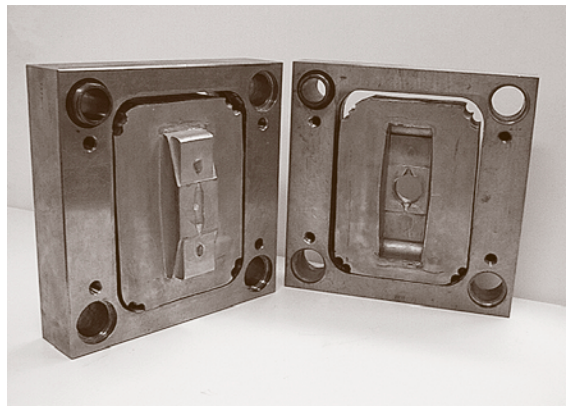

Fig. 7.371 Shell injection mold with cavities made by metal spraying (after [7.414])

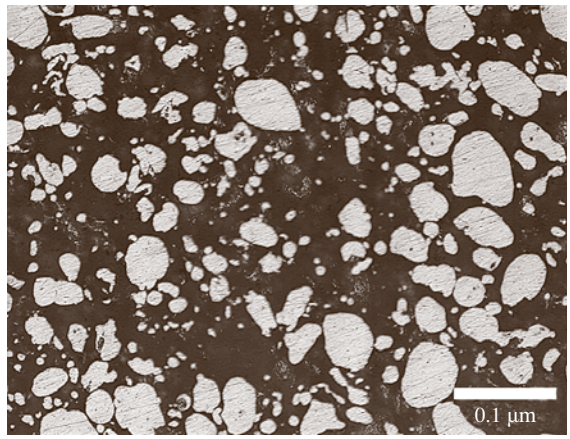

Fig. 7.372 Microstructure of epoxy resin reinforced with aluminum powder. Volume fraction of powder is 34%, grain size from 2 µm to 0.7 mm. Light microscope (after [7.414])

instrumentation for injection molding of plastics. The mold cavity preparation cycle includes:

- Preparing a model (e.g., RP technology) and parting planes
- Pouring the first half of the mold and sealing the cooling ducts
- Preparing the second half of the mold
- Pouring the second half of the mold with cooling ducts Fig. 7.373 [7.414]

With regard to the process of mold cavity preparation that is carried out in a vacuum, cavities prepared in this way can faithfully reflect even complicated shapes (with a large number of roundings and freely shaped

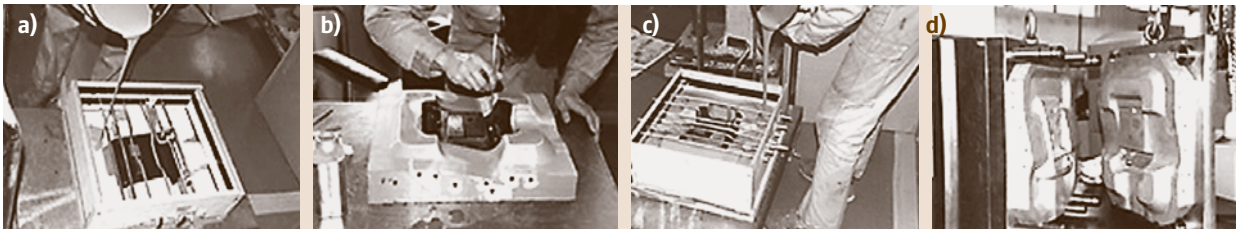

Fig. 7.373a–d Phases of building a composite injection mold in the rapid tooling technology: **(a,c)** filling the space above the model and parting plane with epoxy composite with aluminum filler, **(a)** finishing the prepared first half of the mold cavity, **(d)** finished mold ready to be installed on an injection molding machine

surfaces) that, in the case of traditional methods, would require multiaxial milling. Optionally shaped cooling ducts permit optimum heat abstraction from the cavity area filled with plastic in the process of injection molding.

METALCOPY Technology (IVF Sweden). A Swedish research institute and a Swedish SME have developed a new RT and manufacturing technology called MetalCopy [7.459]. MetalCopy is especially suited for demanding tool inserts and complex geometries and it dramatically reduces costs for producing tools/inserts and cuts lead times.

MetalCopy is a cost-efficient and RT manufacturing technology for injection molding dies for short series production. It is the ideal solution, particularly for applications where traditional methods such as milling, EDM (engineering development model), laser, and epoxy fail. MetalCopy produces durable injection molding tools and inserts for small series, bridge tools, and preseries production, up to 100 000 parts. The method is particularly suitable for complex insert geometries with deep holes and slots.

MetalCopy's rapid tooling process involves the following steps:

1. A primary master of the tool is produced by an accurate rapid prototyping machine.
2. A silicone negative is cast from the rapid-prototyped positive master.
3. The silicone negative is used to produce a *green* secondary master in a mixture of steel powder and binder.
4. The green part is sintered and the pores between the metal powder grains are filled by a low-melting-point metal.

5. The die tool is finished by traditional machining methods, such as drilling for ejector pins, fitting the tool halves together, etc.

The method's strength lies in its ability to deal with the most demanding requirements, such as complicated parts that cannot be milled, serial volumes far above what can be achieved by epoxy tools, or where an insert with good heat conductivity is needed. Main advantages: MetalCopy is particularly suitable for multi-insert tools when the insert geometry is identical. The geometry of this insert is characterized by a great number of thin and deep grooves and slots. This is a good example of where MetalCopy is preferable for manufacturing.

Specification:

- Production: short series and up to 100 000 parts
- Accuracy: 0.1–0.5 mm (0.2%)
- Surface roughness: $R_a < 2\,\mu m$
- Good thermal conductivity
- Cost efficient, especially for complex geometries

More information about these technologies may be found in reports published annually by Wohlers Associates, proceedings of Euro-uRapid conferences, and producer Web sites.

7.6 Precision Machinery Using MEMS Technology

MEMS (microelectromechanical systems) is one of the new approaches to producing or assembling precision machinery with electronics. Originally, MEMS emerged from the silicon process, which is a combination of CVD (chemical vapor deposition), RIE (reactive ion etching), photo or electron beam lithography systems etc.; it is a concept to create small mixtures of machines and electronics regardless of fabrication technology.

7.6.1 Electrostatic-Driven Optical Display Device

Various types of optical switching devices have been proposed and developed. Most of them are intended for switchboard purposes – typically optical-fiber communiation [7.460]. For display purposes, the digital micromirror device developed by TI [7.461] is a good example of a commercial application of MEMS. In the device, an application of mechanical action to the display purpose is one of the promising potential capabilities of MEMS. In particular, the frequency response of the mechanisms reaches more than hundreds of kilohertz because of their small mass.

Two examples of optical switch are shown in order. An interferometric display device (IDD) is composed of a small set of interferometers to control contrast and color [7.462, 463]. An evanescent coupling display device (ECDD) is an application of near-field optics for switching light perpendicularly. The principle of the device, its manufacturing process, and experimental results are shown.

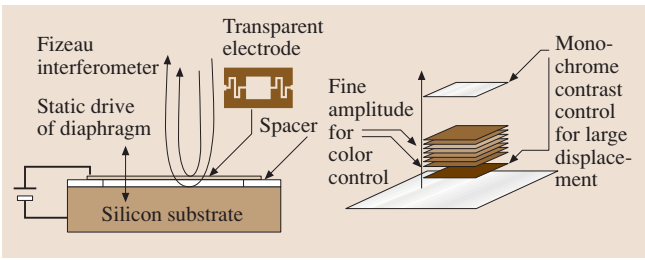

Fig. 7.375 Principle of the interferometric display device

Principle of the Interferometric Display Device

Figure 7.375 shows the schematic construction of the IDD. An SiO_2 half-mirror suspended by leaf springs forms a capacitor to the base plate with a gap of $(n + 1/4)\lambda$ to construct a Fizeau interferometer. When a DC voltage is applied to the capacitor, the half-mirror is attracted to the base plate balancing the leaf springs, and the reflection beam from the base plate interferes with the beam reflected from the half-mirror. When a monochromatic light source illuminates the device, the contrast is changed periodically according to the displacement of every $\lambda/4$. In the case of a white light source, color variation is realized with a fine half-mirror positioning control. Integrating this device like a dot-matrix, a reflection-type display can be constructed. The device has the potential to triple the pixel density compared to RGB space separation displays. Also, static driving consumes little energy, and the mirrors has fast response because of their light mass of tens of micrograms.

7.6.2 Design of the Device

The displacement of the mirror z is a balance of the leaf-spring force and the electrostatic force F. It can be expressed as

$$F = \frac{1}{2}\epsilon S\left(\frac{V}{d-z}\right)^2 = kz\,, \tag{7.212}$$

where ϵ is the dielectric constant, S is the area of the half-mirror, V is the applied voltage, d is the gap length without voltage, and k is the spring constant of the leaf spring. The resonant frequency of the mirror f_n is calculated by

$$f_n = \frac{1}{2\pi}\sqrt{\frac{ml^3}{192EI}}\,, \tag{7.213}$$

where m is the mass of the leaf spring, l is the length of the leaf spring, E is the Young modulus of the spring material, and I is the moment of inertia of the leaf spring. This predicts that the relationship between voltage and displacement is nonlinear.

The maximum contrast of the device is obtained when the intensity of the beam reflected by the half-mirror and that reflected from the bottom is equal. Suppose the following: half-mirror reflectance R_h, transmittance $T_\mathrm{h}(\simeq 1 - R_\mathrm{h})$, and reflectance of the bottom mirror R_b; the relationship is expressed as

$$R_\mathrm{h} = T_\mathrm{h}^2 R_\mathrm{b}\,. \tag{7.214}$$

This is the optical requirement for the device to get the maximum contrast.

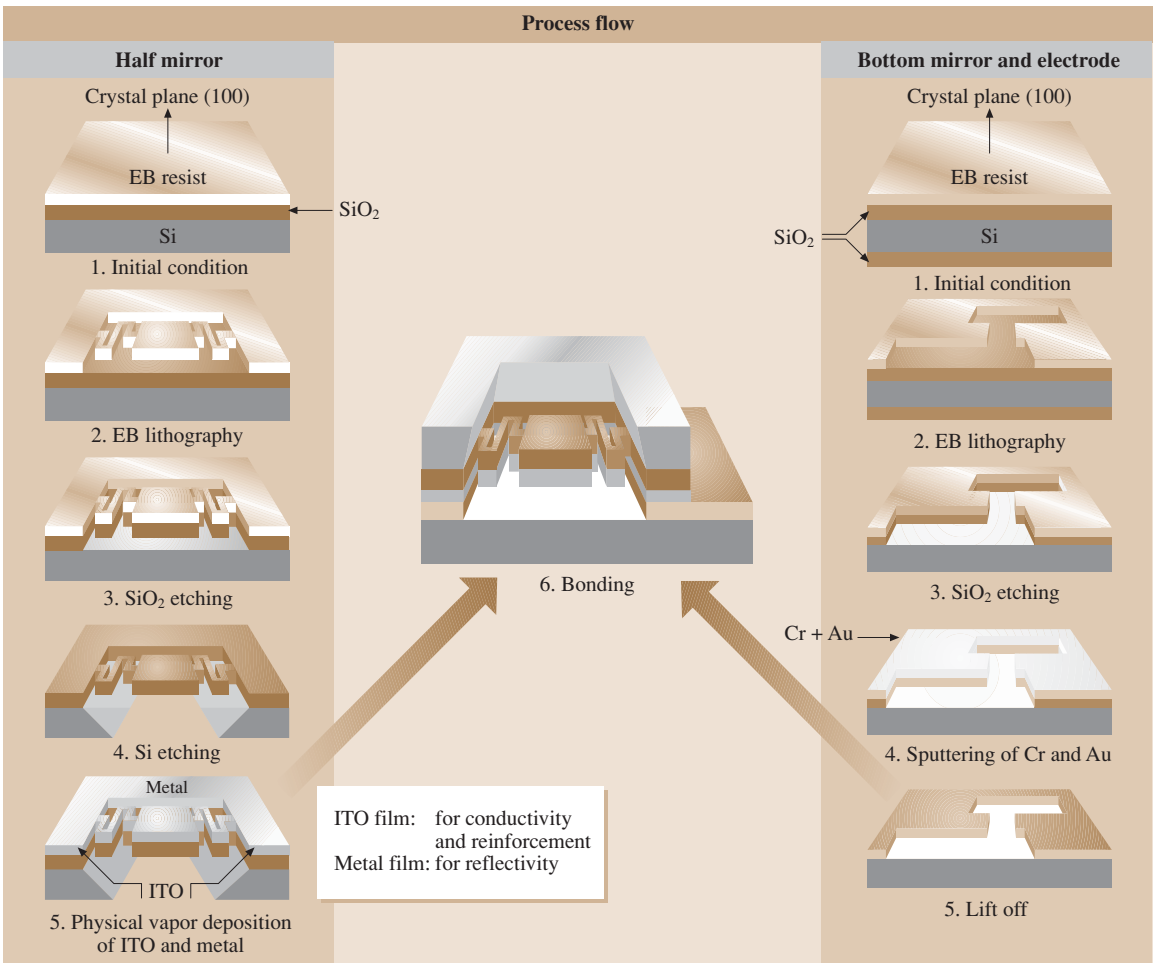

Fig. 7.376 Fabrication process of the IDD

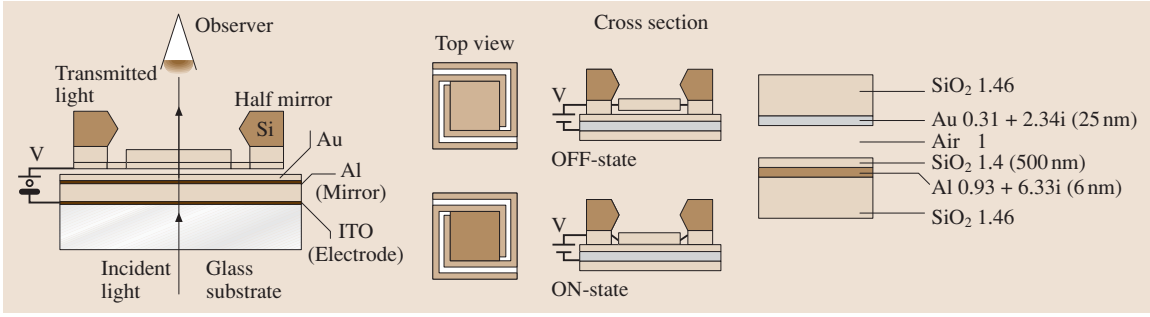

Fig. 7.378 Improved construction of the IDD based on Fabry–Perót interferometer

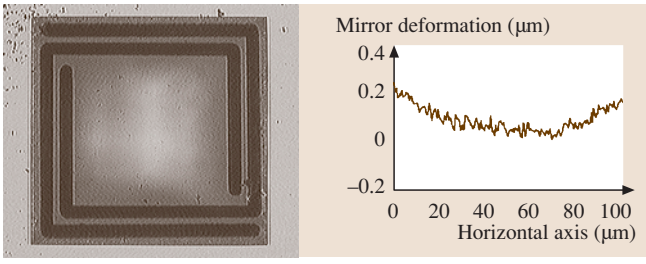

Fig. 7.379 A spiral leaf-spring structure and cross sectional deformation

Fig. 7.380 RGB pixel image

Fabrication of the Device

The half-mirror is the key element of this device and it should have a fine parallel movement to the base plate. A double-leaf-spring-suspended mirror is used for this purpose. A 100 μm square mirror is fabricated from a thermally oxidized silicon film of 1 μm thick, with a spring length of 400 μm, which is folded for a wider pixel aperture. A theoretical resonant frequency of 27 kHz is calculated for the film thickness, a beam width of 5 μm, and an applied voltage of 45 V. Thus, a displacement of the mirror more than a quarter of the wavelength can be obtained by the application of low driving voltage to the mirror gap.

Figure 7.376 is the process flow for manufacturing the IDD. A wafer bonding technique has been employed to adjust the mirror gap easily. The half-mirror and the bottom mirror electrode are fabricated separately. Then the gap is controlled by the film thickness of the SiO_2 as the spacer.

Performance of Prototype IDD

Figure 7.377 is a fabricated example of the IDD. For this prototype, a half-mirror dimension of 100 μm square, a leaf spring width of 10 μm, and a mirror gap of 5 μm are realized. A driving DC voltage of 15 V and a resonant frequency of 5.3 kHz have been obtained. When the device is illuminated by a halogen lamp, interferometric fringes are observed on the half-mirror, instead of uniform contrast change. This originates from the deformation of the half-mirror, because of its thin thickness and short leaf-spring length compared to the width,

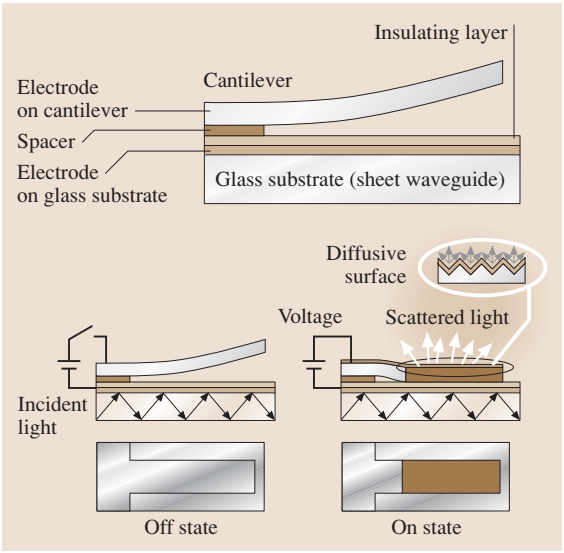

Fig. 7.381 Principle of the evanescent coupling switching device

and should be improved by film thickness increase as well as structural modification.

Improvement of the IDD

The principle of the device is alternated from Fizeau interferometer to Fabry–Perót interferometer, shown in Fig. 7.378, for easier optical adjustment for high contrast and illumination. By an experimental optimization, a combination of gold and aluminum film in the figure was found to be the best for satisfying (7.214). Also, to achieve smaller deformation of the half-mirror, a spiral structure, shown in Fig. 7.379, is adopted to realize longer leaf-spring length so that the deformation may be concentrated only on the leaf spring. With a twofold film thickness of 2 μm surrounding the half-mirror, the deformation of the mirror itself was improved to 0.2 μm, which is comparable to a quarter of the wavelength.

By a CCD video capture system, the RGB contrast of the IDD is evaluated. In Fig. 7.380, RGB contrast is obtained for the halogen illumination. Although the pixel image still has a distribution in both color and contrast, no interferometric fringe is observed for this construction thanks to smaller film deformation.

The average contrast of a pixel for each color $C_{R,G,B}$ is calculated as

$$C_{R,G,B} = \frac{I_{max} - I_{min}}{I_{max} + I_{min}} , \qquad (7.215)$$

where I_{max} is the maximum and I_{min} is the minimum intensity of the pixel. The obtained contrasts for the figure were $C_R = 0.18$, $C_G = 0.03$, and $C_B = 0.08$. The contrast dependence on color may be attributed to the interferometric layer, which is designed to be fit for only one wavelength.

Frequency response was examined by a function generator and high-voltage power source. Up to 100 Hz, the device follows the input voltage, and for higher driving frequency, it has a phase delay because of the squeeze damping effect of the air. For a driving fre-

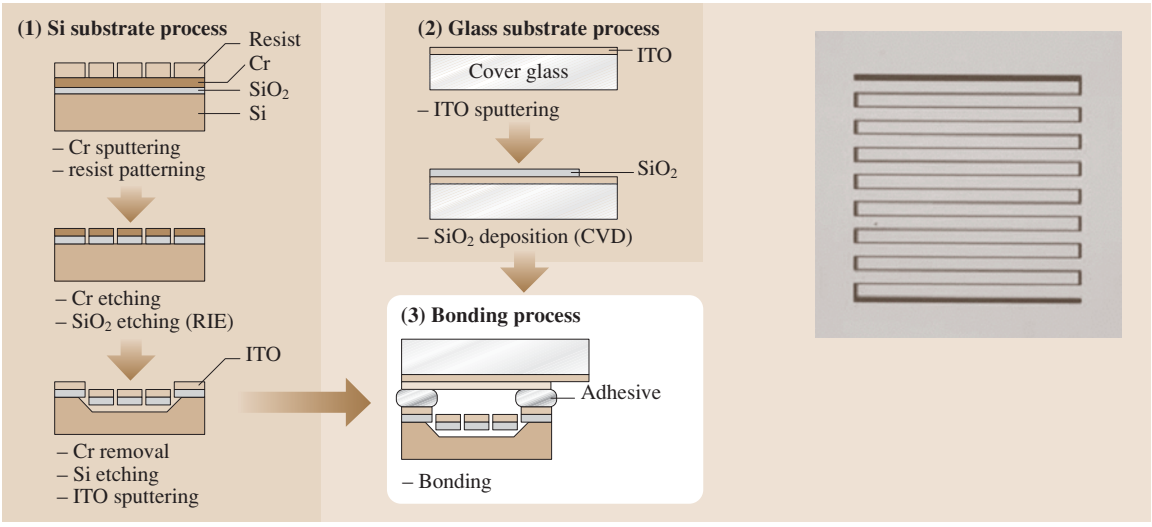

Fig. 7.382 Fabrication process of the ECDD

quency of 2 Hz and a voltage of 10 V, a maximum contrast of 0.3 was obtained.

7.6.3 Evanescent Coupling Switching Device

Fabrication of the device is very difficult because of process problems such as deformation of the half-mirror, adhesion of the mirror to the substrate, etc. An alternative is the evanescent coupling display device (ECDD), which uses microfabricated cantilevers for optical switching and free from mirror deformation [7.464–466]. The principle of the device, its fabrication process, and evaluation are presented in this section.

Principle of the Evanescent Coupling Display Device

The ECDD is fabricated on a glass substrate together with cantilevers as micro-optical switches. The substrate woks as a sheet waveguide propagating light horizontally, and the cantilevers are driven electrostatically by DC voltage to engage in or disengage from switching action. When the cantilevers are attracted to the substrate making mechanical contact, light energy in the sheet waveguide transfers to the optical cantilevers by the evanescent coupling, even if there is a small gap within the wavelength. The transferred light also propagates in the cantilevers horizontally; however, it is scattered from the top surface of the cantilevers because of the rough surface. Then, the cantilevers emit the light perpendicularly, enabling the brightness change of the device. By the on–off switching of driving voltage, the cantilevers work as a pixel of the optical display.

Fabrication Process of the ECDD

As shown in Fig. 7.382, multicantilevers are fabricated from a silicon substrate with a 2-mm-thick thermal oxide layer. The multicantilevers on the substrate are patterned by photolithography and RIE etching, using a Cr layer as a mask for SiO_2 etching. The silicon substrate under the cantilevers is etched in a solution of 15 wt% TMAH (tetramethyl ammonium hydroxide) solution at 90 °C. Next, the ITO layer as a transparent electrode is sputtered on the cantilevers. A micrograph of the fabricated cantilevers is also shown in Fig. 7.382, nesting eight cantilevers from both sides of the substrate to increase the effective pixel area. The length and width of the cantilevers are 490 and 20 μm, respectively. Due to residual stress of the ITO layer, the

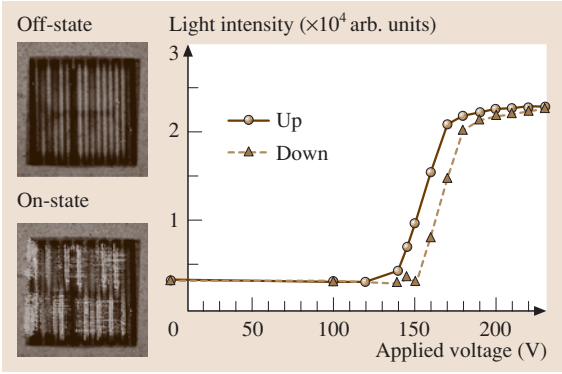

Fig. 7.383 On–off characteristics of the ECDD

fabricated cantilevers are curved toward the silicon substrate with a displacement of 10 μm. Because of the residual stress, the sticking problem between the cantilevers and the substrate is cleared up even after voltage application.

Evaluation of the ECDD

The characteristics of the ECDD were evaluated by the same system as the IDD. A result of the driving evaluation is shown in Fig. 7.383. Although unnecessary scattering is appeared in the off-state, a clear brightness is observed in the on-state of the pixel. A maximum contrast of 0.9, defined by (7.215), was obtained at a driving voltage of 170 V. Hysteresis of the contrast was observed in slow driving test; however, it does not cause the switching speed to deteriorate.

For frequency response, a square voltage of 170 V and a frequency of 1 kHz can drive the multicantilevers. From this performance, the device has a sufficient re-

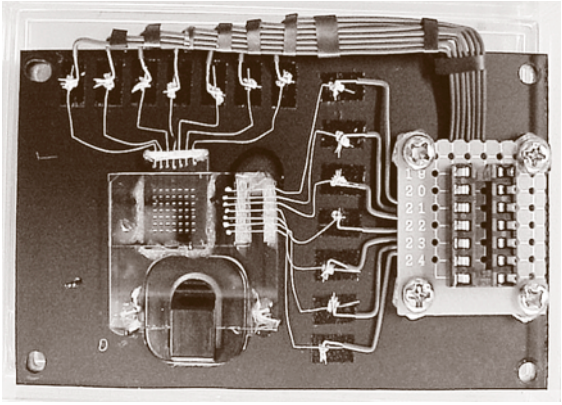

Fig. 7.384 8×8 dot matrix type ECDD

sponse for display application. However, for higher response speed, reduction of the sheet resistance of ITO layers, as well as the size and cantilevers, must be optimized.

A dot-matrix-type device, shown in Fig. 7.384, is fabricated to confirm the function as a display. An 8×8 pixel matrix is constructed in 6×6 mm square, with a pixel size of 500 μm. Using an external voltage driver with a laser incident beam to the glass substrate, the device shows the ability of an individual pixel drive as well as row and column driving.

This type of device can display images on transparent media and can be seen from both sides, when every part is made of transparent material.

8. Measuring and Quality Control

Norge I. Coello Machado, Shuichi Sakamoto, Steffen Wengler, Lutz Wisweh

Considering the incessantly increasing requirements to the quality of products and processes it is necessary to improve a quality-orientated management in all departments of any types of companies and the advantageous application of manufacturing measurement equipment.

In addition to diverse technical requirements are also to consider the requirements of national, international and company-specific norms. The companies must not only fulfill the requirements of the quality, but also the requirements of safety, environment and economy.

As follows some aspects of the manufacturing measurement technology and quality management and their integration into a manufacturing process will be introduced.

Starting with manufacturing geometrical conditions and statements at drawings (nominal state and geometrical limits) the use of measurement equipment and gages to the evaluation of geometric elements will be described. Basic knowledge to measuring standards, uncertainties as well as calibration and measuring instrument inspection will mediates.

Based on physical principles equipment and methods for the registration of measurement values, form- and position deviations and surface characteristics will introduce.

8.1 Quality Management

8.1.1 Quality and Quality Management

Nowadays the quality of products, assemblies and services not only includes the fulfilment of functional requirements by maintaining tolerances. It also includes the fulfilment of numerous requirements such as rendered in parts in Fig. 8.1. In this section some fundamentals of quality management will be described from the multitude of requirements. In Sect. 8.2 some aspects of the requirements of manufacturing measurement technology for the qualification of the geometrical quality of products will be shown.

Among the requirements for organizations involved in quality control, the key concepts of quality management (QM) and total quality management (TQM) include planning, monitoring, and improvement of quality, such as the consideration of representatives and departments relevant to quality, as shown in Fig. 8.2.

8.1.2 Quality Management Methods

To conform to the requirements of modern quality management, nowadays numerous procedures and methods, with many different applications, are available. Fig-

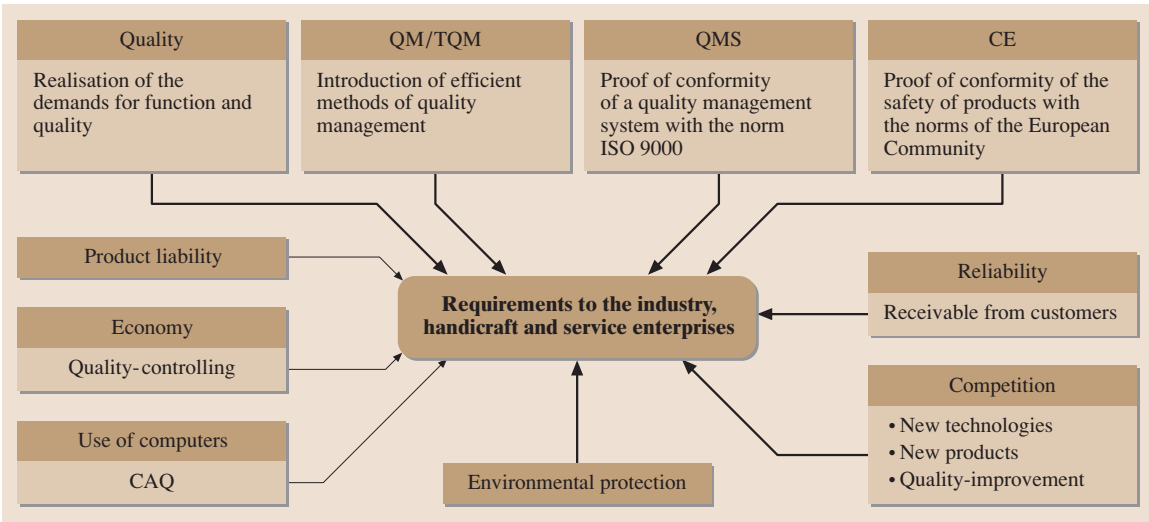

Fig. 8.1 Requirements for industry, craft, and service enterprises

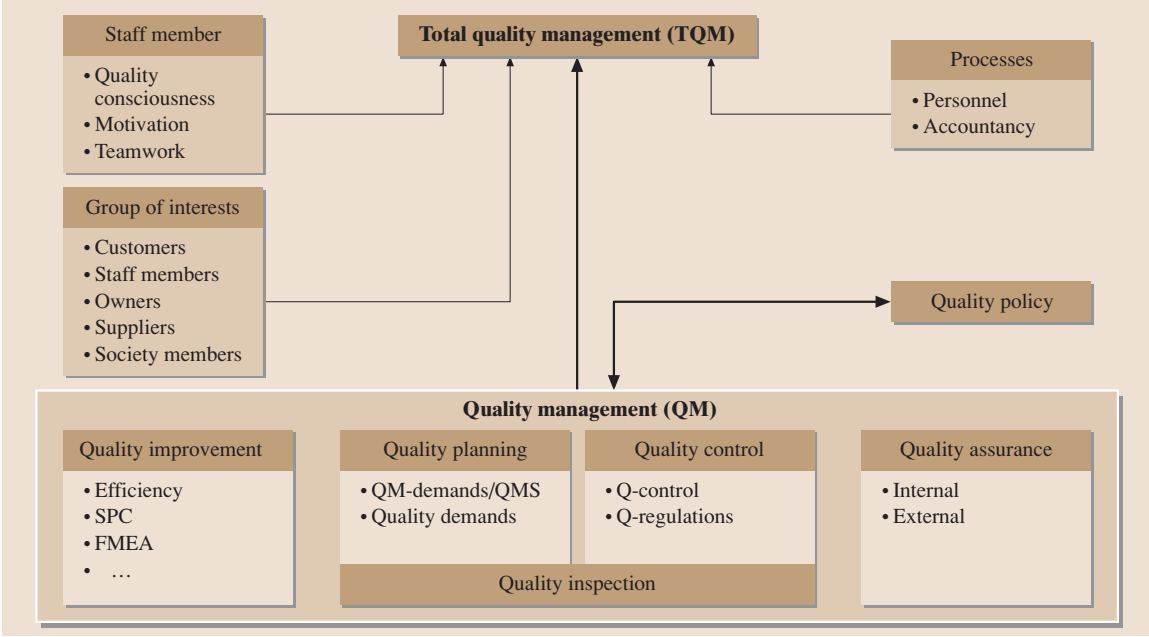

Fig. 8.2 Elements of quality management

ure 8.3 presents a selection of relevant methods used in the area of mechanical engineering.

The different methods can be associated with two essential groups: *problem-resolving techniques* and *preventive techniques*. The problem-resolving techniques can also be divided into the two other categories: those that find causes of existing quality problems and those that help the engineer develop definite aims in a systematically manner (a management method).

The prime conditions for quality analysis are the collection and preparation of quality data with respect to measured data. *Checklists* enable a visualization of the accumulation of certain failures or various kinds of mistakes. *Histograms* demonstrate the probability of

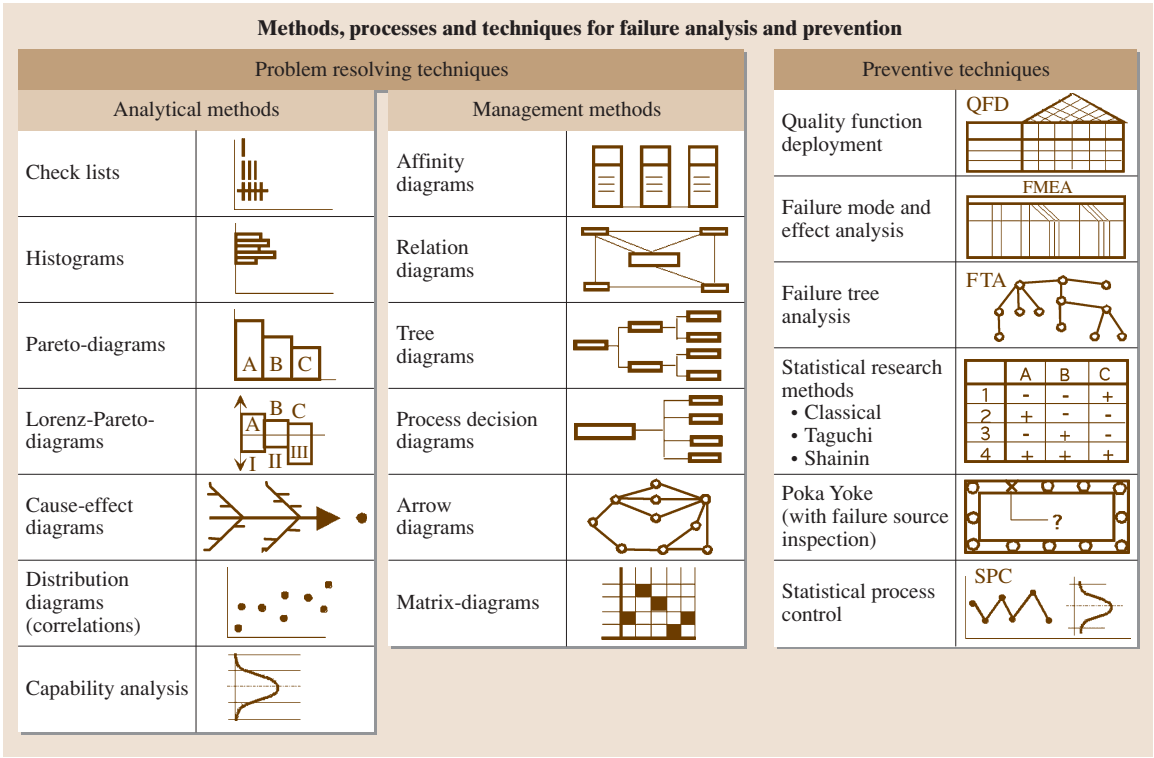

Fig. 8.3 Problem resolving and preventive techniques

the occurrence of a certain event within intervals of the measurement range. *Pareto analyses*, also called *ABC analyses*, enable a weighting of the dominant influencing parameters. In combination with the corresponding costs, they are known as Lorenz–Pareto analyses.

Referring to a definite problem, a comprehensive structuring of clustered influences or causes can be presented as a *cause–effect diagram*, also known as a *fishbone diagram* or *Ishikawa diagram*, which can be used to solve possible problems.

Especially for the experimental aetiology of independent measurements (e.g., quality characteristics) the demonstration of pairs of values in an x–y coordinate system is applicable. These *scatter diagrams* can be described with the help of statistical calculations such as regression and correlation analyses, in which the identified regression function describes the kind of functional connection while the correlation describes the intensity of that connection through the correlation coefficient.

Nowadays an *analysis and evaluation of the quality capability* of procedures and processes takes place in many areas of mechanical engineering by a comprehensive statistical evaluation in terms of capability coefficients, which express the relation of process spread (6σ) to the tolerance and the position of the arithmetic mean of the tolerance borders. In this way it is possible to compare the quality level of different processes.

Management methods support the solution of problems by a targeted systematic procedure. *Affinity diagrams* allow a structured systematization of ideas in order to point out the correlation between these ideas.

Relation diagrams enable the development of cause–effect relations by visualizing networked structures. *Tree diagrams* subdivide specifically aims until directly realizable activities are practicable.

Firstly, *process–decision diagrams* start by arranging possible problems by:

- Urgency
- Probability of occurrence
- Difficulty of prevention

with the aim of detecting potential problems already in the planning phase and to elaborate corresponding countermeasures.

Arrow diagrams or *net plans* are important resources for project planning for the investigation of *critical paths*, which determine the total permanence of a project. In this method the determination of a process sequence is made using series and parallel paths to develop a detailed explanation of the working steps required to achieve the project aim, followed by the assignment of the corresponding process durations.

If a lot of information quantities for certain circumstance are available, *matrix diagrams* are situable for detection of latent structures. By using data evaluation in pairs with the help of matrixes for different characteristics this method enables, for instance, manufacturing and market analysis.

Nowadays, in the field of preventive techniques for failure prevention in technological processes, the schematically compounded methods shown in Fig. 8.3 are mostly applied.

In current quality management product-related customer wishes are the sources of motivation for development from the designing process through the manufacturing process up to the delivery of the products.

With the help of *quality function deployment (QFD)* the *voice of the company* can be developed from the *voice of the customers*. The QFD method systematizes this process under the application of matrixes based on the following four steps:

- Customer wishes in terms of product characteristics
- Product characteristics in terms of part characteristics
- Part characteristics in terms of manufacturing regulations
- Manufacturing regulations in terms of production instructions

Every phase can be described by matrixes in the form of a so-called *house of quality*.

This method offers the possibility to affect the production aim in the conception phase and at the same time to obtain information about the critical product and process characteristics for the fulfilment of the customers expectations. Besides the implementation of marketing information in the product, target conflicts between the individual product characteristics may also become visible.

For the detection of potential failure modes during product development, the introduction of new manufacturing methods, and the modification of manufacturing technologies *failure mode and effect analysis* (FMEA) is used. FMEA is especially used in the case of cost-intensive and risk-affected products and processes. FMEA has universal application and is not connected with a special field. At the base of a standardized procedure, which can be supported by corresponding blank forms, the main steps of a FMEA can be divided into risk analysis, risk assessment, the determination of measures, and the evaluation of effectiveness. The risk evaluation results from evaluation of the probability of occurrence, its importance (for the customers), and the probability of detection of the corresponding failure before delivery to the customer. The advantages of FMEA above all are decreased numbers of failures in the early phases of product manufacturing, and in product planning.

The systematic search for imaginable reasons for a failure, called an unwanted event, is possible with the method of *failure tree analysis*. This method, which originated from the field of safety engineering, enables an evaluation of fixed correlations by the determination of the quantitative probability of the appearance of failures.

For this purpose the function of single components (devices) is described under different conditions using a so-called components tree. A subsequent system analysis aims to describe holistically their organization and the behavior of the technical system. The contribution of the individual components to the protection of the overall function of the system, the evaluation of the consequences of the environmental influences of the overall system, and the description of the reaction of the overall system to failures within the system, of resources, and by faulty operations can be described by a failure tree analysis and be calculated or simulated by various evaluation methods.

The methods of *statistical research planning* have the general aim to adjust the relevant product and process parameters using a systematically procedure in such a way that the quality-relevant characteristics closely approach the ideal value with as few experiments as possible.

The weighting of the influencing factors and the quantification of their effect can be solved based on classical statistical research planning using mathematical models (such as factorial research plans); if there are a very large number of influencing factors this can be solved with the help of the empirical procedures developed by Taguchi or Shainin.

The *Poka Yoke* method (from the Japanese: the avoidance of unintentional errors) is dedicated to preventive avoidance of failures in manual manufacturing

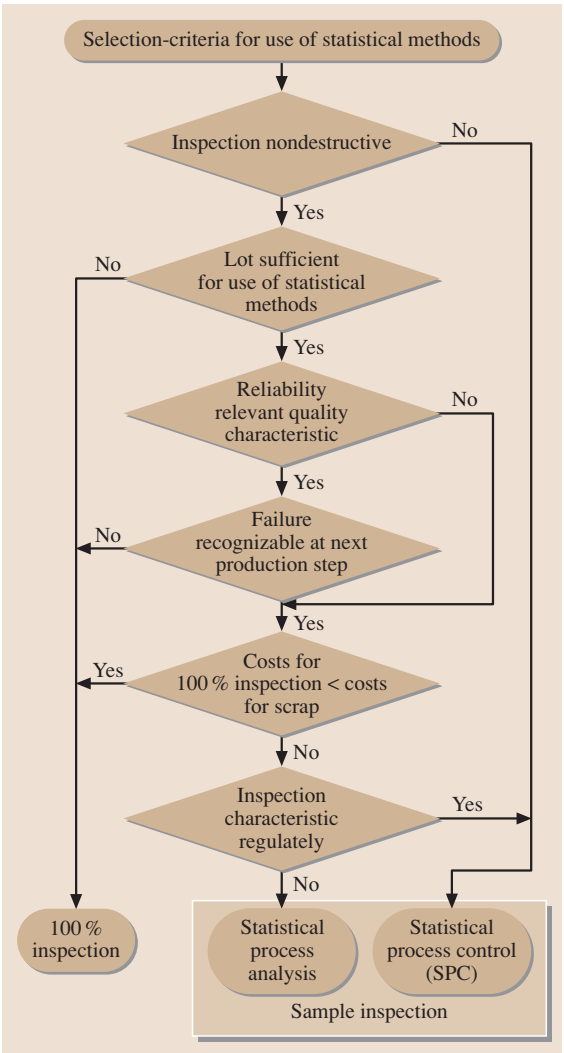

Fig. 8.4 Selection criterions for the use of statistical methods

and assembling processes by the development of precautions (design measures that eliminate incorrect handling) and facilities for failure avoidance for immediate failure detection in the manufacturing process. This can be realized by a comprehensive implementation of applicable rules for product and process design or by the use of simple ancillary equipment.

The *statistical evaluation and control of the quality of processes* [statistical process control (SPC)] is not only a main goal of modern quality management systems but is also required for cost-efficient production processes.

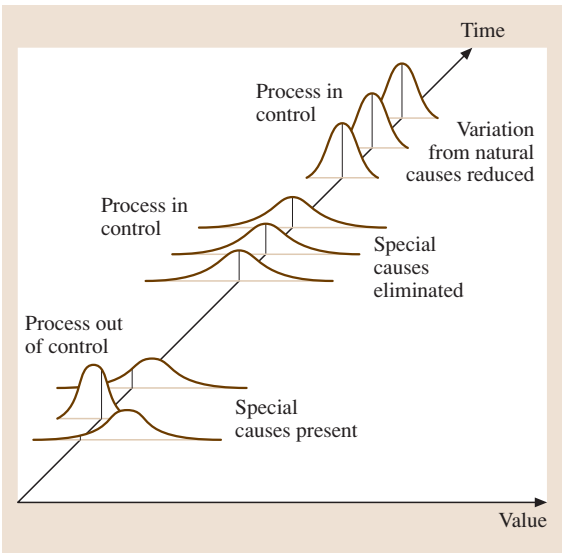

Fig. 8.5 Stabilization of processes through the reduction of systematic and random processes disturbing variables

The aim of the use of statistical methods in quality management exists as well as in the classical detection of faulty products in the manufacturing process and increasingly widespread in the qualitative monitoring, control and improvement of the manufacturing and assembling process.

According to algorithms such as that in Fig. 8.4 some basic decisions can be made.

Quality control of processes can be performed using continuous, 100% inspection or on the basis of periodically chosen samples in the form of statistical process control (SPC).

Statistical methods can also be used to achieve the aim of monitoring and improving product and process quality. Therefore, it is a direct component of the quality control circle. The most important methods in this regard are (Fig. 8.6):

- Measuring controls with statistical control algorithms
- Quality control charts
- Capability analyses and evaluations
- Sample inspection by statistical sample planes

Processes in practice, especially newly introduced processes, are influenced by numerous systematic and random influences, which make the use of statistical methods difficult.

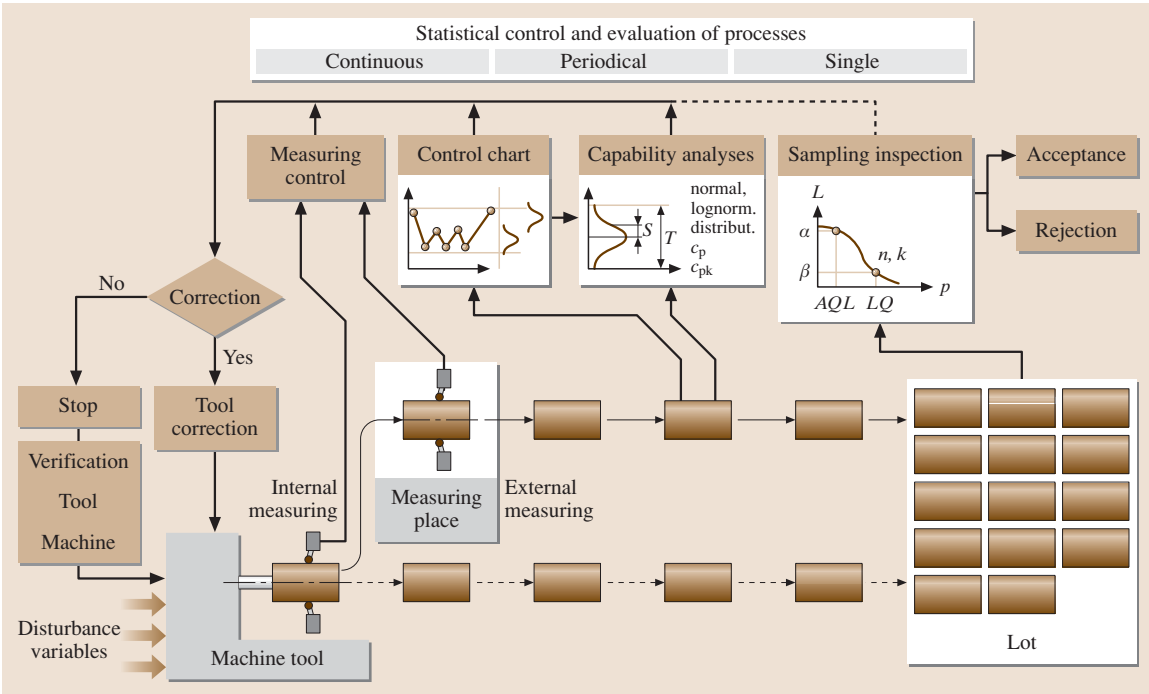

Fig. 8.6 Overview of the use of statistical methods for the evaluation and control of processes

Many statistical methods require the prerequisite of a normal distribution (e.g., double-sided tolerances or limited quality characteristics) or a logarithmic normal distribution (e.g., one-sided toleranced quality characteristics), which are free of systematically influences.

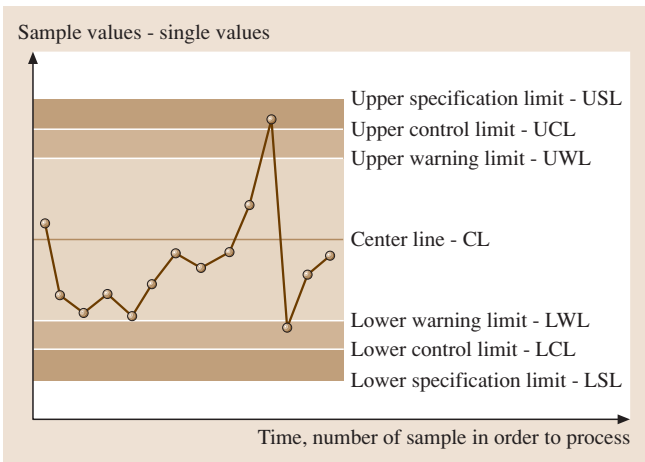

Fig. 8.7 Process monitoring with quality control charts

In such cases it is also spoken from the requirement of stable or stationary processes respectively of so-called *processes in or under statistical control*. (See also Fig. 8.5).

If stable processes are available they can be further inspected using quality control charts. A quality control chart (QCC) is a graphical representation of a process calculated from measured results from a small samples or chronological characteristics. The target of quality control charts is to capture quantitative changes in a process that exceed statistically derived control limits (Fig. 8.7).

The recorded results can then be the basis for subsequent statistical evaluations or characterizations in the form of capability coefficients. These coefficients can also be used for the evaluation of machines and processes.

If a product-orientated decision about the acceptance or rejection of a product series or lot takes place, sample planes can be used. The producer (supplier) may also use these in the form of a final inspection, as may the customer in the form of an inspection on receipt.

Statistical analysis results have a wide variety of uses in quality monitoring, evaluation, control, and management as is shown in Fig. 8.8.

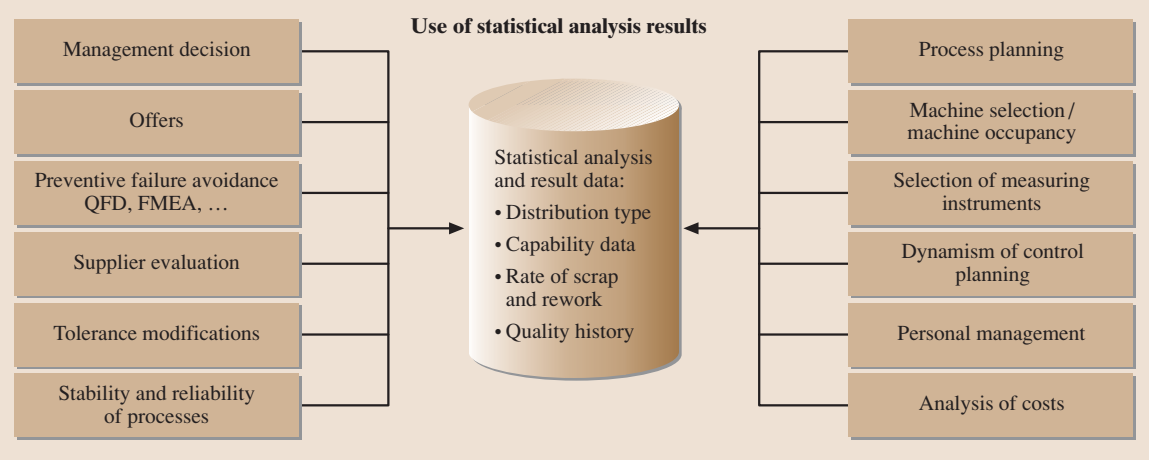

Fig. 8.8 Use of statistical results

8.1.3 Quality Management Systems

The organizational realization of the concept of quality in all departments of enterprise and in all phases of product realization can be supported by *quality management systems* (QMS), as shown in Fig. 8.1. In addition to this, the organizational structure and the processes organization of all quality-relevant departments and operations can be evaluated and compared to standardized regulations. The successful introduction and realization of a QMS can be evaluated and validated by an accredited certification body.

As the basis for this the independent ISO 9000 series of standards can be used. Based on this, for the worldwide automotive industry, comprehensive additional requirements exist, which are fixed in company-dependent standards. Some of the most important series of standards are, for instance, QS 9000 (USA), VDA 6 (Germany), AVSQ (Italy), and EAQF (France). Efforts for the integration of the different requirements of the automotive industry to date are contained in the ISO standard TS 16949.

8.1.4 CE Sign

Within the single market of the European Union, a requirement for the commencement of operation and the placing on the market of products is the fulfilment of harmonized safety requirements. To obtain a conformity certificate for these European Community (EC) requirements, a CE sign is required. This is also valid for products that are produced outside of the European Union, if they are also distributed within it.

Examples of EC directives include those for: machines, toys, electromagnetic compatibility (EMC), detonating devices, and medical products etc.

8.2 Manufacturing Measurement Technology

8.2.1 Introduction

Measurement is the determination of the value of a physical quantity (measured quantity) by comparison with a reference value.

Manufacturing measurement technology is part of the field of measurement technology. It deals with the methods, equipment, and strategies for measurement in the realm of mechanical production processes. Manufacturing measurement technology is utilized in various locations, such as rooms with special, controlled environmental conditions, as well as directly integrated into the assembly line. The aims of manufacturing measurement technology are:

- Evaluation of the product
- Evaluation of processes and machines
- Quality-orientated process control

Here we confine the discussion to the description of relevant geometrical features and/or technical aspects of obtaining such objects from workpieces. These features include lengths, angles, distances, and surface struc-

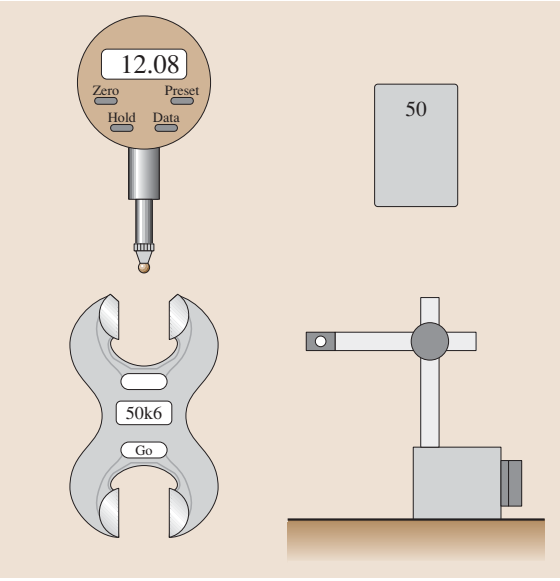

Fig. 8.9 Inspection devices

tures. Most of the principles and definitions described also apply to nongeometrical parameters.

The relevant SI units used to describe these geometrical features are meter and second. Angles are described in degree or radian.

The physical measurement that comes from the measuring process is called the measure. The object from which this quantity was measured is called the measuring object. The value of the measure, which actually exists but is currently unknown, is the true value. The aim of the measuring process is to determine this true value. A variable that does not change with time (for example, a diameter) is measured by a static measurement. Dynamic measurement is the measuring of a variable that changes with time (for example, a vibration) or the measurement of a variable, whose variation arises from the time-dependent behavior of another variable (for example, for a roughness measurement, the dependence of the measured value on the scanned measuring length).

In order to determine whether an object fulfils a particular requirement, it is inspected. As subjective inspection should not be considered, one can differentiate objective inspection into measuring and gauging. The inspection means that are employed can be divided into indicating measuring devices, measurement standards, gauges, and additional measuring devices. Figure 8.9 shows a digital dial indicator and a measuring block, as the most important measurement standard of dimensional measuring technology. Measuring blocks are quadrilateral metal or ceramic gauges, whose parallel end faces have a known width and minimal deviation. A gauge and a stand, an example of additional measuring equipment, are represented on the figure to.

8.2.2 Arrangement in the Manufacturing Process

Measuring technology has become an essential ingredient in manufacturing processes. Figure 8.10 shows the multitude of integration possibilities and the corresponding relationships between the production process

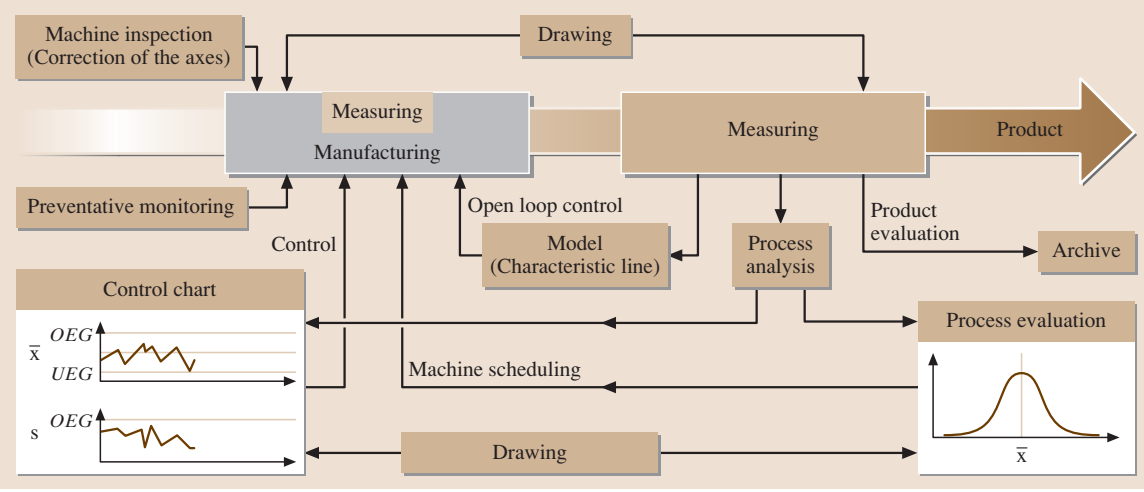

Fig. 8.10 Measuring technology and measuring value analysis in manufacturing processes

and measuring technology as well as different possibilities for analyzing the measured data and its feedback into the process.

Inside every tooling machine integrated measuring devices are used to collect parameters (the position of the axes, temperature, force, voltage, current, etc.). These values can then be directly used by the machine operator or the machine itself to control future operations. In reference to the collection of data from finished products and in consideration of the drawing specifications, these finished product parameters can be evaluated, classified, and documented. Furthermore, parameters can be derived from the measured values through continued analysis, or more specifically, these parameters that can regulate or control the machining or production of the product. Using an adjustment, the measured value (the controlled variable), which has an instantaneous value, is continuously measured and corrected with a controller with respect to a known value (the set value). It is then possible to eliminate disturbance factors from outside the process. The constant, targeted influencing of a process on the basis of a previously defined model without feedback is what is meant by open-loop control.

Starting from the process analysis, the machining process and/or the processing machines themselves can be evaluated (for example, for machine and process capabilities) and documented. The result of the machine evaluation is, for example, a quality-orientated machine selection. Should the machine not be in a position to produce the desired tolerances, selective inspection and correction of the machine systems may be necessary, or a complete overhaul or a new revision of the machine may even be necessary.

Through the additional use of measuring technology for preventive monitoring of a machine, it is possible to implement maintenance procedures or schedules to avoid losses or stops in production.

8.2.3 Specifications on the Drawing

The drawing is the defined input to the manufacturing process, based on the required functions outlined by the designer, and is therefore the basis for the manufacturing measuring process. The complete, integrated product drawings, as well as single-product element drawings, are used to clarify the permitted allowances and thereby the tolerances for manufacturing. The geometrical specifications can be separated into measuring tolerances and shape tolerances. Shape tolerances include not only form and position tolerances, but also surface finish tolerances, which can be divided into roughness and waviness.

Measuring specifications consist of the nominal size and defined permissible upper and lower allowances. The nominal size plus the upper allowance is the largest acceptable measure and the nominal size plus the lower allowance is the smallest acceptable measure. The difference between the upper and lower allowances is the tolerance. The definition on the drawing is shown through the specification of a nominal size supplemented either directly by a coded specification of the allowance or through a letter and a number combination (ISO 286). The letter describes the position of the tolerance field with respect to the zero line and the number represents the magnitude of the tolerance. The specification $36^{-0.025}_{-0.050}$ corresponds to the drawing specification, 36 f7, which means in manufacturing terms

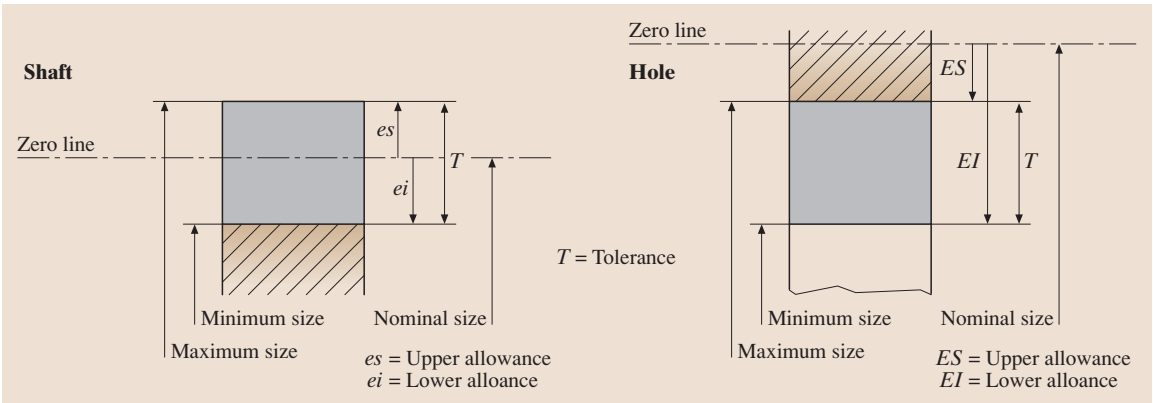

Fig. 8.11 Measuring specifications

Table 8.1 Form tolerances

Form tolerances	Straightness	—	Single elements
	Flatness	▱	
	Roundness	○	
	Cylindricity	⌭	
	Profile	⌒	

that the largest acceptable measurement is 35.975 mm and the smallest acceptable measurement is 35.950 mm. Whenever the nominal sizes are the only values displayed on the drawing, free size tolerances according to ISO 2768, can be specified.

The position of the tolerance with respect to the zero line (which corresponds to the nominal size) and the size of the tolerance determine the function of the proposed piece. The size of the tolerance is furthermore decisive for the cost of the manufacturing process.

Table 8.2 Position tolerances

Position tolerances	Direction	Parallelism	//	Related elements

	Place	Alignment	⌖	
		Concentricity	◎	
		Symmetry	⌯	
	Run	Run-out	↗	
		Total run-out	⌰	

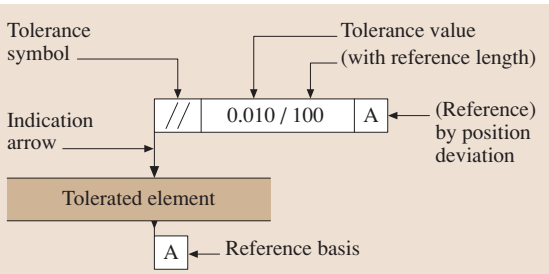

Fig. 8.12 Tolerance frame as drawing entry

The form and location tolerances define in each case zones, into which the corresponding element must fit in, when it is within the tolerance. Form tolerances, which are defined in ISO 1101, are shown in Table 8.1. Single elements, such as lines, rectangles, circles, cylinders, and profiles are specified as form tolerances. Position tolerances are divided into direction, place, and run tolerances, as summarized in Table 8.2. In each case, position tolerances refer to a individual element of the workpiece. On the drawing, the necessary specifications are represented in a tolerance frame (Fig. 8.12). The tolerance frame contains a symbol that describes the type of tolerance that is being signified and a tolerance value, possibly with a reference length. The indication arrow connects the tolerance frame with the associated element, or rather the associated lines of measurement or symmetry on the drawing. Whenever the type of tolerance requires it, the reference element is indicated at the end of the tolerance frame through the specification of a letter, which repeats the necessary reference basis. In a few cases, more reference elements are possible.

The tolerance specification for surface finish is shown on the drawing by a basic symbol and supplemented by additional specifications. Whether material cutting machining is *necessary* or *not permissible* is also indicated, as shown in Fig. 8.13. additional specifications include tolerances for the roughness value [most of the time, the arithmetic average surface finish (Ra)], and

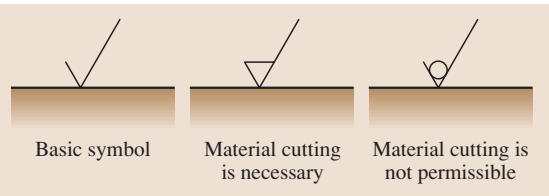

Fig. 8.13 Symbols for surface conditions

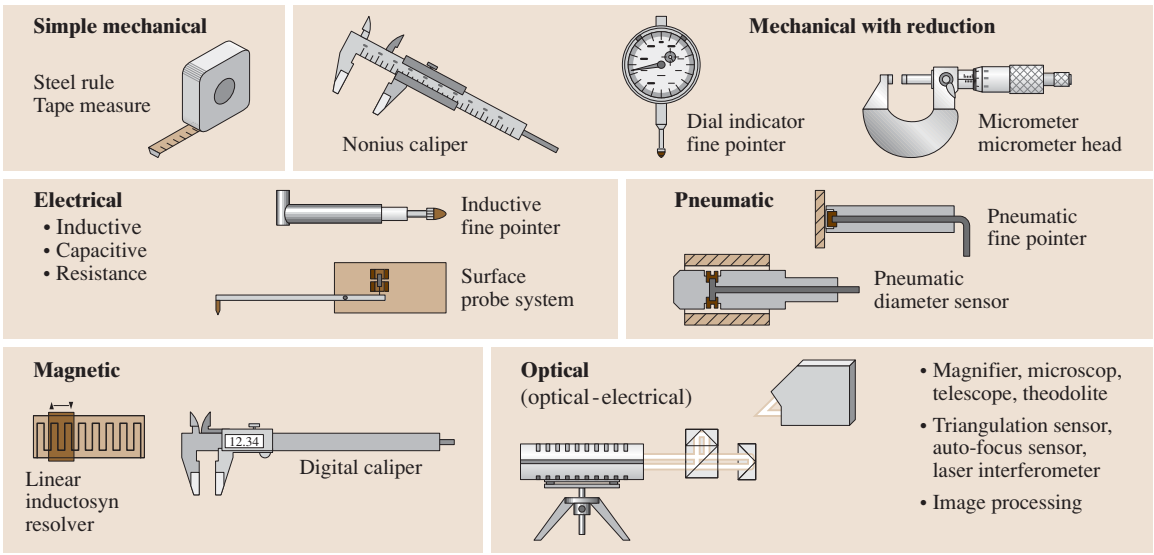

Fig. 8.14 Physical principles of measurement value collection and example instruments

when necessary, amongst others, specifications for the manufacturing process, tolerances for further roughness or waviness parameters, and the grooving direction.

8.2.4 Gauging

Gauges are inspecting devices that represent the dimension and/or form of the workpiece that is to be tested. There are three types of gauges: limit gauges, receiving gauges, and so-called *go and no-go* limit gauges. The procedure is always the same: to try to mate the workpiece elements with the correct gauges. A simple yes or no decision is the result of this process. With limit gauges, one can determine whether the value of a test object is larger or smaller than the value of the gauge (for example, with a pin gauge). With receiving gauges (for example, radius or screw pitch gauges), a comparison is made with the workpiece's form and the form of the gauge and the best-fitting pieces can then be separated out.

Go and no-go limit gauges are the most important for the inspection of manufacturing toleranced elements. Figure 8.9 shows an example of an external calliper gauge, which is suitable for the inspection of shafts. Limit gauges consist of a *go* and a *no-go* side, which correspond, respectively, to the largest and smallest measurement possible; the *go* and *no-go* sides are verified one after the other to check for mating. The inspection result is *good* when the workpiece fits comfortably into the *go* side and not into the *no-go* side. The Taylor principle states that, on the *go* side, all the measurements or control measurements are tested at the same time, but on the *no-go* side, every measurement or control measurement is tested in isolation.

8.2.5 Application of Measuring Devices

Measuring devices work on very different physical principles. Simple mechanical measuring devices include the steel rule or measuring tapes. Measuring devices with mechanical reduction include nonius calipers, dial

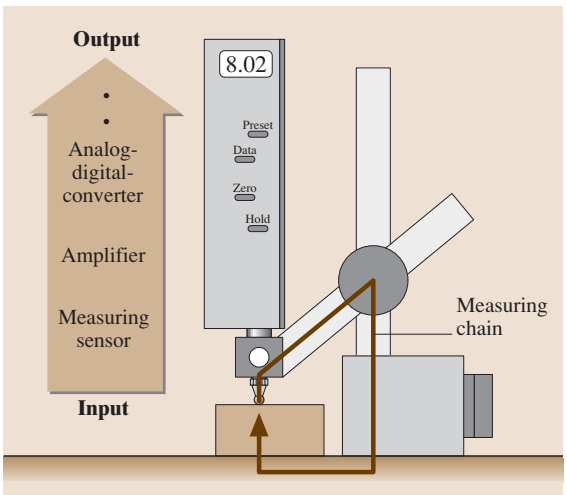

Fig. 8.15 The measuring chain

indicators, and micrometers. Pneumatic systems have long been used because of their noncontact scanning. At present, electrical, magnetic, and optical (more specifically, optical-electrical) principles have emerged in the field of measurement. Their common essential property is that the measured value can be directly transformed into an output signal or onto a recording media. A few examples of equipment are shown in Fig. 8.14.

Essential for a secure measuring value collection is the construction of a measuring chain that is as short as possible, and stiff. The measuring chain in Fig. 8.15 is composed of a measuring device, the supports of a stand, a base plate, and the measured object. In the measuring device, starting from the input value (in this case, the displacement of the probe by the measuring object) the output (in this case, the measuring value 8.02 mm) is obtained through the measuring sensor, an amplifier, and an analog-to-digital converter. Depending on which measuring devices are used, their internal parts may be quite different. The output value can then be transferred to a storage device or a processing machine (for example, a personal computer).

The following explains several essential properties of measuring devices. These properties determine the applicability of the equipment. The achievable *information content* of a measurement is an essential distinction criteria. Also, the *accessibility* of the measuring value to the workpiece reduces the possible selection of measuring devices. The *type of probe* (contact and noncontact) is also relevant. Spheres, planes, or cutting edges are the fundamental probe shapes.

The *indicating range* of a measuring device is the range of values over which the device can indicate (smallest to largest indicated measuring value). The *measuring range* can deviate from the indicating range, and corresponds to the section of the indicating range over which the measuring deviations remain within defined boundaries. The *scale division value* is the change in the measuring value that leads to the movement of the pointer from one to the next dash on a line scale (on digit scales to a digit step). When the measuring devices are clamped (for example, by a support Fig. 8.15), the range of adjustment of the support and the measuring range of the measuring devices constitute the *range of application*. The relationship between the value of the input and the corresponding output value is the *transfer function*. A linear transfer function is usually aimed for. The *threshold limit* is the smallest possible change in the input that leads to a recognizable change in the output. The effect whereby the same value of the input produces two different results

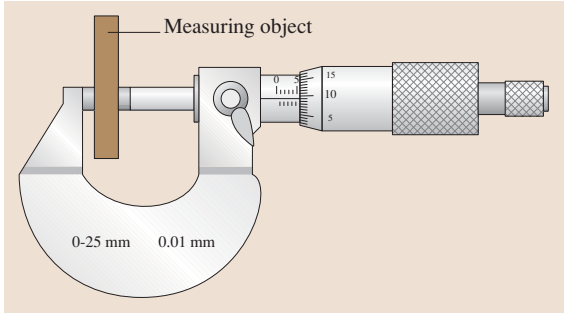

Fig. 8.16 Direct measuring

depending on the direction in which the value is approached, is called the *hysteresis*. A slow, time-varying change of the output without a change in the input value is called *drift*. The *response time* is the time between a step change of the input and the time when the output value remains constant within a prescribed range.

Additionally the *measuring uncertainty* should be highlighted as an essential characteristic of measuring devices. A measuring device is qualified for a designated measuring task only when the uncertainty does not exceed a ratio with the tolerance of $\frac{u}{T} = 0.1$ to 0.2. Because the exact uncertainty of a chosen measuring devices is often not known, one can make do with the *limit of error*. The limit of error is the largest measuring deviation of a measuring device, and is usually defined for a group of measuring devices through a standard or by the manufacturer.

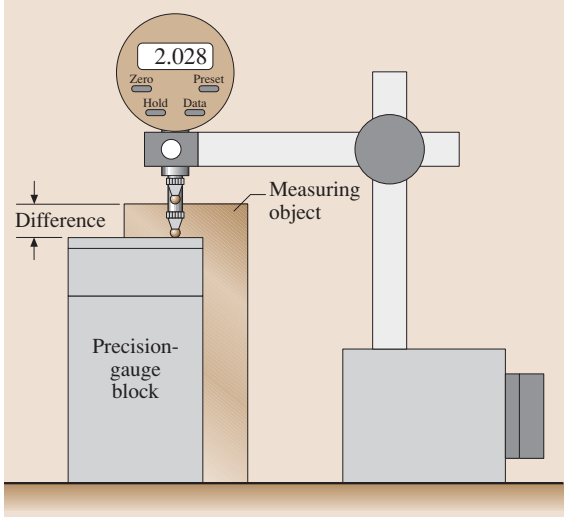

Fig. 8.17 Difference measuring

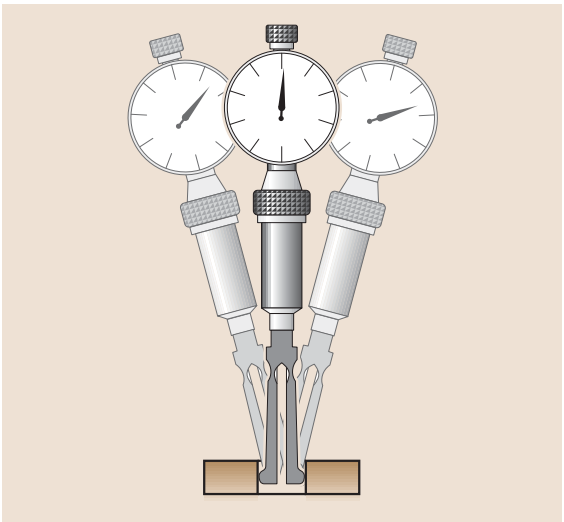

Fig. 8.18 Inversion point

The *direct collection of measuring values* (for example, with callipers or micrometers) is the easiest type of measuring implementation. The measuring range of the measuring devices must overlap with the measuring object. In Fig. 8.16 the measurement of a length by means of a micrometer is shown. The range of measurement of the displaced micrometer is shown as being 25 mm. Objects with lengths ranging from 0 to 25 mm can be measured. The measuring uncertainty for such a micrometer can be expected to be in the range 10–20 µm.

If the tolerance of the measuring value is so small that the required ratio between the measuring uncertainty and tolerance can no longer be met, one must choose a measuring devices with a smaller measuring uncertainty. Smaller measuring uncertainties are often accompanied by smaller measuring ranges. Whenever, for example because of the requirements of the measuring uncertainty, a measuring device whose range of measurement is smaller than the measuring value must be used, one can employ *difference measuring* (Fig. 8.17). One chooses a measurement standard, in the figure shown as a combination of block gauges, whose value differs from the measuring value by no more than the measuring range of the measuring device. The measuring device is used so that the readout both by probing the measurement standard and the measuring object is possible. The length of the measuring object is the sum of the length of the precision gauge block and the difference between the readout for the measurement standard and the measured object.

Another important application option is the search for an inversion point. Figure 8.18 shows an example of the measurement of an inside diameter with a two-point measuring instrument (two probing points on the cylinder's interior). Through the measuring force and supported by special structures, the instrument aligns itself so that the cylinder axis intersects the connecting line between the two probe points. The instrument can be pivoted from the left in Fig. 8.18, through the middle, to the right position. One can see that the displayed measuring value at first becomes smaller but, after the middle position, becomes larger. The smallest displayed value, the inversion point of the needle, corresponds to the shortest connection of the probed cylinder surface line, and thus the diameter.

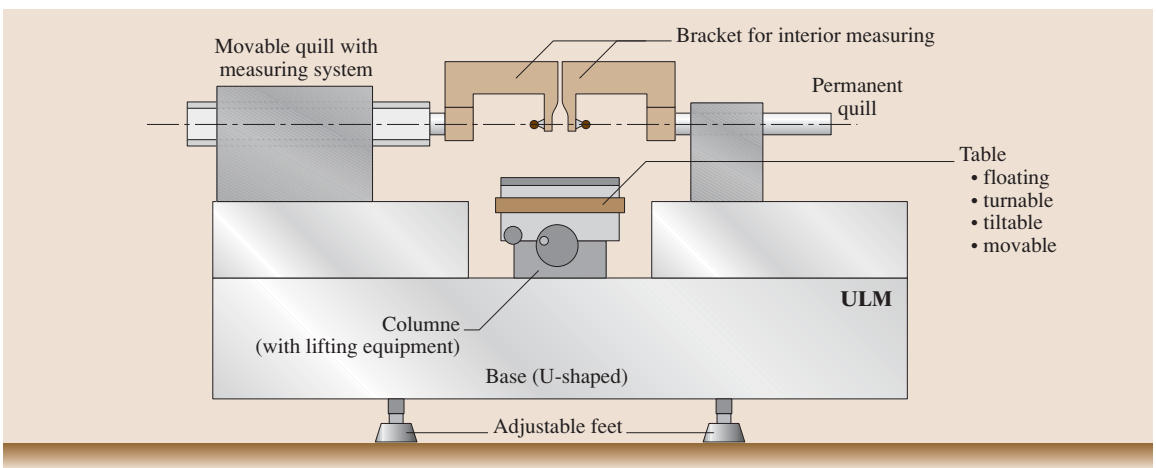

Fig. 8.19 Universal measuring gauge

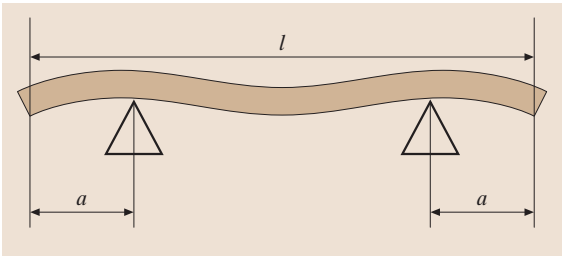

Fig. 8.20 Bessel points

When measuring workpieces, different influences have a negative impact on the measuring result. For example, inclination between the measuring instrument and measured object, bending, deformation on account of the measuring force, and environmental conditions can lead to deviations of the measurement. Some of these effects can be avoided or notably reduced through proper equipment operation.

Through the adherence to a fundamental measuring technology principle, the Abbe comparator principle, one can reduce the influence of tilting errors. According to this principle, the measured object and the measuring rule are to be aligned flush. Figure 8.19 shows the universal length gauge as one of the essential instruments using this principle. The measured object and the integrated measuring system, which is inside of the movable quill, are consecutively aligned flush. Brackets for interior measurement are attached. After removing the brackets the instrument is suitable for the collection of external measurements. As measuring systems, glass measuring scales and laser measuring systems are utilized. Such measuring instruments are suitable for the monitoring of gauges and measuring means.

The deflection of workpieces due to their own weight also has a considerable impact on their length. On a bar-type component, one obtains the smallest shortening of the whole length whenever the piece is supported on the so-called Bessel points (Fig. 8.20). These support points are located at a distance $a = 0.220 \cdot l$ from the ends. Similar effects lead to deformations on account of the measuring force. Deformations of the material are mostly only problematic for soft materials (plastics) and non-massive workpieces. Here, the workpiece can bend itself whenever the measuring force presses against thin-walled positions. This effect can be reduced using proper fixtures.

Environmental conditions are generally specified by the room where the measurement takes place. Measuring rooms are classified into five classes. Precision measuring rooms (class 1) serve for the calibration of reference standards. Fine measuring rooms (class 2) serve for the calibration of used standards and for acceptance inspection of precision parts. In standard measuring rooms (class 3), measuring tasks for the monitoring of a process, measuring of fixtures and tools as well as the control of inspection equipment (factory standards) and first prototype inspections are conducted. The production-related measuring room (class 4) serves for monitoring production, machine settings, and instruments. Production-related measuring takes place on the manufacturing measuring site (class 5). The spectrum is supplemented by the special measuring room, for example, for the measuring of semiconductor wafers. Properties whose limit values in every measuring room class are predefined include temperature (basic temperature, time and local temperature variation), vibrations, air quality (fine dust, suspended matter), air humidity, and lighting.

Table 8.3 Linear expansion coefficients

Material	Linear expansion coefficient (µm/(m K))
Steel	13
Copper	16
Aluminum	23
Magnesium	26
Polyvinylchloride	80

A substantial influential parameter for geometrical data acquisition is temperature. The reference temperature for measurement is 20 °C. The reference temperature is the temperature at which workpieces have their true measurement value and at which the inspection equipment detects it. These specifications apply to all pieces in the measuring chain. Table 8.3 shows the linear expansion coefficients of different materials. For example, for a temperature increase of 1 K, a 1 m-long piece of steel will become about 13 µm longer. The alternative measuring of the existing temperature and consequent correction of the measuring value is particularly problematic for geometrically and compositionally inhomogeneous inspection equipment or workpieces and by temporally and spatially varying temperatures.

8.2.6 Coordinate Measurements

Basics

Coordinate measuring machines are universal, flexibly applicable equipment for the recording of workpiece geometry. As well as measurements of parameter (for

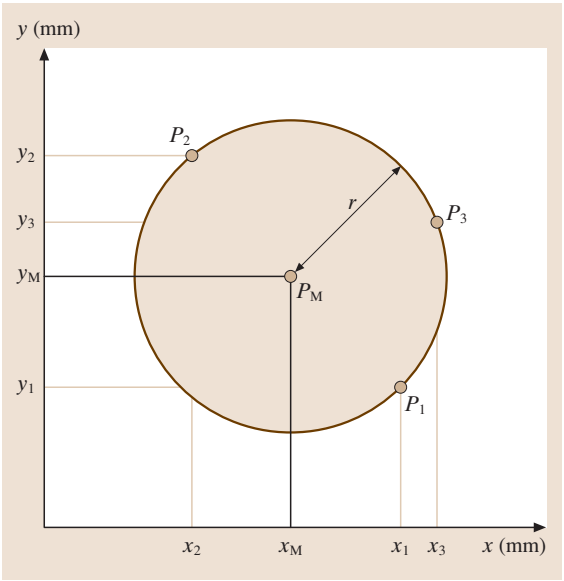

Fig. 8.21 Measuring points on a circle

example, diameter and length) position and form (for example, roundness and concentricity), specials (for example, cylindrical or bevel gears) and free-formed surfaces (castings) can be measured.

In contrast to conventional measuring techniques the desired measurements are not measured directly. The principle is the acquisition of single data points from geometrical elements. These elements include circles, planes, cylinders, spheres, and cones. Furthermore, these elements can be combined together to identify distances, angles, or position deviations. The acquired measuring points, which are on the boundary of standard elements, are mostly described by a Cartesian coordinate system (x, y, z). However, it should be noted that cylindrical and spherical coordinate systems are also possible. The described size of these geometrical elements will then be calculated from these measured points. The following example shows the strategy for identifying the radius r and the middle point coordinates x_M, y_M of a circle. For simplification, this example will be confined to a circle in the x–y plane.

The equation for a circle whose center point does not lie at the origin is as follows

$$r^2 = (x - x_M)^2 + (y - y_M)^2 \,.$$

The variables r, x_M and y_M are unknown. One appoints a measuring point on the circumference of the circle for the variables x and y. Now, because there are three unknowns and we need a clear description of the circle, we need three equations, which means three data points (the smallest number of data points for determining a circle

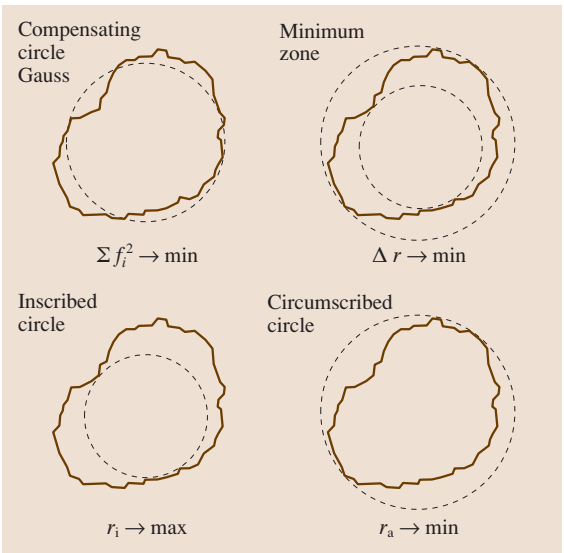

Fig. 8.22 Compensation methods

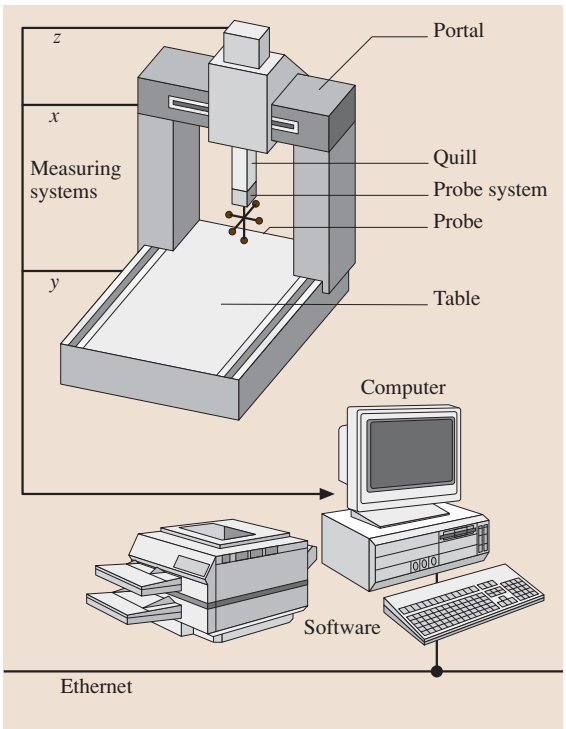

Fig. 8.23 Basic configuration

is three). This yields the following system of equations

$$\text{For } P_1 \text{ with } [x_1, y_1]: \; r^2 = (x_1 - x_M)^2 + (y_1 - y_M)^2 ,$$
$$\text{For } P_2 \text{ with } [x_2, y_2]: \; r^2 = (x_2 - x_M)^2 + (y_2 - y_M)^2 ,$$
$$\text{For } P_3 \text{ with } [x_3, y_3]: \; r^2 = (x_3 - x_M)^2 + (y_3 - y_M)^2 .$$

Since we are dealing with elements of measured, real-world objects, whose bordering areas deviate from geometrical standards, the collection of a large number of data points is essential for the determination of the elements parameters. An overdetermined (no longer explicitly solvable) system of equations results from a higher number of measured points. This system has the following form

$$\text{For } P_1 \text{ with } [x_1, y_1]:$$
$$f_1 = (x_1 - x_M)^2 + (y_1 - y_M)^2 - r^2 ,$$
$$\text{For } P_2 \text{ with } [x_2, y_2]:$$
$$f_2 = (x_2 - x_M)^2 + (y_2 - y_M)^2 - r^2 ,$$
$$\vdots$$
$$\text{For } P_n \text{ with } [x_n, y_n]:$$
$$f_n = (x_n - x_M)^2 + (y_n - y_M)^2 - r^2 ,$$

where f_i represents the deviation of the corresponding data point from an ideal circle. One can employ a compensation method to solve this system of equations. A widely used method is the regression equation by Gauss. The sums of the squared deviations are minimized with this method

$$\sum_{i=1}^{n} f_i^2 \rightarrow \min .$$

This least-squares method ensures that all measuring points are included in the calculation. Problems especially arise when one wishes to verify mating. In this case the inscribed circle gives the description for holes, while the circumscribed circle gives the description for shafts. (The *inscribed circle* is the largest possible circle that has all of the measuring points outside, while the *circumscribed circle* is the smallest possible circle that contains all of the measuring points.) In certain cases an outlier test may be necessary.

Equipment, Sensor Technology, and Software

One can subdivide coordinate measuring machines on the basis of their construction into portal, bridge, and standing measuring machines. In Fig. 8.23, the basic configuration of a portal measuring machine is repre-

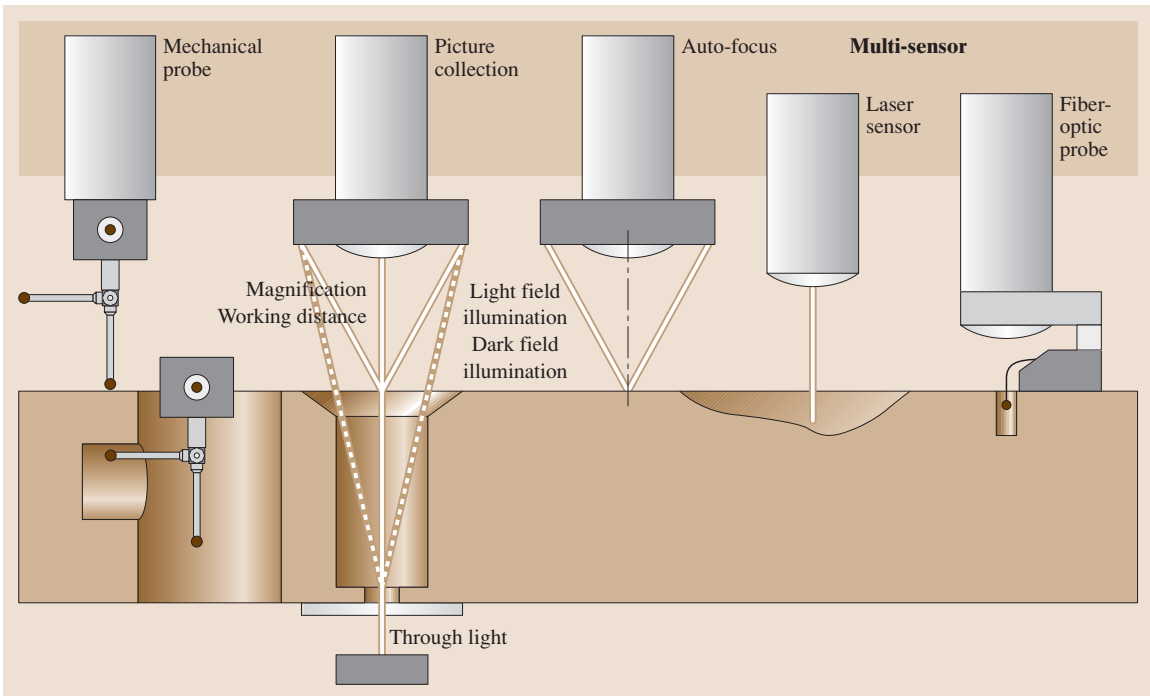

Fig. 8.24 Multisensor technology

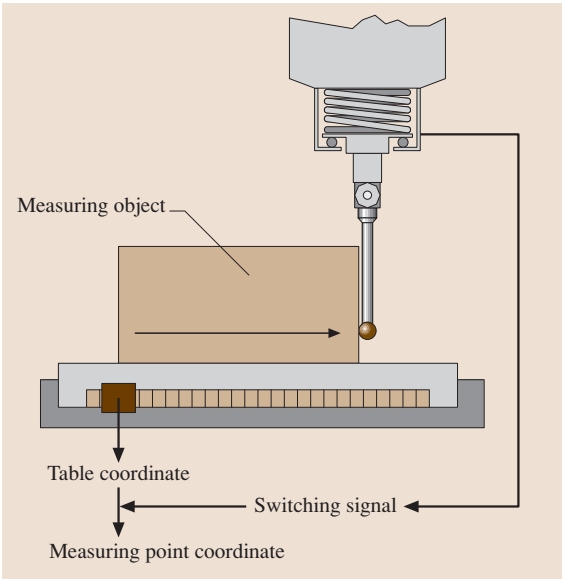

Fig. 8.25 A switching probe system

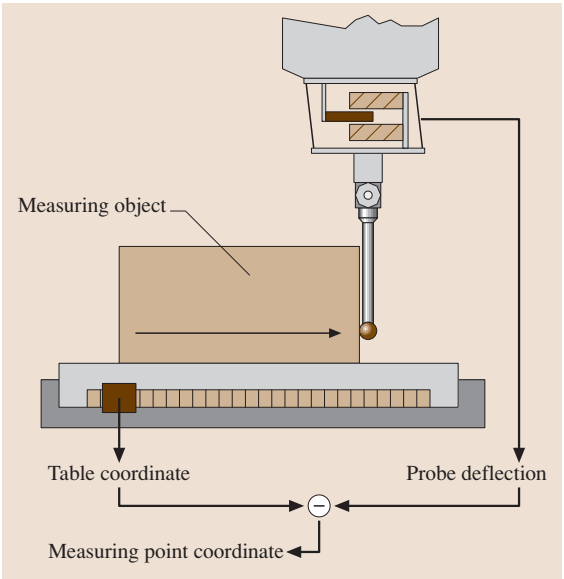

Fig. 8.26 A measuring probe system

sented. The mechanically embodied axes (in the shown example, portal and quill) are arranged on the measuring table at right angles to each other. Additionally, the axes of rotation can be integrated for the realization of rotary movement. The instantaneous positions of the axes are logged through the measuring system and forwarded to the connected computer. Glass measuring scales are mostly used in measuring systems.

The probe system is attached to the quill. In addition to the frequently utilized, mechanical probe systems there are contactless options such as edge recognition, optical methods, and/or laser probes. One speaks of a multisensor coordinate measuring machine when various probing systems are arranged inside (Fig. 8.24).

Figures 8.25 and 8.26 illustrate various mechanic probing systems. One can distinguish between measuring and switching mechanical probing systems. In both cases, the workpiece is touched with the probe element, which is fixed onto the probing system. The probe element consists mostly of a shaft and an almost ideally round, wear-resistant sphere (in most cases, made of ruby). In a switching measuring system (Fig. 8.25), the contact between the probe sphere and workpiece releases a impulse. At the moment of this signal, the x, y, and z coordinates of the current position from the table, portal, and pinole are transferred to the computer and stored there for further processing as required.

Contact between the probe and workpiece leads to deflections of the probe head in all three coordinates in a measuring probe system (in Fig. 8.26, the deflection is only represented in one direction). These deflections are measured and combined with the associated coordinates of the inherent positions of the table, portal, and quill. The measuring point coordinates obtained in this way are passed to the computer. However, care must be taken to note that the measuring point coordinates acquired always refer to the middle point of the probe sphere of the reference probe, not to the contact point between actual probe and workpiece.

Very flat outlines or color transitions are not mechanically probable. In these cases, optical acquisition is an option. For this purpose, the measuring object is illuminated, according to the target measurement (using through light, light-field or dark-field illumination) and imaged through optics. The optics used may work with changed or zoom objectives in order to obtain different magnifications between the measured object and the image. In the simplest case, only the contours to be measured are scanned, using an edge finder. In the next most sophisticated system, based on image processing, the measured object is displayed on a charge-coupled device (CCD) matrix. As by a mechanical measuring probe system the measuring point coordinates results as a combination of the pixel coordinates and the inherent positions of the table, portal, and pinole.

While the optical variants described so far operate in the x–y plane, the focusing of an optical system can also capture the z-coordinate. The focusing can be auto-

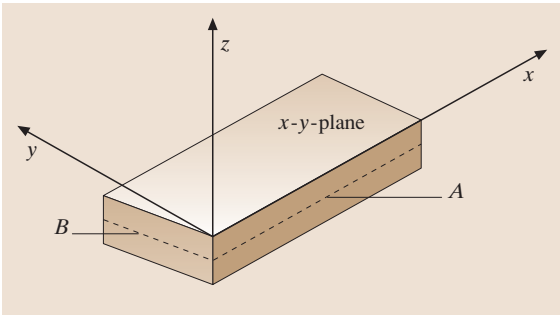

Fig. 8.27 The workpiece coordinate system

mated by means of a laser or contrast evaluation in the image-processing system. The sensor controls the shift of the quill in the z-direction. The respective z-value supplements the x–y coordinates of the associated position to actual measured three-dimensional (3-D) values. Instead of autofocusing options, one can also use a direct laser measuring system for the addition of the third coordinate, for example, a triangulation sensor. This method forms a laser point on the surface of the workpiece. Using observational optics arranged at a defined angle with respect to the sensor, a difference in height of the surface of the workpiece is recorded directly. When the measuring range of the triangulation sensor is not sufficient, one can extend its application range by shifting with the quill. The measured z value can then be calculated from the z-axis of the measuring system and the measured value from the triangulation sensor.

One very new and interesting sensor variation is the fibre-optic sensor patented by *Werth-Messtechnik* (see also Fig. 8.24). It consists of an extremely small glass sphere, which is suspended by a glass fibre. Over this light pipe, the sphere can be directly illuminated. To capture the measuring points, the glass sphere is placed on the workpiece to be measured. The image-capturing system (CCD matrix) can detect this probe either in transmitted light or through its self-lighting. The center of the sphere describes the coordinate of the measuring point, just as for normal mechanical probes.

The *software* in the attached computer essentially has the following tasks:

- Capture of the measuring points
- Corrections, for example, perpendicularity and guideway deviations of the measuring machine components, probe radius and middle point, probe bending, temperature influences
- Coordinate transformations, for example turntable and workpiece coordinate systems
- The calculation of ideally geometric substitution elements from the measuring points
- The combination of single elements
- Conversions, projections, etc.
- Evaluation (nominal-actual comparison), protocol, statistics

Device control (point- or path-control, scanning) comes with the computer numerical controled (CNC) coordinate measuring machines.

For the archiving of results or for further processing data transfer by means of a network is possible.

Proceeding with the Measurement

The completion of a measuring task by means of coordinate measuring machines is explained in the following. Three phases will be differentiated.

Phase 1: Planning. Planning can take place far from the machine but is based on knowledge of the technical capabilities, available probes and clamping elements as well as extensive experience. This phase is decisive for measuring-technically proof and economically justifiability of the measuring process. The test task, which is generally fixed on the drawing, forms the basis for the planning of the measurement. Differences in the path arise, whenever the aims of measurement (evaluation of the part), quality-orientated production control or check for assembling possibility are changing. In this case knowledge about the production of the piece (for example, the machining base) or its later application (subsequent machining and assembly) is useful. The test task is divided into its single elements and combinations. A sequence from easiest to most complicated is then sought.

It is to ones advantage to specify a coordinate system on the workpiece not only for the measurement, but also for the evaluation of the results. This workpiece coordinate system must be mathematically clearly described. To do this, the following steps are required:

1. Space adjustment: description of a coordinate axis (mainly z) as the main direction of important form elements (for example, the direction normal to a surface, the axle of a cylinder). The z-axis is described in the example picture (Fig. 8.27) by the normal to the upper workpiece plane.
2. Plane adjustment: hindering the rotation of a coordinate system around these under 1. defined axes (for example, by fixing to an edge or the straight line connecting the middle of two holes). The direction of the x-axis in the example picture (Fig. 8.27) is

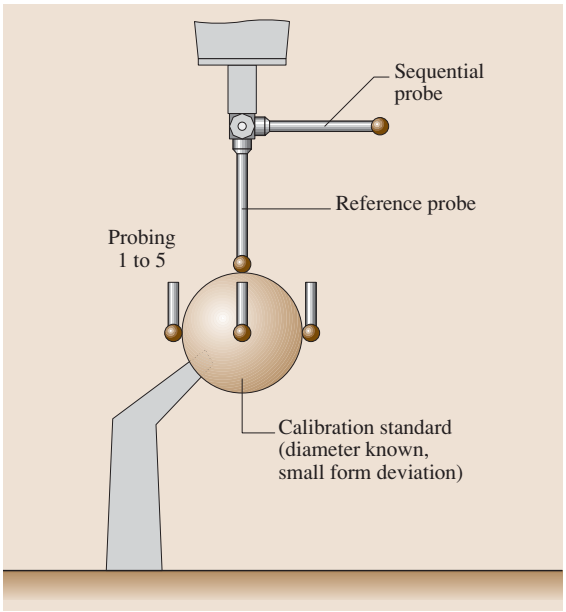

Fig. 8.28 Probe set-up and calibration

defined in the x–y plane by the corresponding direction of the long rectangular surface (dashed line A). This fixes also the direction of the y-axis, which must be orientated at a right angle to the x-axis.

3. Point adjustment: definition of the origin for x, y, and z. The origin of the z-axis through the measured x–y plane and the origin for the x- and y-axes through the intersection of lines A and B are described in Fig. 8.27.

The probe element must be chosen so that all of the elements to be measured are reachable. For this reason, more probing elements may be necessary, as shown in Fig. 8.28. One calls the connection of more than one probe elements a probe combination or a probe tree. It can also occur that different sensors are needed for a particular measuring task. In the preparation for the calibration, a probe element is specified as a reference probe element. With multiple probe combinations or sensors, there is only one reference probe. Whenever more probe combinations are necessary, the work is implified by an automatic probe-changing mechanism.

The workpiece is set or clamped onto the measuring machine table, so that it lies as firmly and clearly as possible. Easy clamping elements, clamping element component systems, or special clamping devices are available. All of the form elements to be measured must be reachable with the chosen probe configuration. It is not allowed to come into contact with gripping or clamping elements.

The specification of the sequence of probing occurs essentially from an economical point of view (shortest routes between the elements). The type of probing (for example, mechanical or optical, point-to-point or scanning, auto-centering) is substantially limited by the technical capabilities of the measuring machine. Remark: Scanning is the independent tracing of a workpiece contour by the measuring machine. One must give a starting point, end point, the direction, and a scanning plane. The path results from the cut of the scanning plane with the workpiece surface. The scanning speed and point density must be provided by the operator. The minimum measuring point court follows from the type of geometrical elements (see Sect. *Basics*). The aim of measurement (parameter or form deviation) forms the basis for the definition of the real used measuring point count. With increasing numbers of measuring points, the determination of the individual form elements becomes more certain. In any case, more measuring points than the minimum should be utilized. Around 2 to 3 times the minimum point count for the recording of a measurement and its deviation is sound from a measuring technology and economic viewpoint. For form deviation, one needs substantially more points. Here, the number depends on the size of the smallest geometric portions to be recorded. The measuring points should, if possible, be evenly distributed on the measured element and in addition must be able to represent these form elements with the desired deviations.

Phase 2: Preparation and Measuring. The probe combination is assembled as defined and then calibrated. Figure 8.28 shows the calibration of one probe of a two probe combination. Through measurement of a calibration standard (a sphere with a known diameter and a very small spherical deviation) with both probes, the actual diameter of the probe tips and the distance of the middle of the sequential probe sphere to the middle of the reference probe sphere in the x, y, and z directions determined. After clamping the workpiece the machine parameters (e.g., velocity, measuring force) are to define.

The degree of automation of the measuring machine is of deciding importance for the probing of the measuring points. For manually controlled machines, the entire course (measuring point probing and manoeuvres in space between the machine elements and gripping devices) at every single point is realized by the operator. CNC-controlled machines allow the programming

of a course of motion and have an automatic drive to adopt the required positions. One distinguishes between three possible programming methods:

- By teach-in, the machine learns the course of the measuring directly from the handling of the operator, i. e., his motion. He executes the course to the points to be measured as on a manually controlled machine. In this way all of the measuring point coordinates and all necessary points for collision-free manoeuvring between the machine parts and gripping mechanisms can be recorded. Afterwards, the control system can independently reproduce this course.
- The generation of the target coordinates can take place far from the machine. In this method, all measuring coordinates and position coordinates are derived from the figures or drawing data. This procedure requires great spatial imagination from the programmer. This approach is used mostly in conjunction with teach-in portions.
- Computer-aided design (CAD) systems that have a measuring module at their disposal can directly provide measuring machine programs (compare with next section).

Phase 3: Evaluation. The description parameters for the associated geometric elements are determined from the measuring points through compensating calculations (for example: Gauss, inscribed circle, circumscribed circle). Take notice that either the measuring points or the description parameters are to correct by the calibration data (probe sphere diameter, distance to the reference probe). On the foundations of the description parameters, elements can be mathematically linked or joined with each other. So new characteristics that describe the geometry of the entire workpiece can be developed. The parameters of the individual elements (diameter, length) and the resulting parameters from the links (distance, angle) can be compared with the nominal and tolerance data. Afterwards, the results can be represented graphically or numerically.

Integration into CAD and CAM

Coordinate measuring machines (CMM) are suitable for integration into CAD/CAM environments. This integration is possible under two criteria.

In CAD systems, the geometric data for a new workpiece is created. With that, outstanding conditions exist for the derivation of the measuring program on the basis of this data. In addition to the data describing the workpiece, a measuring module implemented in the CAD system needs data for the possible elements of the probe combination and the gripping system. *The complete measuring program can be produced in a simulated measuring run.* It is important for later functions that the coordinate system for the description in the CAD system agrees with that for measured workpiece on the measuring machine. The measuring program can be written in a specialized programming language for the measuring equipment manufacturer or in the manufacturer-independent universal language dimensional measuring interface specification (DMIS), depending on the available measuring modules. For integration into the measuring machine program a special interpreter is then necessary. After successful measuring, the possibility exists for the acquired deviations to be transferred back to the CAD system, to be processed or represented. Of course, an external process through best-fit and distance determination of the CAD data is possible.

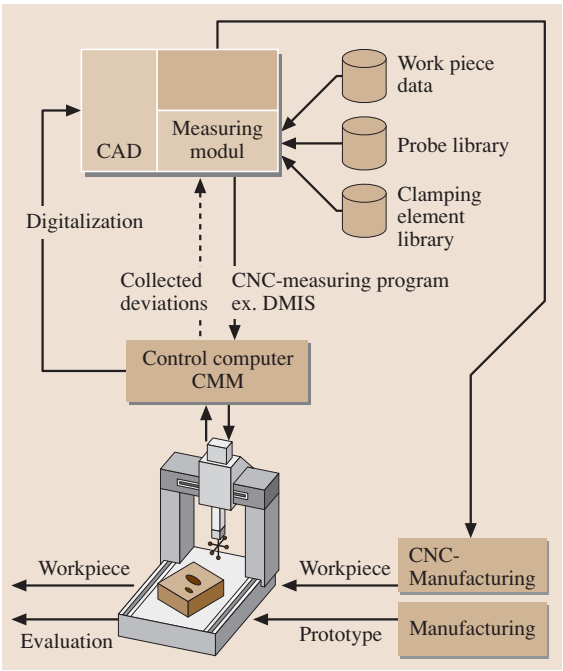

Fig. 8.29 Connection CMM–CAD

The second possibility for the integration of a coordinate measuring machine is the *digitalization of an unknown workpiece geometry*. Here a manufactured sample forms the basis (prototype). This sample is touched in a previously defined grid. The measuring

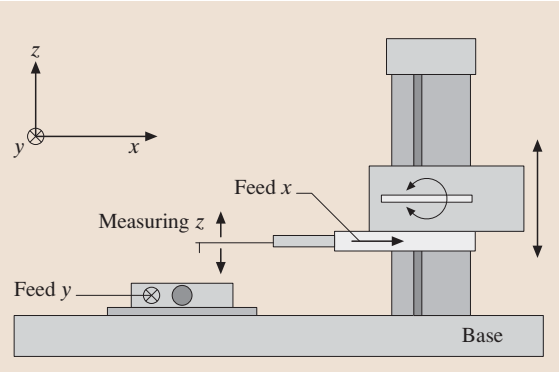

Fig. 8.30 Stationary surface metrology instrument

point coordinates acquired are handed over to the CAD system. There, a surface feedback or reproduction of the data model takes place. This can then be transferred to a manufacturing machine that makes a copy of the prototype.

8.2.7 Surface Metrology

Instrument Technology

The surfaces of geometric objects continuously provide an informative testing object. Considerations include appearance, the evaluation of the expected functional behavior, and manufacturing and wear conditions. The application of modern measuring devices in conjunction with sophisticated computer technology facilitates detailed evaluations and conclusions, which only a few years ago were unthinkable. With the available equipment and the demands of the user, these approaches are being widely applied.

Small, independent, portable instruments with skid pick-up systems are easily implemented to directly monitor tooling processes. In addition, stationary laboratory instruments with free probing systems, with correspondingly large measuring ranges and higher resolutions, have become established. Figure 8.30 shows the basic construction of a stationary surface metrology instrument. It consists of a base and pillar. The feed unit, attached to the pillar, can be positioned aloft and be pivoted opposite the base. The probing system is positioned with high precision on the feed unit. This positioning constitutes the measuring basis for the probing of a measuring object. If required, the system can be supplemented with an additional y-table. This y-table facilitates the step-by-step movement of the workpiece perpendicular to the feeder movement enabling three-dimensional scanning.

Instruments constructed as component systems allow a surface probing system to be used as a contour probing system (larger measuring range, many different types of possible probes) and therefore, to expand the application range of the instrument considerably. It is also possible to implement, instead of a mechanical probing system, a noncontact probing system if the surfaces are sensitive to mechanical probing. One option is to use auto-focusing laser sensors (see capitel laser measuring technology).

Developments in electronics over the last few years have made it possible to digitize large quantities of data with a higher decimal precision (higher number of levels) with sufficient speed. This has enabled the collection of many measuring points (with a smaller distance between measuring points at an acceptable collection speed) over larger measuring ranges with greater resolution (small Δz). The accessories for roughness measuring instruments range from stylus stop attachments to a large selection of speciality probing elements and various skids. The instrument can be tailored to the measuring task with these specialized accessories. As well as instrument equipment, the environmental conditions are also an important aspect to consider. The implementation in the laboratory setting, in contrast to the factory floor, brings with it a significant improvement in environmental conditions. This facilitates tasks with greater demands for precision.

ISO Standards and Consequent Requirements

The relevant ISO-standards give not only the definition of characteristics but also requirements on measuring instruments (e.g. probe tipradius; distance between measuring points) and software (e.g. phase-correction Gauss filter). The profile, which is obtained by means

of the section probing method, is called, after the application of the filter for short wavelengths λ_s, the primary profile (*P*-profile). The roughness profile (*R*-profile) is obtained through the deletion of the long-wavelength profile features (threshold wavelength λ_c) from the primary profile. The waviness profile (*W*-profile) is made by filtering the primary profile by means of λ_c and λ_f, as depicted in Fig. 8.31.

The threshold wavelengths λ_c and λ_s necessary for this filtering readable in Fig. 8.32 after profile classification between periodic and aperiodic. No concrete definition currently exists for the threshold wavelength

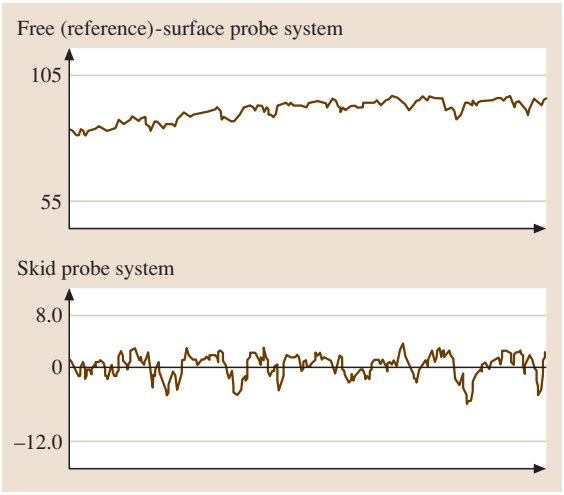

Fig. 8.34 Primary profile

λ_f, only the recommendation of $\lambda_f = 10(5)\lambda_c$. Besides the threshold wavelengths for the separation of profile elements, definitions of the maximum probe element radii and the distances between measuring points are being established. However, there are severe restrictions for the use of instruments in this way.

Characteristics can be calculated from all profile types (P, R, W). Figure 8.33 shows the arrangement of surface characteristics based on the example of the roughness profile. Fundamentally, horizontal, vertical, and hybrid characteristics can be differentiated. These are supplemented by characteristic curves from which parameters can be derived.

Because the explanation of the single characteristic definitions would be too lengthy, the corresponding standards (ISO 4287) is referred to instead.

Analysis of a Surface

Whereas the previously explained, easy-to-handle instruments with skid pick-up systems can only collect and evaluate roughness, instruments with reference-surface probing systems produce data that, with proper software, can measure not only roughness and waviness characteristics but also size, form, and positional deviations. Also, a description of surface alterations by abrasion and coating, amongst other effects, is possible with these systems.

The difference in the information content of the data is immediately recognizable in Fig. 8.34. Whereas the skid pick-up system only approximately captures the roughness portion, a slant and curvature can be recognized in the data collected from the reference-surface

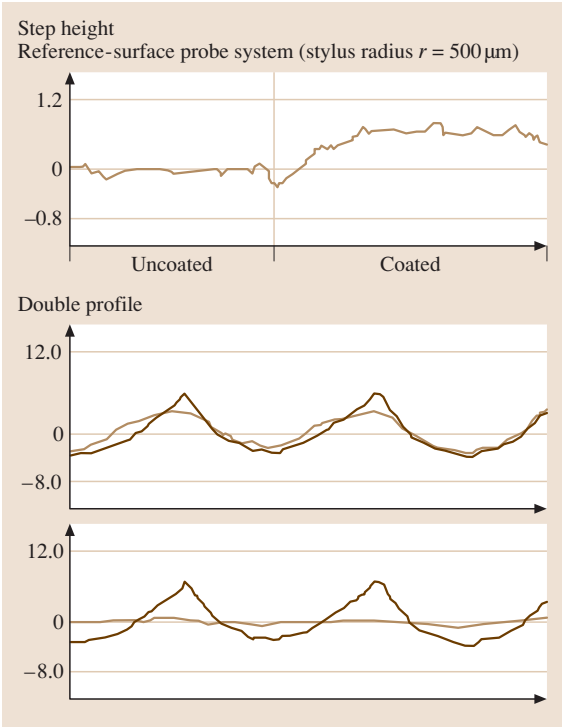

Fig. 8.35 Application for the manufacturing measurement technology

probe system. The skid pick-up system manages with essentially small measuring ranges and poor guidance, which makes these instruments much more affordable. However, one should pay attention to the fact that the mechanical filtering of the signal, by means of the skid, cannot be removed during the follow-up evaluation.

The larger information content collected with a reference-surface probe system is accompanied by substantial disadvantages related to the instrument technology. The disadvantages are the relatively large measuring range of the probing system, which is required in order to obtain the primary signal within a justifiable adjustment effort and the fact that the straightness of the feed unit movement must be very good, as it contributes to the measuring signal. Both effects lead to relatively high instrument costs.

Figure 8.35 shows the example of the implementation of surface metrology equipment with a reference-surface probing system. On the top, data collected from a partially coated workpiece is shown. The implementation of a probe element with a comparatively large radius ($r = 500\,\mu m$) leads to the low-pass mechanical filtering. For the compensating calculation, only data

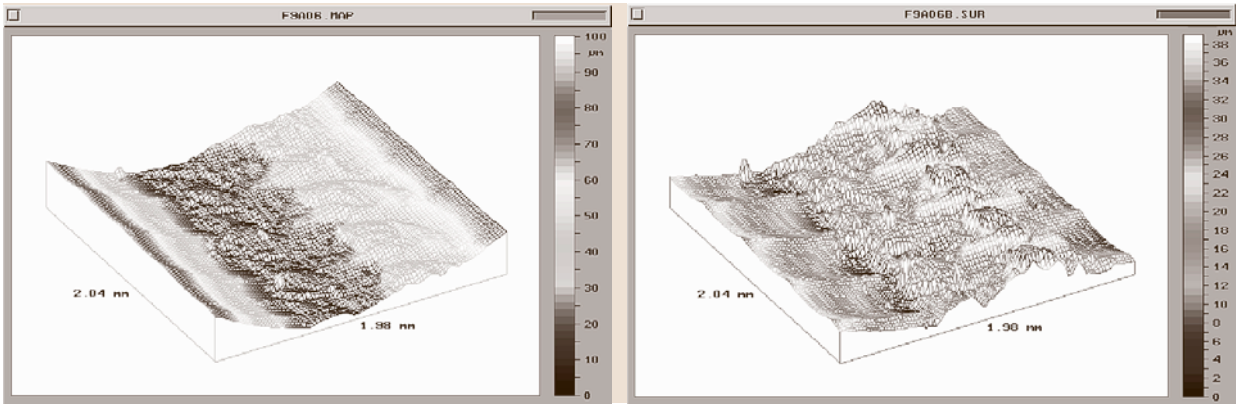

Fig. 8.36 3-D surface structure

that represents the uncoated material is used. After this calculation, the course of the layer thickness between the measured profile and the extended compensation profile is clearly recognizable in the coated section. Similar approaches are also suitable for wear measurement whenever unworn workpiece sections are still available. On the lower part of Fig. 8.35, production-progress is shown by a double profile. The basic result is a turning surface profile, which is then smoothed in a second processing step. Clearly, the varying manufacturing results achieved by changing the machining parameters (low or optimal pressing force on the tool) can be noted.

The additional assembly of *y*-shift table perpendicular to the actual feed direction (Fig. 8.30) allows the collection of data from flat, three-dimensional structures. By the use of an appropriate software package, one can derive three-dimensional surface characteristics from this data, or rather a visual impression of the surface for the benefit of the user. This allows conclusions on properties of the surface, which one cannot easily derive from a single profile. Figure 8.36 shows the three-dimensional measured structure of a workpiece that was milled with a spherical-headed milling tool. In the left-hand side of the figure, a detail from the actual surface, is shown. The differences in altitude are represented by different brightness. There is also the choice of an isoline representation (connected lines of equal height). The curvature left behind by the spherical cutter is clearly recognizable. Under this relatively strong curvature, the detailed structure remains hidden.

The right-hand side of Fig. 8.36 shows the same section. In order to make the details clearer, the dominating curvature in the left part of Fig. 8.36 is removed with the use of a compensating calculation (a three-dimensional second-order polynomial fit), Now the milling feed is clearly recognizable. The unclear structure in the middle of the illustration emerges because there are no definite cutting properties in the domain of the center of the cutting tool.

8.2.8 Form and Position Measuring

Instrument Technology

Form inspection equipment in most cases consists of a base and a column. A turntable is integrated into the base. On the column, an arm is located, which carries the measuring system. Even after construction of the instrument, the turntable, the column, and/or the arm can be arranged as a measuring base. The measuring system is in most cases inductive. The probing is carried out with a spherical probe element. In order to keep abrasion to a minimum, ruby probing elements, as used in

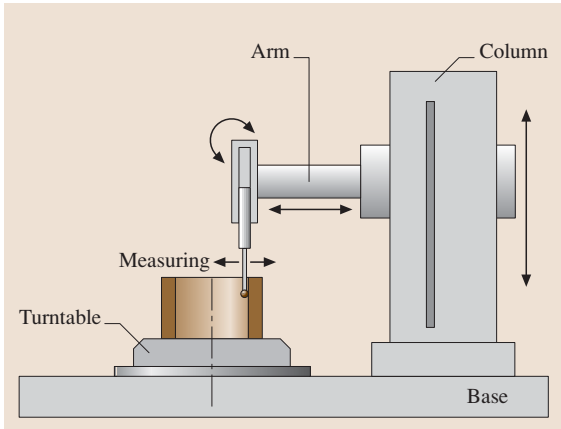

Fig. 8.37 A form inspection instrument

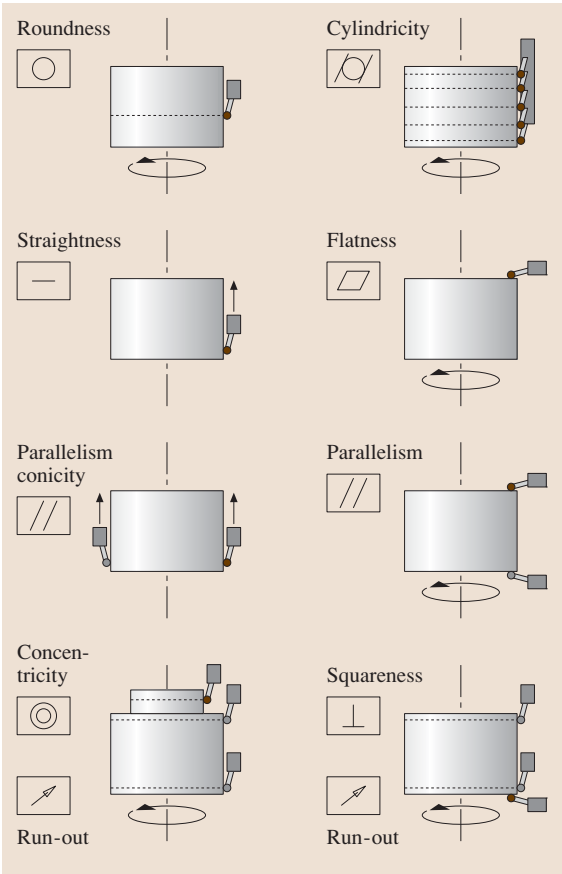

Fig. 8.38 Measuring execution

coordinate measuring machines, are utilized. The measuring system is inclinable so that the direction of the measuring force can be reversed. Therefore, almost all necessary measuring points can be reached. Figure 8.37 shows a vertically arranged probe system, by which the measuring force from the workpiece acts radially outwards. Subject to the measuring task, one or more feed axes can be implemented.

Measuring Execution

Figure 8.38 shows, in the upper left-hand corner, a roundness inspection. After positioning the piece on the turntable, the piece is orientated to the rotating axis so that the measuring system remains in the measuring range during the course of inspection. By a large measuring range, visual judgement suffices for orientation. The large measuring range leads to a bad resolution. A more-accurate orientation of the piece is demanded for a smaller measuring range, leading directly to a better resolution.

After the probe is brought into contact with the desired position on the object, the measuring object is rotated 360° by the turntable and, while the object is turning, the measuring points are scanned. An ideal circle is calculated from the measuring points. For this, depending on the aims of the inspection, compensating methods (for example, Gauss, circumscribed circle, inscribed circle, see Sect. 8.2.6) can be chosen. In reference to the compensating circle, the range between the lowest point and the highest point is the roundness deviation. For the investigation of causes of deviations, one can filter the desired frequency domains or use a frequency analysis e.g. a fast Fourier transform (FFT) (Fig. 8.39).

In the left-hand side of the figure, the unfiltered circle form deviation is depicted for evaluation of the

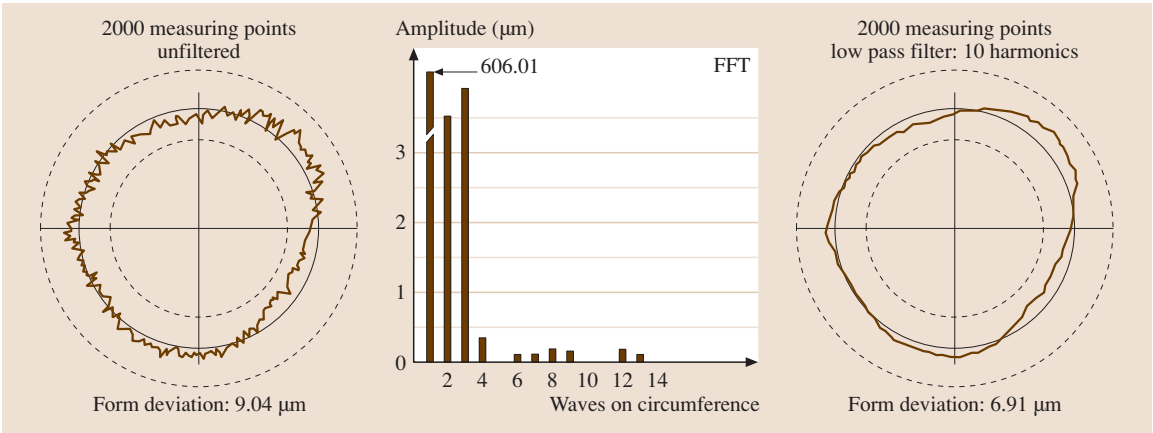

Fig. 8.39 Roundness deviation

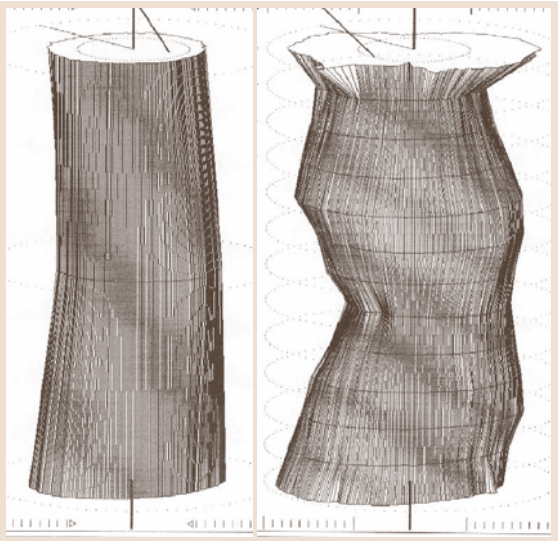

Fig. 8.40 Cylinder form deviation

workpiece. The frequency analysis in the graph next to it shows that waves, especially with a period of 2 and 3 harmonics, dominate the result. The right-hand side of the figure shows the measuring result after running the data through a low-pass filter (limit wavelength of 10 harmonics). Here, it is easier to recognize causes of deviations and to implement corresponding quality-orientated corrective action into the manufacturing process.

Figure 8.40 shows the collection of cylinder form deviation. Here, in addition to a high-precision rotating axis, a column axis with correspondingly small straightness deviation is used in order to facilitate vertical movement. When positioning, movement of the arm should be avoided. All of the collected measuring points, located on circles, are put through a compensating calculation together. From the distances between the single measuring points and the compensating cylinder, the cylinder form deviation is derived.

Just as the number of points on a circle is important for the determination of the circle form deviation, so the number of measured circles for the cylinder form deviation is not to be neglected. Figure 8.40 shows, on the left, a picture that used three circles and on the right, a picture that used 13 circles to calculate the cylinder form deviation. Clearly, there is a noticeable difference in information content between the two.

To detect referenced elements, like for example, the concentricity depicted in Fig. 8.38, one uses the methods already known from coordinate measuring technology. First, both of the circles on the lower cylinder are probed. The circles should have the largest possible distance from each other in order to reduce the measuring uncertainty. Compensating circles are calculated from the corresponding measuring points. The line that connects both mid points of the circles serves as the reference axis. After the inspection of the circle on the smaller cylinder and the corresponding determination of the parameters of the compensating circle, the eccentricity is calculated as the distance between the midpoint of the circle and the reference axis. The tolerance zone for the concentricity describes a circle around the reference axis.

8.2.9 Laser Measuring Technology

Basics

Based on its properties, laser measuring technology has gained a strong position in the field of integrated measuring technology inside the manufacturing processes. In this section, a few examples are explained and the advantages and disadvantages highlighted. The application profiles of laser measuring systems are as different as their parameters, and range from simple dimensional completeness checks to high-precision measuring systems that determine surface roughness or even the acceleration of tooling machine components. From the many possible implementation variations, only a few are considered, those that use the various properties of light. Next to the time-of-flight method, which is not commonly implemented in mechanical engineering applications, come uses of such properties include linear propagation, reflection, or interference. The selection of the best sensor for the specific application and the arrangement of the sensor to the measuring object is based on criteria such as:

- Operating distance
- Measuring range
- Resolution (scale value)
- Measurement uncertainty
- Measuring spot diameter
- Light color and intensity

However, the price of the entire system, which consists of sensors, processing electronics and possibly components for the movement of the measuring object or the lose, is also quite relevant.

In addition to the technical and scientific considerations, protection against accidents is also an issue that should not be ignored. Because most laser meas-

uring systems are equipped with low-power lasers (hazard category 1–3), skin burns are rather improbable. However, the eyes must be well protected. Reflected radiation from metallic surfaces is also problematic. The mandatory guidelines, for instance in Germany, demand labeling for hazard category 3B and above, the application of opaque enclosures, laser protection eyewear, and special warning and emergency facilities.

Laser Applications in Measuring Technology

The *linear propagation* of a laser beam is used by a whole range of measuring devices. To clarify this application, two examples are presented. The first is a laser scanner (Fig. 8.41), which amongst other applications is used here for the quick scanning of the diameter of shafts.

The laser beam, created by a diode, is expanded into a fan shape and aligned so that the beam is parallel. As shown in the figure, this alignment is done by optical components. There are also laser scanners in which the beam expansion occurs by means of a spinning polygonal mirror. The laser beam is directed toward the measuring object. Behind the measuring object, a receiver is arranged where the laser beam strikes a light-sensitive CCD line array. Because the laser beam is broken by the measuring object, in this case the shaft, the size of the shadow on the receiver can determine

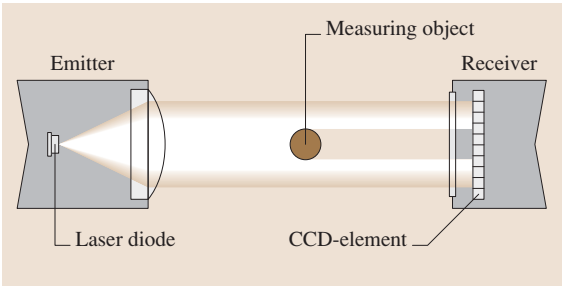

Fig. 8.41 Laser scanner

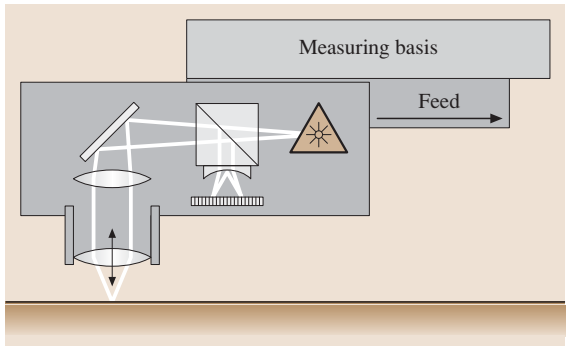

Fig. 8.43 Autofocus sensor

the diameter of the object. The emitter and receiver can be adjusted axially to the shaft very quickly, so that in a short time, the diameters of various shaft sections can be determined.

A second application of linear laser expansion is shown in Fig. 8.42. The emitter, which emits a laser beam with a narrow diameter, is arranged on the fixed part of a tooling machine base. The receiver is assembled on the sliding bed and consists of a CCD matrix sensor field (in the middle of the figure). Different manufacturers also use four quadrant diodes at this location as a receiver.

Now, the sliding bed of the tooling machine is steered to its home position. The point at which the laser beam strikes the sensor field is registered (y_1, z_1 at $x_1 = 0$ mm). On the way to the end position, it is stopped at defined points and for each stop the laser point is registered on the sensor field (y_2, z_2 at x_2, and so on). From the obtained points, the straightness deviation of the sliding bed movement is shown divided into the x–y and into the x–z planes.

A laser beam reflected by the measuring object is generally used by laser distance sensors. These are employed for the contactless measurement of deformable, very rough, sensitive, hot, or moving surfaces. A laser

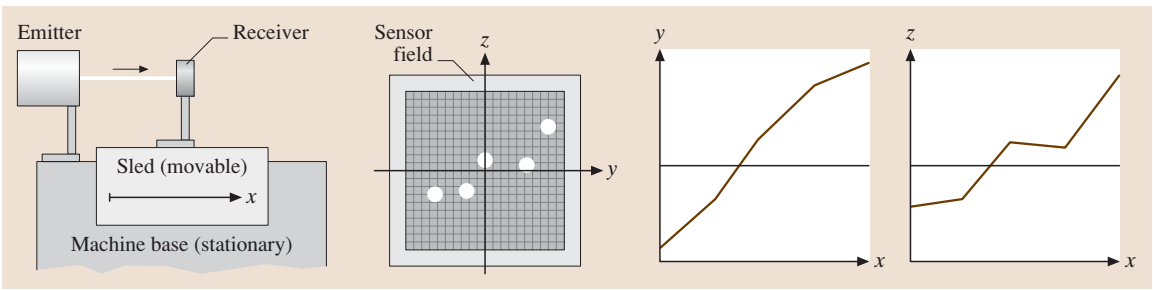

Fig. 8.42 Alignment measuring system

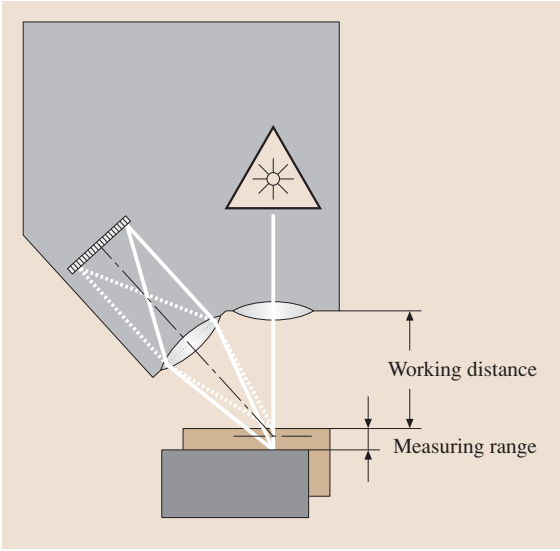

Fig. 8.44 Triangulation sensor

autofocusing sensor and a laser triangulation sensor are given as application examples. Figure 8.43 shows schematically the construction of an autofocus sensor (Mikrofokus from UBM). The laser beam is projected onto the surface of the measuring object and, from this surface, the laser beam is reflected. Specialized electronics monitor the focusing and, when necessary, readjust the lens system. The displacement of the lenses is recorded as the measuring value. The previously mentioned sensor example has a working distance of about 5 mm and a measuring range of 1 mm. The focused laser spot on the surface of the measuring object has a diameter of 1–5 µm, while the beam has an angular aperture of 30°. The electronics used in the example, allow the measuring signal to be broken up into steps of 16 nm. With these parameters, the sensor is well suited for contactless surface inspection. The advantages of noncontact probing are also accompanied with disadvantages. Problems especially arise due to locally strong reflective (for example, single grains on grinding wheels) and also by nonreflective materials as well as by steeply inclined surfaces (over 30°). In these cases, the reflected beam cannot be collected for evaluation. The reaction of the system to such problems is variable (measuring value setting, holding or searching) and must be take into consideration by evaluation of the signal.

Triangulation sensors (Fig. 8.44) likewise project a light point onto the surface of the measured object. This light point is observed from a defined angle. By changing the distance between the sensor and measuring object, the reflected point wanders across a CCD row. In this way, the change of the distance is collected directly. In addition there are some sensors project one or many laser lines onto the inspected surface. These lines can then be evaluated in terms of the contour of the measuring object by means of a CCD matrix.

The chosen example sensor has an average working distance of 105 mm, a measuring range of ±25 mm, a projected laser spot diameter of 0.1 mm, and a triangulation angle of 18°. With these parameters, these sensors can be applied, for example, to:

- Size or form inspection
- The collection of runout and position deviation
- The collection of thickness
- The collection of deformations
- Completeness or integrity control

As Fig. 8.45 shows, single or combined sensors are necessary for these applications. The measuring signal collects the surface of the measuring object in the range of the entire measuring spot diameter. So a low-pass filter processes and determines the mean distance in this

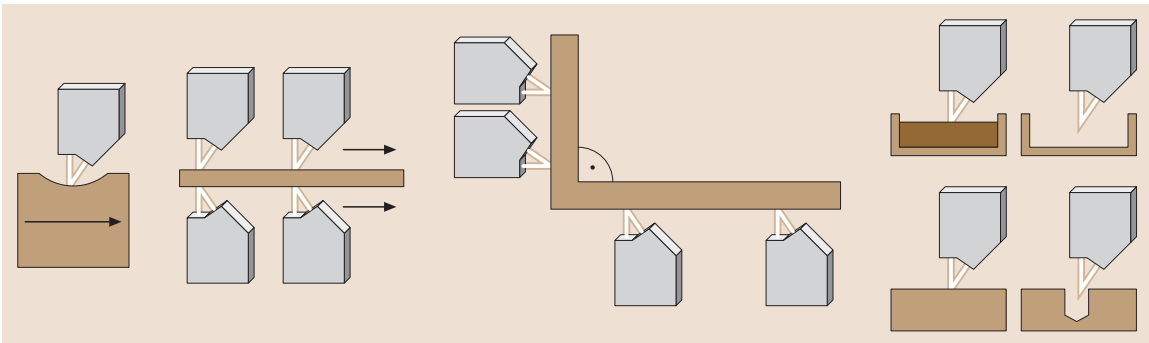

Fig. 8.45 Examples of applications using triangulation sensors

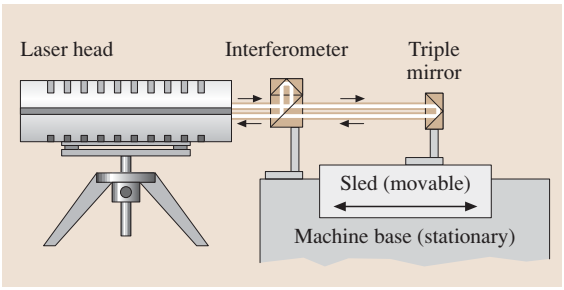

Fig. 8.46 Interferometer for the determination of position

area. The plane in which the beam is sent and reflected is arranged parallel to the surface structure to guarantee a reflection.

In laser interferometers, the laser beam is separated into two beams (reference and measuring beam) by means of a semireflecting mirror. While the reference beam always follows the same path inside the interferometer, the measuring beam is reflected off a triple mirror on the object to be measured, as shown in Fig. 8.46. When the two beams come together, interference occurs (Fig. 8.47). When the peaks of the waves meet (phase shift 0°), the light is amplified. When the peak of one wave meets the valley of the other (phase shift 180°), the waves cancel. The distance between the interferometer and the tripel mirror changes when the sled moves. The phase between the reference and measuring beam shifts. This resulting change in the interference is interpreted as the measuring value.

This type of measuring system is used for applications with large lengths (10–20 m) and with a high resolution (5 nm). It only collects, in each case, the changes from an initial state. A disadvantage is that the optical components must be mounted on the object that is to be measured and that the frequency of the light, and therefore the measuring result, is strongly influenced by environmental conditions such as air temperature, humidity, and pressure. Corrections can be made by collecting these environmental conditions and carrying out a subsequent adjustment of the data, or more specifically, through the application of a refractometer (an instrument in which the effects of the environmental

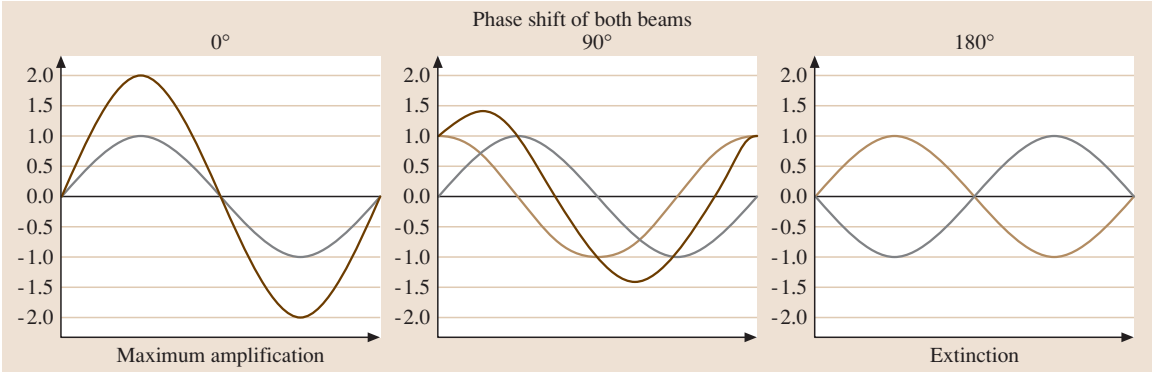

Fig. 8.47 Phase shift and interference

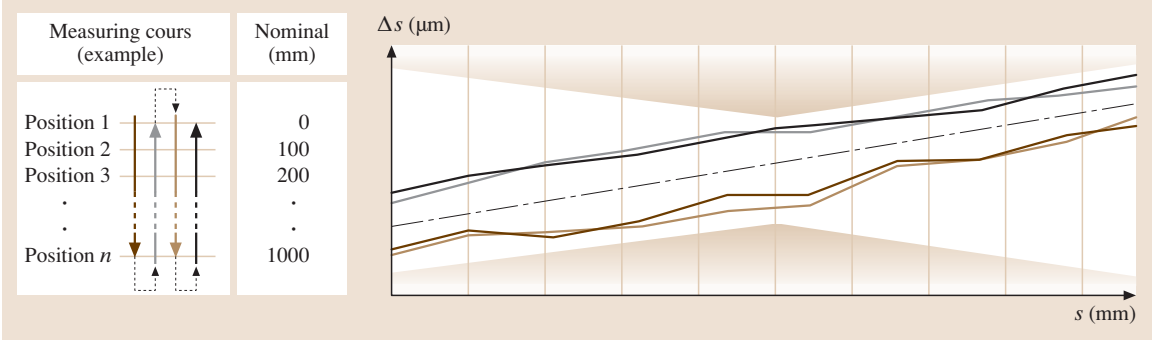

Fig. 8.48 Position deviation, measuring course and results

conditions can be directly compared with the light properties in a vacuum).

Figure 8.46 shows an example combination that determines the position of a machine component in respect to another, or rather to a chosen fixed point. This set-up is used as an independent measuring system (for example, with coordinate measuring machines) but also as a measuring system for the collection of position deviations. Figure 8.48 shows the procedure for the collection of position deviations of a tooling machine. While the machine, controlled by its measuring system, follows the defined positions labeled 1 to n, the position deviations are determined by means of a laser interferometer. The measuring course, which is step-by-step executed over the entire range of to be measured positions, is completed multiply in both directions (increasing and decreasing values). The deviances collected in this way are shown on the right-hand side of Fig. 8.48. From the depicted course of measuring values, a linear trend and span superimposed with random sections can be read. The limits, shown in the diagram, depict usual tolerance ranges for tooling machine position deviations. The systematic parts are compensated for, when necessary, through mechanical aligning of machine components, or afterwards by means of a correction table or correction function.

Similar arrangements allow the collection of tilt and rotation angles as well as the determination of straightness deviations. When the measuring value transmission frequency can be chosen to be sufficiently large, a dynamic series (for example the reaching of a desired position) can be collected with the layout shown.

8.3 Measuring Uncertainty and Traceability

The result of measuring is the measurement value. This measurement includes the true value and also systematic and random deviations of the measurement. It is possible to estimate the expected value of the measurement by calculating the arithmetic mean of several independent measurements. The more single values that are processed, the more the random parts of the measuring deviation are reduced. The systematic part of the measuring deviation can be determined by measuring an object with a known value. Such objects, measurement standards, are measuring blocks for lengths. Angles can be represented with angle gauges, precision polygons, or with sine bars used in conjunction with measuring

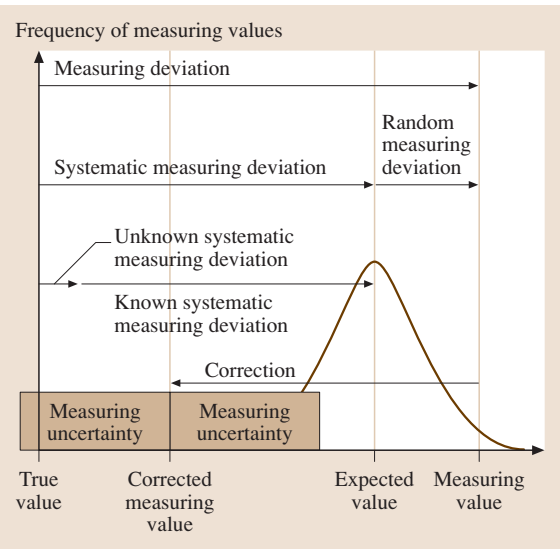

Fig. 8.49 Summary of measuring values

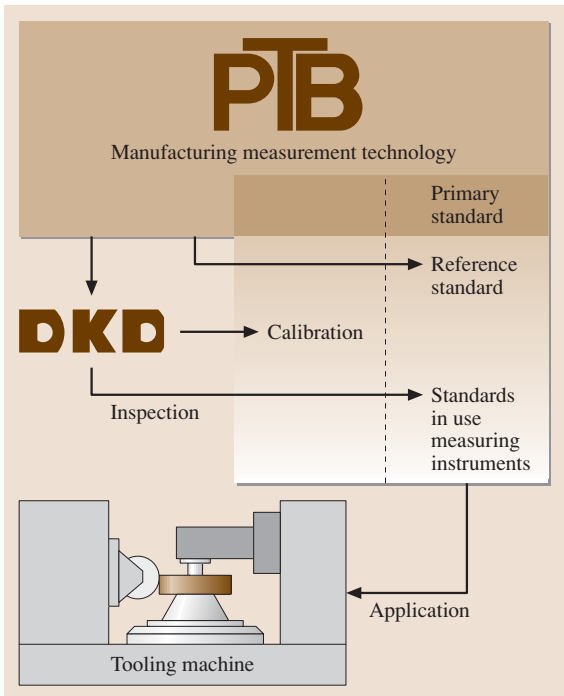

Fig. 8.50 Traceability

blocks. The known value of the measurement standard (whose small deviation from the true value is negligible for the purpose of comparing), is called the correct value. The systematic measurement deviations can be calculated from the difference between the measured value of the measurement standard and its correct value. Afterwards one can correct all measuring values by use of the known systematic deviation. The non-measurable or not measured (for instance too expensive) elements of the systematic measuring deviation are combined with random measuring deviations to constitute the measuring uncertainty. So, the measuring uncertainty is a parameter obtained from the measurement. It describes the region around the corrected measuring value where the true value must be found. The complete result of measuring is given as the corrected measuring value plus/minus the measuring uncertainty.

In order to guarantee the correctness of measuring results, measuring devices must be affiliated to the national standard of the respective measurement. In Germany for instance, this is the National Physical Technical Institute (PTB), located in Braunschweig, which are responsible for the representation and propagation of physical units. Through the PTB, calibrating laboratories are accredited, so that their measuring devices and measuring standards coincide with the national standards (the units), according to the defined and accepted techniques. These are the laboratories of the German Calibration Service (DKD).

All in-company measuring devices, or rather standards, should consistently be traceable back to the national standard of the PTB. In order to verify this, the instruments are calibrated by a DKD laboratory or the PTB themselves. *Calibration* is defined as the inspection of measuring devices and measurement standards with reference to the accepted national standard. The successful calibration is generally documented through a protocol, the calibration certificate. On the calibration certificate, all of the calibration results, the reference standards, and additional measuring equipment (used during the calibration), the environmental conditions, and the calculated measuring uncertainty are documented.

One should use certified instruments, standards, and methods in order to achieve cost-effective, in-company control of inspection instruments. Otherwise, a traceability certificate is not possible.

The setting-up and balancing of a measuring instrument, by which known systematic deviations of the measuring result are eliminated, is called *adjusting*.

8.4 Inspection Planning

Inspection planning means the planning of quality inspection in the entire production process, from the arrival of raw products until the delivery of the final product. For this, inspection tasks and procedures are specified with inspection feature, inspection location (close to production, measuring room), frequency of inspection, point of time within the production process, inspection methods, inspection equipment, and operators. One should consider both technical and economic aspects. The inspection planner must consider knowledge of the function and application of the piece or the components, safety hazards, the production process, technical documentation (drawings, standards, stipulations), and the inspection equipment. It should be consistently checked that the data is complete, current, and inspected (approved by the operating department).

For the choice of inspection procedures, a systematic search in the drawing(s) ordered by

- The type of parameter (measure, form and position tolerance, surface tolerance, etc.)
- The drawing view
- Grid squares (for example, upper left starting clockwise)

in the work plan according to maintenance sequences, in the documentation, delivery instructions, and contractual arrangements, is essential. The definition of the inspection frequency (number of samples, size of sample) occurs on the basis of mathematical statistical facts. The time point in the production process allows company organizational and economical considerations. The late recognition of inadmissible errors can bring about several disadvantages.

The definition of inspection methods and inspection equipment are related and thus should each be chosen with the other in mind. The choice of measuring device begins with consideration of the required information content of the measuring result. In this way the aim of the inspection (evaluation of workpiece or process, manufacturing control) and the impact of the measuring instrument itself can be taken into

account. Geometrical limitations, such as the accessibility of the piece, the geometry of the probing element, the range of measurement (direct measuring, difference measuring) of the instrument, and especially for soft materials, the measuring force, are previously decided. Finalized statements for the usability of a measuring instrument can be made after inspection of the scale division value and the measuring uncertainty. The measuring uncertainty must adhere to the ratio to the inspected tolerance by the relation $\frac{u}{T} = 0.1$ to 0.2. Alternatively, it is possible to obtain measuring capability coefficients and check the adherence of these characteristics to previously defined limits. Supplemental criteria are, for example, the surfaces available for the measurement, and transfer for processing, protocol and archiving.

The required measuring time (capability of the measurement to be automated) in conjunction with the number of pieces to be tested is the essential criteria for the cost effectiveness of the application of a measuring device. Included in the inspection costs are also the equipment costs, equipment observation, calibration, and personnel costs (work time, education).

To guarantee the comparability of the measuring result and low uncertainty of the acquired characteristics the following conditions should be taken into account when specifying measurement methods:

- Explicit guidelines for the measuring procedure including, the required parameters for an appropriate measurement. Specification of the reference basis for the measuring procedure, to the accuracy of the applied measuring instruments and measurement standards, gripping elements employed, and additional measuring equipment.
- Details of the measuring strategy, for example, the definition of the measurement location on the piece, or the number and arrangement of single measurements as a basis for a good average value.
- Details of the measuring value collection method for selective inspection and of the further steps of measured value processing, or guidelines for the application of analyzing software (for example, the selection of a compensating method).
- Legal warranty of adequate qualification of the personnel who conduct the measurement.

The result of inspection planning is the inspection plan.

9. Engineering Design

Alois Breiing, Frank Engelmann, Timothy Gutowski

The development and design of engineering systems following a methodical approach based on information from the literature [9.1–6] is a useful procedure. The guidelines for design methodology have also been applied to interdisciplinary development projects of this type, using aids such as requirements lists, the functional structure, and morphological boxes, to name just a few. During the design phase of the product development process it is important to comply with the basic design rules: *simple*, *clear*, and *safe* [9.3]. Several examples that clearly show the realization of these three criteria are included in this chapter.

9.1 Design Theory

9.1.1 Product Planning Phase

It is possible to structure technical products in individual life stages. These are often the basis for work done by the product manufacturer, but also by the product user. Examples include schedules for the development of a product or maintenance plans.

Figure 9.1 shows essential product life stages of a product in the sequence of production and the application. For examining the structures further, it is possible to subdivide the individual product life phases into steps. In practice, this provides the engineer with a tool, which allows him to categorize his activities accurately.

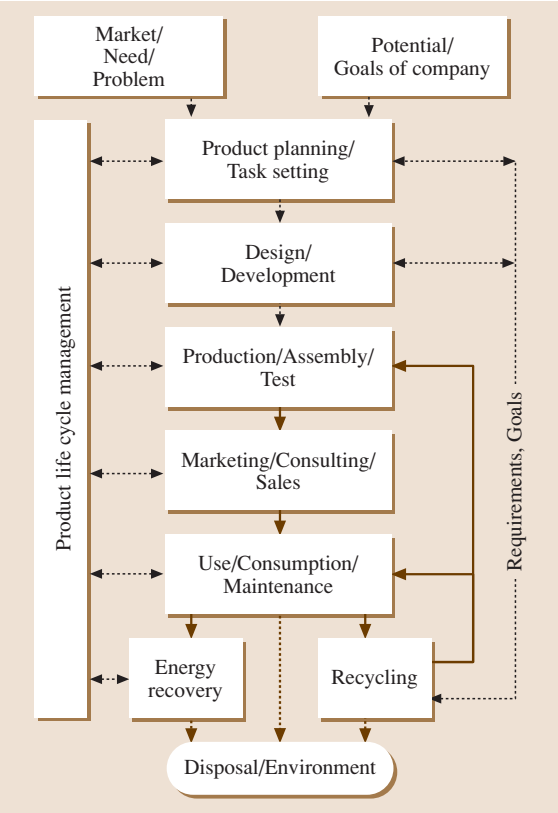

Fig. 9.1 Life cycle of a product (after [9.3])

Product Life Stages and Technical Life Cycle

The life cycle of technical products is closely linked with the general *material cycle* (Fig. 9.1). The cycle starts with an idea for a product, arising from a market or customer need. This is concretised the first phase of product life: product planning. The result is the setting of a task which provides the basis for the second phase of product life: Development and construction. At this stage, the implementation of the idea and/or task-setting into a viable product takes place in individual steps. The life cycle then continues onwards with the manufacturing process with the manufacturing of the parts, assembly and quality testing. The process ends with the product manufacturer when the product is passed on to the distribution department.

This product life phase is the interface to the application of the product, something which can be described as the product's usage or consumption. Intermediate maintenance steps can serve to extend the useful life. Product recycling follows the primary use of the product, something which can lead to a further use for the same invention or changed product functions (reuse/further use) or to secondary usage with the same or changed characteristics to the secondary materials (recycling or further utilization). Non-recyclable components will then end up in a landfill site or burnt to produce thermal energy.

Except for recycling or landfill, the life cycle applies both to the physical products of machinery, equipment and devices as well as to software products. It is usual for companies to use such structuring techniques for product tracking.

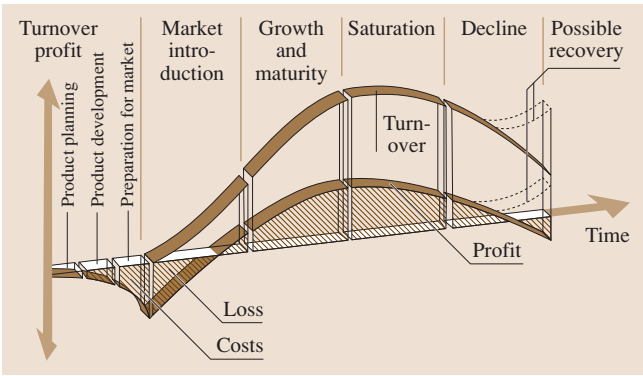

Fig. 9.2 Life cycle of a product (after [9.3])

Economic Life Cycle

The life cycle of a product can not only be seen in terms of the succession of product life stages on top of each other and/or concrete steps of manufacture and application, but also in terms of economic data, related to the respective stage of the product life. Figure 9.2 shows the relation of the product phases to turnover, profit and loss. It can be seen that before turnover starts the respective company has to make investments as implementation costs. The amount that this investment costs is heavily dependent on the product. They must first recover their investment until they break even. Only then can they gradually realize their ultimate goal to make profits.

This profit zone is characterized by a phase of growth and a phase of saturation in the market before decline sets in through a reduction in turnover and profit. A revival in sales and profits, for example, through special sales and promotional activities, is usually only for a short period, so it is more promising to achieve rising life curves of new products in a timely way through the development of new products than to offset declining life curves of old products.

Product Planning

Importance. The first two phases of product life, product planning and product development, are among the most important tasks in industry. The continuous generation of marketable products is the foundation for the economic success of the company. Because of the inevitable downturn phases for existing products or product groups (Sect. 9.1.1), the systematic planning of new products must take place, something which can also be seen as an innovative product policy [9.4]. Strategies for product planning should not be a barrier for creative companies and their engineers. Rather, these should have a supporting effect as methodological aids.

Fundamentals. The bases for the planning of products are the relationships in the market, relationships within the environment of the company and within the company itself. These can be defined as external and internal influences on a company, particularly towards its product planning.

External influences come:

- From the world economy (e.g. exchange rates)
- From the domestic economy (e.g. inflation rate, labour market situation)
- From legislative and administrative acts (e.g. environmental protection)
- From the buying market (e.g. suppliers' market and commodity market)
- From research (e.g. government-funded research priorities)
- From technology (e.g. developments in microelectronics or laser technology) as well as
- From the market

As such, the conditions of the market are crucial. A distinction can be made between a buyer's market and a seller's market. In the former, the supply is the larger than the demand and in the second the demand is larger. In a seller's market, production is the bottleneck however on the other hand, in a buyer's market, products must be designed and developed, which have to be successful in competition with the products of other providers.

Further criteria for the identification of markets are:

- Economic areas: domestic market, export markets
- New factors for the company: current market, new market
- Market position: market share, strategic free reign of the company, the technical value of its products

Internal factors come:

- From the organization of the company (e.g. product oriented vertical or task oriented horizontal organization)
- From the staff (e.g. availability of qualified development and manufacturing staff)
- From financial strength (e.g. investment opportunities)
- From the size of the company (e.g. in terms of turnover which can be sustained)
- From the production fleet (e.g. with regard to certain manufacturing technologies)
- From the product programme (e.g. with regard to components which can be adopted and predevelopments)
- From expertise (e.g. development, marketing and production experience) as well as
- From the management (e.g. as project management)

The influences listed are also described as potential of the company.

Product Development

General Approach. The second phase of product life is development and construction. This is also often referred to as product development. To further structure this phase of product life, it is usual to break stages down into individual steps. This procedural approach in handling constructive tasks is based on general solution methods and/or working method approaches as well as the general relationships in building technical products. It is not a rigidly prescribed approach, but instead, it is an essential tool for the engineer in product development. The individual working steps are the basis for other activities, e.g. the preparation of schedules or the planning of product development costs. They also help the engineer in finding where he is in the development process. A possible structure can be seen in Fig. 9.3.

Despite the variety of product developments, it is possible to work out a sector-independent flowchart, the work steps of which have to be modified to the special conditions in stetting the tasks. The approach begins with clarifying and specifying the task, something which is especially important for new design tasks. The basis for this is the stetting of tasks with individual needs which are developed from product planning tasks. From the wealth of specified requirements, the designer engineer must identify the essential problems to be solved and formulate these in the language of his field of design. The result is a requirements list, which is also known as a specification sheet. It is the

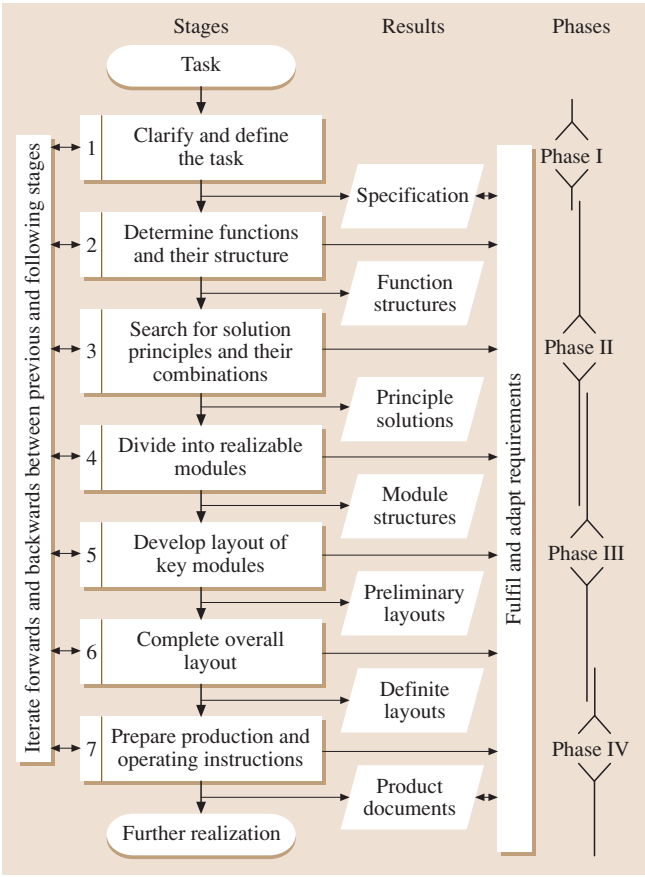

Fig. 9.3 General approach to design (after [9.3])

not only the technical but also, the legal basis for all other activities.

In the next work step, the *solution-neutral* definition of the task takes place, i. e. adopting the assumption that solutions are not prefixed. This has been proven in the form of functions, whose links lead to functional structures.

As a result of this work step, such functional structures already demonstrate an abstract form of a solution concept and as such, must be subsequently implemented gradually (Sect. 9.1.2).

The search then follows for solution principles for the key subfunctions. For mechanical products, these are based on physical effects and their fundamental realization with the help of geometric and material characteristics (Sect. 9.1.2).

The individual solution principles are represented with the help of a *morphological box*. At the same time, for each key subfunction, a maximum of three to four solution principles should be worked out. With the help of the morphological box (Fig. 9.18), the linking of individual solution principles leads to an effective structure. Even here, it is not usual to work out more than three effective structures. The effective structures which are generated in this way (or principle solutions) are compared with each other through appropriate evaluation mechanisms are (Sect. 9.1.3). Thus, it is possible, as a result of this work, to give a green light to a principle solution (also known as a concept) for further treatment. In further treatment, the principle solution is divided into realistic modules which lead to a structure and allows functional design or design priorities to take shape before the labour-intensive concretisation stage. Furthermore, it is necessary to consider the possibility of realizing a structure for further work steps which is production-like, easy to assemble, easy to maintain and recycle and/or, which is *building block-like*. The result is the modular structure.

The designing of relevant structural modules takes place in the next work step, e.g. in mechanical systems, the assemblies, components and the necessary connections are specified. Essentially, this work step includes to the following activities: Procedural calculations, stress and deformation analyses, arrangement and design considerations, as well as manufacturing and assembly examinations. As a rule, these procedures do not yet serve production-related and material engineering-related detail specifications, but first of all, the specification of key characteristics of the design structure in order to be able to optimise these according to technical and economic considerations. The results are draft concepts.

The next work step includes the design of other, usually dependent functional elements, i. e. micro-designing all sub-assemblies and components, and their combination in the overall design. For this a variety of calculation and selection methods, material catalogues, machine parts, norm parts and purchased parts are used as well as costing procedures for finding out costs. The result is the overall design.

The last work step serves to prepare tasks related to execution and usage, i. e. the development of full diagrammatic documents, including parts lists for manufacturing and assembly as well as the development of operating manuals and maintenance specifications. The result is the complete product documentation.

In practice, several work steps in the development and construction phases are often combined, e.g. for organizational or work related reasons. Thus, in me-

chanical engineering, the first three sections are seen as a *concept* phase, the next three sections as a *draft stage* and the final section is seen as a *preparation* phase.

Product Specification. The general approach has to be modified in task setting and/or for products, in which *several specialist units* are involved.

The goal is to carry out the corresponding technical tasks largely independently, but in a coordinated way. Such relationships apply, for example, to products in the biomedical field, where the medicine, biology, mechanical engineering, electrical engineering and computer science are all involved. Furthermore, precision engineering can be added to this list. Here, the design of the mechanical component, the development of the electrical and electronic circuits and control parts and the development of the necessary software take place largely independent of the different specialists.

Whilst the preparation of the requirement specifications and the functional structure takes place advantageously for the overall product, the other working steps are split into the parallel development paths, naturally in close coordination with the various specialist areas. For this, it is helpful after major concretisation jumps (e.g. to set the modular structure and after presenting the individual working drafts) to summarily document the results of the work (system structure, system draft) in order to detect missing coordination and to obtain an overall homogeneous product. Product documentation takes place for the overall product. While in the case of *new developments*, all work sections have to be followed through, steps 2 and 3 are often dispensed with in *further developments* (Fig. 9.3). The same applies in *adaptation constructions* (where steps 4 and 5 are dispensed with).

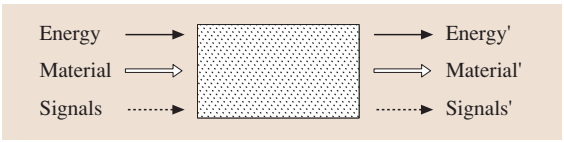

Fig. 9.5 The conversion of energy, material and signals. Solution not yet known; task or function described on the basis of inputs and outputs (after [9.3])

In many cases, it has proved advantageous, to supervise and/or reconstruct development steps again in order to make a comparison with the current state of knowledge. The development represented takes places for *products made individually*, usually only once. In the case of unsatisfactory work results, individual work sections are performed again. For *mass production* products, such as motor vehicles or household appliances, direct realization in the end product would be associated with high economic risk. According to Fig. 9.4, it is usual for such products to undergo the development and manufacturing cycle several times in order to identify vulnerable areas in the production process, initially in functional and laboratory samples and where necessary, in additional prototypes and/or pilot runs in the intermediate trial and testing phases. These are then optimized in a re-design and manufacturing process.

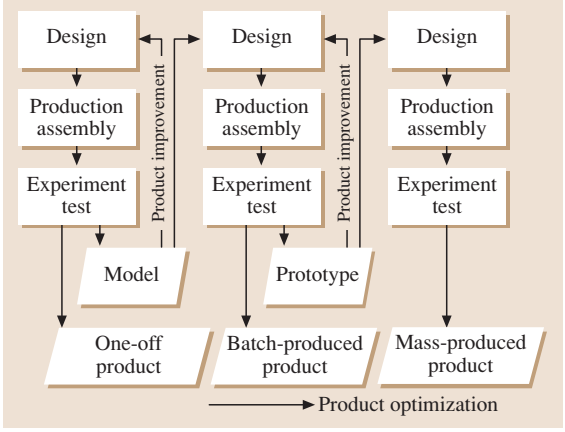

Fig. 9.4 Stepwise development of a mass-produced product (after [9.3])

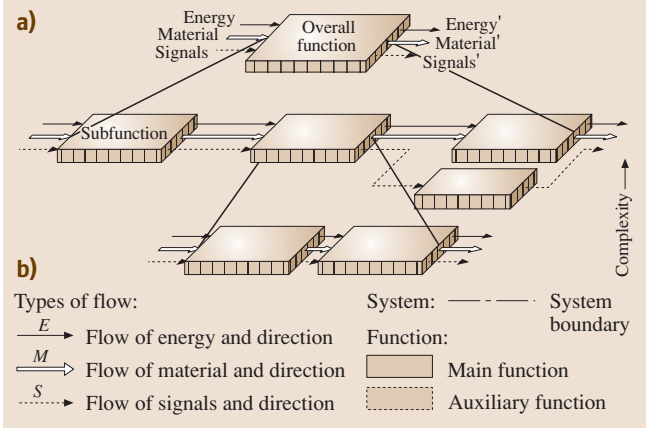

Fig. 9.6a,b Establishing a function structure by breaking down an overall function **(a)** into subfunctions **(b)** (after [9.3])

9.1.2 The Development of Technical Products

The construction of technical products is characterised by several general relationships, which also determine the different levels of specific product development.

Function Relationships

The term function, describes the general relationship between the input and output of a system with the goal of fulfilling a task (Fig. 9.7).

In the case of technical products or systems, the input and output variables are *energy variables*, *material variables* and/or *signal variables*. As a signal is the physical realization information transmission, *information* is often also selected an as input and output variable for the signal.

The target function, or target functions are an abstract, solution neutral and clear form of task setting. They result in the development of new products from requirement schedules.

Corresponding to Fig. 9.6 a difference is made between:

- The overall function for describing an overall task of a product and/or system which is to be solved.
- Subfunctions which come about by subdividing an overall function with the goal of making tasks easier to solve. At the same time, the most practical degree of subdivision is dependent on the degree to which the task setting is new, the complexity of the product to be developed as well as knowledge about solutions for fulfilling the functions.

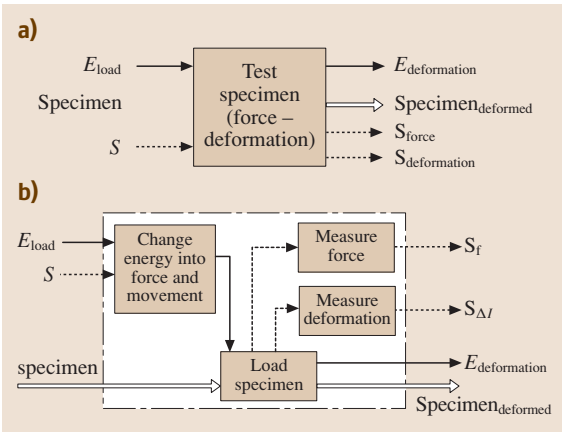

Fig. 9.7a,b Overall function (a) and subfunctions (main functions) (b) of a tensile testing machine (after [9.3])

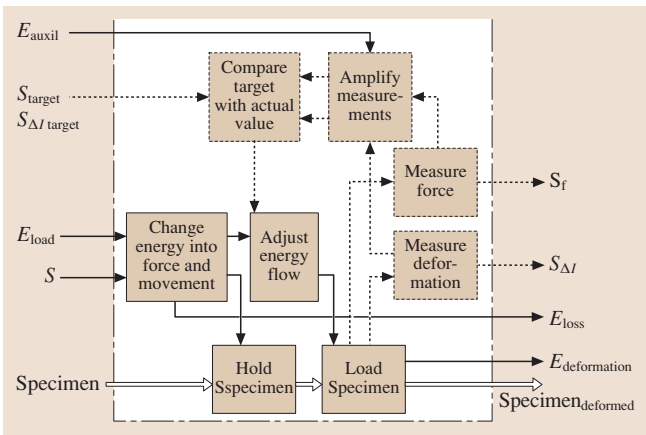

Fig. 9.8 Completed function structure for the overall function set out in Fig. 9.7 (after [9.3])

Subfunctions are linked to a *function structure*, wherein the linkages are determined by logical and/or physical compatibilities.

As an example, Figs. 9.7 and 9.8 show the function structure of a testing machine [9.3]. The overall function to be realized (overall task) is to define the stress applied to a test specimen and to measure deformity. The transfer from a function's/function structure's input to output and/or the processing of energy, material and signal variables is portrayed as energy volume, material volume, signal flow or volume. The various flows or volumes typically occur simultaneously, wherein one or several flows or volumes dominate, i. e. can determine the product. The latter are termed *main flows* or *main volumes*. They immediately serve to fulfil the function of a product. As such, we can imagine a conveyor system through which material volume as seen as the product-determining main volume, while energy volume is the driving function and the signal volume realises the control functions.

Such volumes and/or flows accompanying the main volume serve are supportive and are only indirectly related to the functional performance of the product, because they are not directly derived from the nominal functions (main functions) in the task setting. The bases for the accompanying flows are always the generated solutions for the main functions. Accordingly, they are also referred to as *tributaries* and the participating subfunctions as a *side functions*. In the function structure illustrated in Fig. 9.7, all of the listed subfunctions which result from the overall function (overall task) are main features. The subfunctions which result from the

measurement principles as necessary (*amplify measurements* and *compare target with actual value*) are, on the other hand, side functions, Fig. 9.8.

In summary there is no material or signal flow without an accompanying flow of energy, even if the energy required is very small and can easily be provided. Signal volume without accompanying material volume, e.g. in measuring devices, is however possible. Even energy volume e.g. for the production of electrical energy, is connected to material volume, wherein for controlling, the accompanying signal flow is a major tributary.

Specific Functions.

Logical Function. Bivalent or *binary* role variables often play a role when designing and describing technical systems: Conditions (fulfilled – not fulfilled), statements (true – false) and switch positions (on – off). The design of systems to realize the required dependencies between binary variables is known as logical design. It uses mathematical statement logic in the form of boolean algebra with the fundamental linkages AND and OR, and negation [9.3].

Using Boolean combination elements, complex circuits can be build which for example, increase the safety of control and reporting systems.

As an example, Fig. 9.9 shows the monitoring of a oil supply system for bearings in which respectively the nominal and actual values, the pressure monitor and the flow monitor are linked by an AND function, while the output signals of the pressure and flow monitors are connected to each other by an OR function. All bearings are linked in turn by AND links, i. e., all bearings must at least have effective oil monitoring for the machine to be ready.

Generally Valid Functions. These are increasingly recurrent functions in technical products, which can serve as sort keys for solution catalogues, as a basis for functional structural variations and as an abstraction aid in the analysis of existing products according to their functional relationships.

In Fig. 9.10, five such functions are brought together, which with the help of a cluster variation, have been derived from the input and output of a function in terms of type, variable, number, place and time. For other suggestions concerning general functions [9.3]. In this context it must be noted that such an approach and task structure is very abstract. For this reason, they are usually only used for new construction designs.

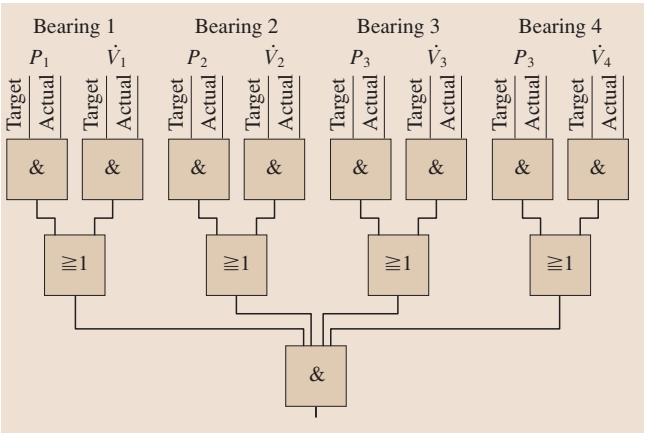

Fig. 9.9 Logical functions for monitoring a bearing lubrication system. A positive signal for every bearing (oil present) permits operation. Monitor pressure p; monitor oil flow (after [9.3])

Cause-Effect Relationships

The subfunctions and the functional structure of a technical functional relationship must be fulfilled by a cause-effect relationship. Accordingly, this arises from *active principles* for fulfilling the subfunctions and from an *active structure* for fulfilling the function structure. The *active structure* then, results from a linkage of several *active principles*. An *active principle* is determined by a physical, chemical or biological effect, by a combination of several effects as well as through their principal realisation using geometric and mater-

Characteristic Input (I) / Output (O)	Generally valid functions	Symbols	Explanations
Type	Change		Type and outward form of I and O differ
Magnitude	Vary		I < O I > O
Number	Connect		Number of I < O Number of I > O
Place	Channel		Place of I ≠ O Place of I = O
Time	Store		Time of I ≠ O

Fig. 9.10 Generally valid functions derived from the characteristics type, magnitude, number, place and time for the conversion of energy, materials and signals (after [9.3])

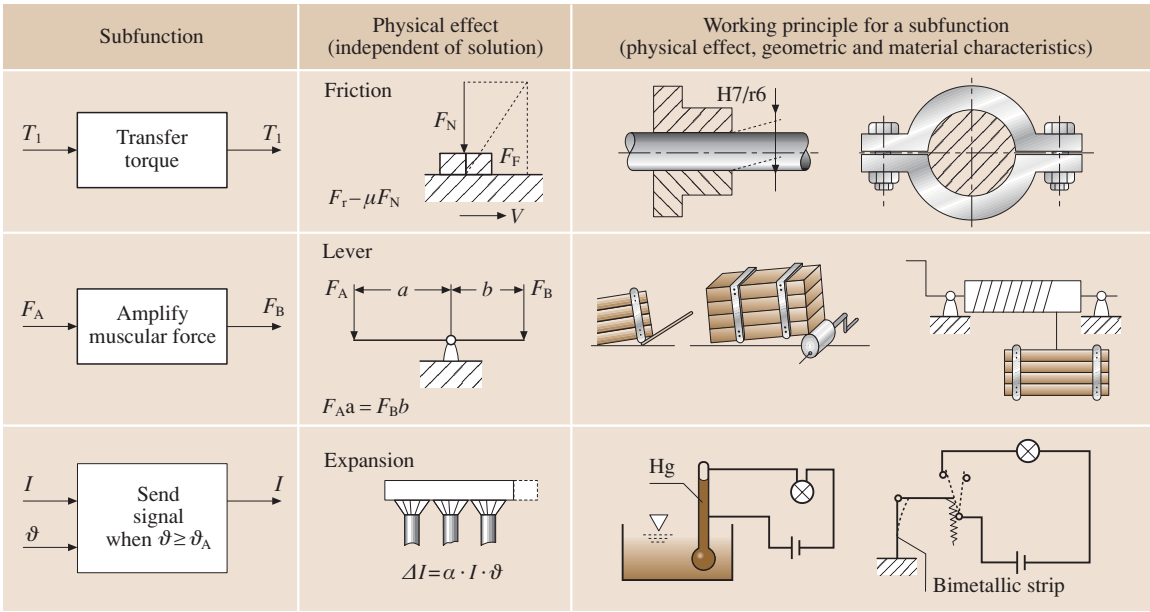

Fig. 9.11 Fulfilling subfunctions by working principles built up from physical effects and geometric and material characteristics (after [9.3])

ial characteristics (active structural characteristics). In engineering, it is usually physical effects which predominate. Examples can be seen in Fig. 9.11.

Physical, Chemical and Biological Effects. In the case of material products produced by system, machinery, equipment and manufacturing, the foundation for the solution is formed from effects, especially from physics but also from chemistry and/or biology. Effects are described by laws, which assign each of the variables involved, even quantitatively. For example, in the clutch in Fig. 9.12 the subfunction *change switching force* F_S *into normal force* F_N is realised by the physical leverage effect and the *generate tangential force* F_U is realised by the friction effect. *Rodenacker* [9.5], *Koller* [9.6] and *Roth* [9.2] in particular have all described physical effects on structures. The fulfilment of a subfunction can often only be generated by linking multiple effects which are established e.g. in the impact of a bimetal, from the effect of thermal expansion and that of Hooke's law (stress–strain relationship). The screw connection can be cited as another example. Apart from Hooke's law, here the linkage takes place between the friction effect, the wedge effect and the leverage effect.

In general, a subfunction can be fulfilled by various effects, such as the hydraulic/pneumatic effect listed in Fig. 9.12 or *force change function* which arises through the leverage effect, the wedge effect and the electromagnetic effect. From this, various solutions arise in setting tasks and with it different products with different characteristics.

Geometric and Material Characteristics. The place at which an effect or a combination of effects become(s) effective (active) is known as the *effective location*. Here, the fulfilment of the function is forced by applying the respective effect through *effective geometry*, i. e. the arrangement of effective surfaces or active areas and by selecting working motions (in the case of moving systems). With the *effective geometry*, the effective material properties already need to have been established in order for the effective relationship to be identified. Only the combination of effects and geometric/material characteristics (effective geometry, working motion and material) form the solution principle. This relationship is referred to as the active principle. The combination of several active principles leads to an (effective structure) solution (also known as the solution principle). In Fig. 9.12, the participating effective surfaces are in the form of clutch discs (friction discs) for example, and the rotational working motion of the lever to produce contact pressure can also be seen. Here, examples can be seen for the various effective surfaces, e.g. a friction clutch [9.7].

Structural Relationships

The design-related concretisation of the effective relationship leads to the *structure*. This materialises an effective structure through individual components, units and connections (Fig. 9.12) which are especially defined according to the needs of design, manufacturing, assembly and transportation with the help of scientific principles from the laws of material strengths, materials engineering, thermodynamics, fluid mechanics and manufacturing among other things. Good machine elements are also important fundamentals [9.8].

System Relationships

Technical products are components of superior systems which can be formed by persons, other technical systems and the surroundings (Fig. 9.12). At the same time, a *system* is determined by system elements and subsystems which are bordered by a system boundary. These are linked to each other and to the surroundings by energy, material and/or signal variables. A system and/or product is initially characterized by its own *system structure*. Figure 9.13 shows such a system structure for the gear out from Fig. 9.12 in combination with an elastic coupling (rotationally elastic). In a higher order system, this forms the purposeful effect (target function). Added to this are disturbing (effects) from the surroundings, side effects on the outside world and within the system as well as the effects of man and retroactive effects on human beings (Fig. 9.14). All effects must be viewed in relation to one another (system context, Fig. 9.12).

General Objectives of Technical Products

Objectives and restrictions for technical products are first received as requirements, requests and conditions in the requirement list (tasks setting) as a basis part of specific product development. However, beyond this, general objectives can be mentioned which although having a different weighting in a particular instance, have general validity. Such goals serve as a guideline for setting up requirement lists, and for the choice of solutions in the various concretisation stages of the construction process.

Table 9.1 contains a list of such general objectives for tangible products, oriented on the life stages of a product (Fig. 9.1).

Applications

The general relationships which determine the construction of technical products are important bases for several applications.

Inter-relation-ships	Elements	Structures	Examples
Functional inter-relation-ship	Functions	Functions structure	Working inter-relation-ship	Physical effects and geometric and material characteristics → Working principles	Working structure	Constructional inter-relation-ship	Components Joints Assemblies	Construction structure	System inter-relation-ship	Artefacts Human beings Environment	System structure	
Fig. 9.12 Interrelationships in technical systems (after [9.3])

In product development, they enable a gradual approach, in which at first, principle solutions are sought for the required set of functions. These solutions are then concretised in design and material specifications. At each practical level, a variety of solutions can be set up as the basis for solution optimization through the different characteristics/solution characteristics of the respective relationship.

Another important area of application is the analysis of existing technical products with the aim of making an improvement, further development or adaptation to

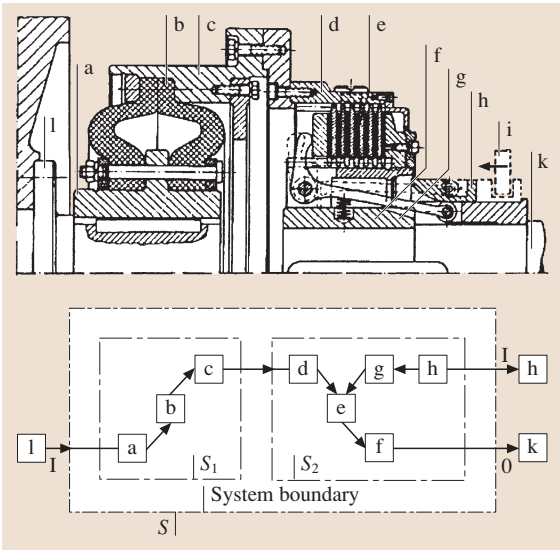

Fig. 9.13 System *coupling*: a–h system elements; i–l connecting elements, S overall system; S_1 subsystem *flexible coupling*; S_2 subsystem *clutch*; I inputs; O outputs (after [9.3])

specific conditions [9.9]. For such system analyses, procedural steps and characteristics are necessary which can be derived the general relationships. An important example which can be cited is value analysis which attempts to minimize to the functional cost of technical products [9.10]. Distinctive product features, also called *component parameters* [9.11, 12], are responsible for regulating construction catalogues and databases as well as providing useful assistance when looking

for stored solutions and data from similar information storage media [9.13]. General relationships and general objectives have also been relied upon in the derivation of *component parameters* [9.14].

9.1.3 Construction Methods

General Solution Methods

Regardless of the specific degree of concretisation in the course of searching for a solution, several general methods are introduced which can also be seen as a working methodology [9.15–17]. The requirements for a methodical approach are:

- Definition of goals
- Identification of conditions
- Resolution of prejudices
- Search for variations
- Passing of judgements and
- Decisions.

General Solution Process. The solving of tasks consists of an analysis and a subsequent synthesis. This takes place in alternating work and decision steps. At the same time, it is usual that an advance is made from quantitative to qualitative steps or from abstract to concrete steps. The breakdown into work and decision steps ensures that the necessary uniformity of objectives, planning, implementation and control is maintained.

With reference to [9.18, 19], Fig. 9.15 shows a basic pattern of a general solution process. Each task setting initially effects a confrontation with an *unknown* which by gaining additional information, can be more or less resolved. A subsequent definition of the key problems to be solved specifies the task setting without predetermining solutions, thus leaving possible solu-

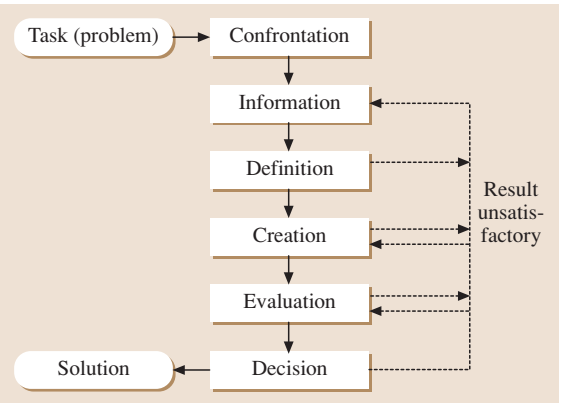

Fig. 9.15 General problem solving process (after [9.3])

tions open. The subsequent creative phase involves the actual finding of solutions. Where there are several appropriate ways, an evaluation of these has to be made in order to be able to make a decision concerning the best solution. In the case of a work step delivering unsatisfactory results, it or several work steps must be repeated, wherein in repeating the work process, even better results can be expected through a higher level of information. Therefore, this iterative process can be interpreted as a learning process.

Systematic Approach. As an inter-disciplinary science, system technology has developed methods for analysis, planning, selection and the optimum design of complex systems [9.20]. Based on system definition, a process model is introduced which is used for the different life stages of a system (Fig. 9.1). It can be seen in Fig. 9.16 that the work steps are practically identical with those in Fig. 9.15 and that the time continuum in a system runs from the abstract to the concrete.

Problem and System Structure. New and complex tasks are usually easier to solve if the overall problem to be solved is initially divided up into subproblems and individual problems. This way, subsolutions or individual solutions can be found [9.21].

A methodological basis for this approach is the structuring of systems into subsystems and system elements for the easier identification of relationships and effects within the system and outwards, on the surroundings. The extent to which a system is broken down is determined by utilitarian considerations and depends on the extent to which the problem is new and the knowledge of the engineer/scientist.

Such structuring also encourages the adoption of known and proven subsolutions, the working out of alternative solutions, a systematization technique for using solution catalogues and databases, the identification of integrated relationships as well as the introduction of rational working divisions.

While the overall division of problems into individual problems makes solutions easier to find, the subsequent combination process, of linking the subsolutions to the overall solution creates problems concerning the compatibility of subsolutions among themselves. Combination schemes such as that described by *Zwicky* [9.22] e.g. the morphological box, (Fig. 9.17) have proved an important tool which in a two-dimensional order scheme, assigns subsolutions to the subfunctions to be fulfilled.

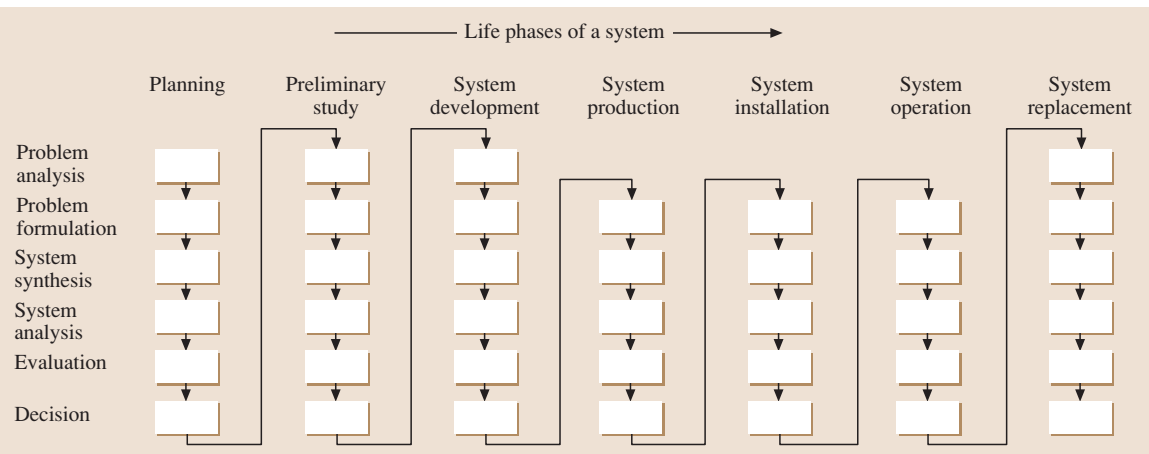

Fig. 9.16 Model of the systems approach (after [9.3])

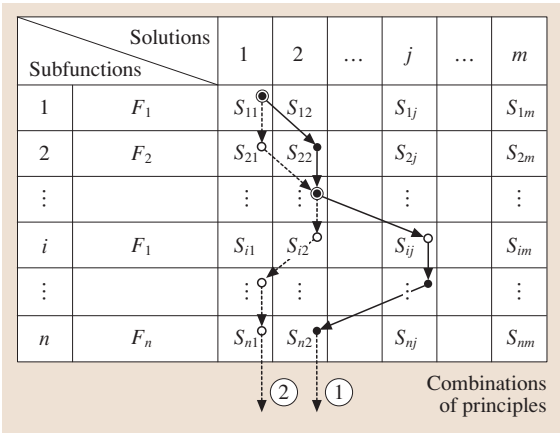

Fig. 9.17 Combining solution principles into combinations of principles: Combination 1: $S_{11} + S_{22} + \ldots S_{n2}$; Combination 2: $S_{11} + S_{21} \ldots S_{n1}$

There are also task settings for which a problem breakdown at the beginning of the solution process would not be helpful, but instead, tasks which require the initial elaboration of an integrated approach. Products for which the *industrial design* has a special significance are typical examples of this, e.g. cars or household appliances. Here, the conception of the overall appearance including ergonomic features takes a higher priority than construction details [9.23]. Industrial design and methodological problem solving are not opposites. Rather, in this case, the methodological breakdown of problems and the finding of solutions are only applied after adopting a draft for the overall appearance of the product.

General Aids. *Literature research* in books, journals, patents and company documents provide a summary of the state of the art and the competitors. They also offer the solution-searching designer new suggestions.

Through the *analysis of natural systems* (bionics, biomechanics) it is possible to identify natural forms, structures, organisms and processes and use these principles for technical solutions. For the designer, nature can provide many suggestions [9.24–27].

Through the *analysis of known technical systems*, whether those of a scientist's/designer's own company or whether those of competitors it is possible to transfer trusted solutions to new task settings and to identify fruitful further developments or alternative solutions [9.3].

Analogical considerations enable the transfer of problem to be solved or system to be identified onto an analogous system, solved problem or identified system. Ostensibly, this assists in the investigation or assessment of a system's characteristics as well as facilitates simulation or modelling [9.3].

In order to particularly identify new solution characteristics and to carry out step by step further developments, *measurements* of running systems and *model experiments* taking advantage of similar mechanics are among the main sources of information for designers. *Heuristic operations* increase creativity in the search for solutions, primarily in conventional approaches carried out by people. These operations are also known as creativity technology and are understood as tool for methodological solving and as an introduction for thinking and working in an orderly and effective form. They also repeatedly appear alongside special solution and approach methods [9.17].

Conception Methods

In conceiving working out a fundamental solution principle or a solution concept for a task setting (function) (Sect. 9.1.3), the following methods are suitable for locating principle solutions. They can be used of course, in each individual case, for more concrete design tasks.

Intuitive Methods. Intuitively stressed methods exploit group dynamic effects with which the intuition of people be stimulated through mutual association between the partners. At the same time, intuition is understood as being an imagination-stressed, barely influenceable or comprehensible action which produces ideas for solutions from the subconscious or conscious: something which can be termed *primary creativity* [9.28]. In [9.3], the following methods shall be described in detail: During the dialogue method discuss two equal partners discuss the solution to a problem, wherein as a rule, a first solution approach is assumed.

With brainstorming, a group meeting with an interdisciplinary composition takes place without aids. Ideas should be expressed without criticism and evaluation *quantity goes before quality*.

With synetics, during the group meeting, additional analogies from non-technical areas or semi-technical areas are used to generate ideas.

Method 635 is a brainwriting method in which 6 participants each express 3 problem solving ideas, in written form in 5 rounds. The proposals of the previous round are known to the participants and the level of information is constantly increased. The *gallery method* combines individual work with group work in such a way that each individually worked out proposals in the

Type of energy Working principle	Mechanical	Hydraulic	Electrical	Thermal
1	 Potential energy	 Liquid reservoir (potential energy)	Battery 	Mass 2	 Moving mass (transl.)	Flowing liquid	Capacitor (electr. field) 	Heated liquid
3	 Flywheel (rot.)			Superheated steam
4	 Wheel on inclined plane (rot. + transl. + pot.)			
5	Metal spring 	Other springs (compression of fluid + gas) 		
6		 Hydraulic reservoir a. Blader b. Piston c. Membrane (pressure energy)		

Fig. 9.18 Different working principles that satisfy the *store energy* function obtained by varying the type of energy (after [9.3])

form of group sketches are hung up in a kind of gallery. Through the discussion of these suggestions with appropriate connotations, other solutions or improvements are hit upon which in turn are worked out by the group members individually. Evaluation and selection again takes place in a group meeting.

Discursive Methods. Discursive stressed methods consciously seek solutions through gradual, influenceable and documentable procedures (*secondary creativity* [9.28]).

In the *systematic study of the physical events* are derived from a known physical relationship (a physical effect), with several physical variables are derived by different solutions, that analyse the relationship between a dependent and an independent variable with all other variables held constant. Another possibility lies in dissecting known physical effects into individual effects and to look for the implementation for these effects [9.5]. A *systematic search with the help of order schemes* assumes that an order scheme (for example, a two-dimensional table) stimulates the search for other solutions in certain directions outside of the identification of key solution characteristics and corresponding linkage options. Possible starting points are one or more known solutions which are characterised according to

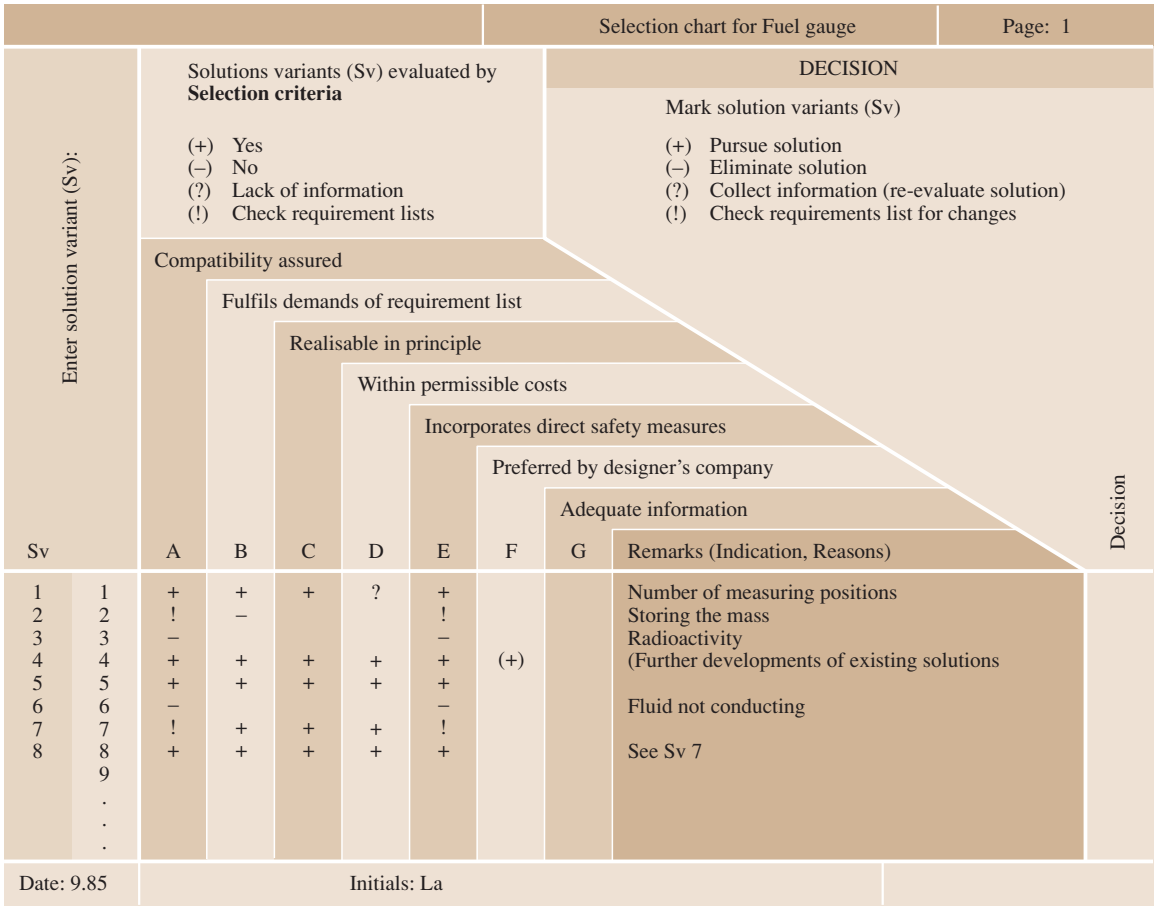

Fig. 9.19 Systematic selection chart: 1, 2, 3, *etc*. are solution variants (after [9.3])

organizational aspects or differentiating features. Such organizational aspects and/or variation features are for example, types of energy as well as the effective structural features of effective geometry, effective movement and substance. Such an order scheme is Zwicky's morphological box (Fig. 9.17).

The designer quickly arrives at solution proposals by *using construction catalogues* as collections of known and trusted solutions of various concretisation and complexity levels, but they often have to be developed or adapted [9.2]. What is important is the allocation of selection characteristics in the accessed part of a catalogue in order to recognize the suitability of a solution for the realization of a required function (task) (Fig. 9.18). Catalogues and databases are also naturally important works in looking for design options in the draft phase of product development.

Methods of Selection and Evaluation

In each design phase or concretisation stage of the development and construction process, selection methods serve to assess and select solution variations with the goal of recognizing those solution variations for which further realization is worthwhile from the quantity of solution options. Depending on the level of knowledge about the characteristics of a solution to be reviewed, procedures are employed to make a rough selection or a finer selection. A rough selection is characterized by the tasks of rejecting (–) and preferring (+). With the help of a selection list (Fig. 9.19), the initial totally unsuitable solutions can be rejected. Such rough selection processes have proved successful, especially for listing and/or designation in morphological boxes connected with the drafting of effective structures.

Table 9.2 Points awarded in the utility analysis and VDI guideline 2225 (after [9.3])

Value scale			
Use-value analysis		Guideline VDI 2225	
Pts.	Meaning	Pts.	Meaning
0	absolutely useless solution	0	unsatisfactory
1	very inadequate solution		
2	weak solution	1	just tolerable
3	tolerable solution		
4	adequate solution	2	adequate
5	satisfactory solution		
6	good solution with few drawbacks	3	good
7	good solution		
8	very good solution	4	very good (ideal)
9	solution exceeding the requirement		
10	ideal solution		

If several solutions remain, they are obviously preferred. The selection criteria are to be adjusted to the goals of product development and the company. For a more accurate selection, evaluation procedures are used, in particular, VDI guideline 2225 [9.29] and the utility analysis [9.30]. In Table 9.2, a comparison is shown between the two procedures. A detailed approach can be taken from VDI guideline 2225 [9.30].

Design Principles

After evaluating the effective structures which have been worked out and/or principle solutions, a structure/solution is usually released for drafting. The design stage in the drafting of a product requires the use of mechanics, the knowledge of strength science as well as knowledge of manufacturing technology, materials technology and other fields. The fine shape is gradually generated from the rough shape:

- Rough design: spatially and significantly correct, but without details, i. e. preliminary drafts
- Fine design: all the necessary details are conclusively defined by applying guidelines / regulations, norms, calculations and consider the impact of auxiliary functions

When generating fine shape, it is appropriate to structure the approach in individual work steps.

The starting point is the principle solution. Following clarification of the spatial conditions, the designing of the design-determining main functional elements begins and following this, the designing of the other main functional bodies. If they are sufficiently specified, the search takes place for solutions to the auxiliary functional elements [9.3]. In this step, these are often bought-in parts. The result of this working step is to define the design of the principle solution, i. e. all the characteristics of geometry, material and condition.

The following methods and rules are recommendations, strategies and hints for the designer with which he can successfully work out a structure for a product [9.3].

Basic Design Rules. Basic rules are always valid instructions, whose observance helps ensure the success of a solution and whose non-observance leads to major drawbacks. They are derived from general objectives in the construction process.

Observance of the basic rules:

- Easy
- Clear and
- Safe

leads to the clear fulfilment of the technical function, its economic realization and to safety for humans and the environment.

Observance of the basic rule *clear* helps, to reliably predict the effect and behaviour of structures. Figure 9.20 shows an example of a shaft-hub connection. This is a cross-compression connection. The additional parallel key does not make it any more secure. Sectional weakening results and there are additional notches (lo-

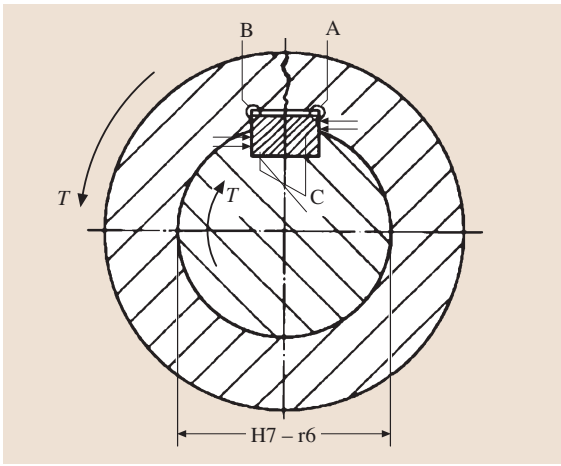

Fig. 9.20 Combined shaft–hub connection achieved by means of shrink fit and key: an example of not applying the principle of clarity

cation B) and thus, the stress condition and handling is made more complicated (location C). As a result, the whole connection is insecure!

The basic rule criterion *simple* should ensure an economic (cost effective, feasible) solution however the basis has to be formed by the functional performance. This functional fulfilment determines where the border for the *easy* criterion lies.

It is possible to apply the following basic principle: Few parts with simple design! To enforce this principle a compromise is often needs to be made between the two aspects:

- Functional fulfilment and
- Economic efficiency

The functional fulfilment conditionally requires, among other things, a minimum number of parts which must have the necessary shape to fulfil the required function.

Economic efficiency requires the necessary number of parts and the necessary shapes which emerge to be manufactured cheaply and fast (on schedule).

The demand for safety forces designers to consistently take into account durability, reliability, the extent to which the part is free from accidents as well as environmental protection. The following criteria are available to the designer at various levels [9.3]:

- Immediate safety engineering (*safe existence*, *limited failure*, *back-up arrangements*
- Indirect safety engineering (protection systems, protective equipment) and
- Indicative safety engineering (identification of the danger)

Figure 9.21 shows the key safety areas.

From the designer's point of view, the stage of immediate safety engineering is always strived for. For realizing this, three principles are available.

The principle of safe existence (safe-life behaviour) ensures that all components and their relationship in the product survive the intended stress and operational life without a failure or a fault.

The principle of limited failure (fail-safe behaviour) allows for a functional fault or damage during the operational life without at the same time causing serious consequential damage.

The *principle of back-up arrangements* enhances security through reserve elements taking over the full or partial function of the regular element in the event of failure. In the case of active back-up, both normal elements and reserve elements actively take part in fulfilling the function, however in passive back-up, the reserve element is only in reserve during normal operation. Principle redundancy exists when the normal element and reserve element depend on different effective principles. Back-up elements can be engaged in parallel, serial, quartet, cross quartet, 2 out of 3 and comparative back-up running.

If, with the three principles listed, risk can not be excluded, complementary indirect safety equipment and the indicative safety equipment is used.

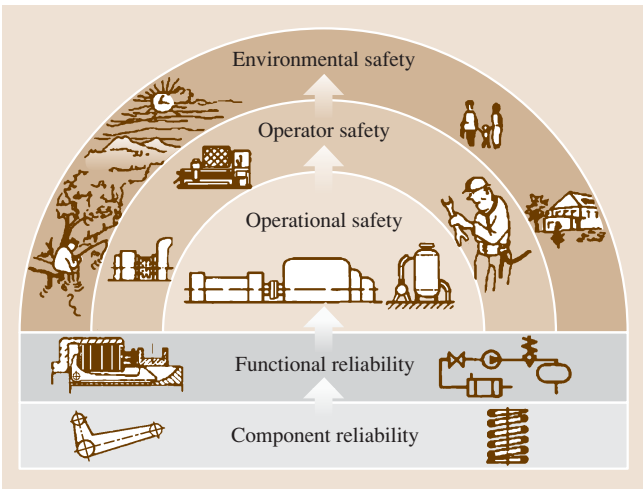

Fig. 9.21 Relationship between component and functional reliability on the one hand and operational, operator and environmental safety on the other (after [9.3])

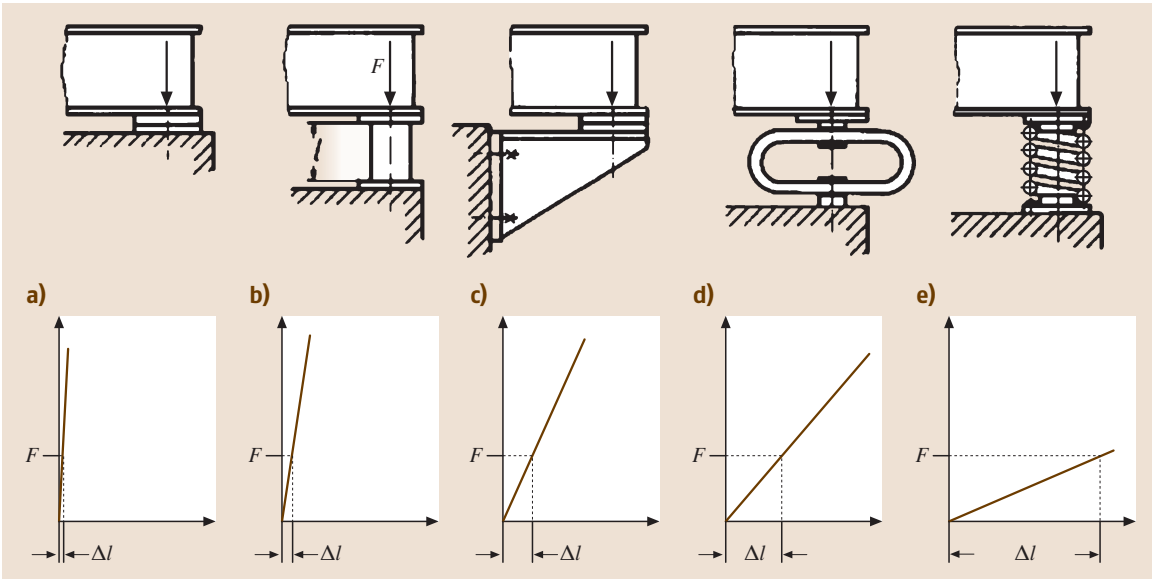

Fig. 9.22a–e Supporting a machine frame on a concrete foundation: **(a)** very rigid support due to short force transmission path and low stress on the baseplates, **(b)** longer force transmission path, but still a rigid support with tubes or box sections under compression, **(c)** less rigid support with pronounced bending deformation (a stiffer construction would involve the greater use of materials), **(d)** more flexible support under bending stresses, **(e)** very flexible support using a spring, which transmits the load in torsion. This can be used to alter the resonance characteristics (after [9.3])

Design Guidelines. In this section, the principles will be explained for developing a construction on the basis of the effective structure as well as defining the nature and (especially) the setting up of functional bodies. These principles are:

- The force transmission
- The division of tasks
- Self help
- Stability and bi-stability
- Low-fault design

Force transmission principles ensure equal shape stability, economic and load-favourable channelling of the flow of force/power flow, adjustment of component shaping as well as force equilibrium. It is worth additionally noting that the following subfunctions of force are implemented in many machine engineered products (including precision engineering):

- Pick up (induction)
- Channelling (onward channelling)
- Release (channel off)

(momentum belongs to these forces). When considering power channelling problems, the image of force flow is often very helpful. In designing the following guidelines should always be adhered to:

- The flow of force must always be closed.
- Sharp deflections in the flow of power.
- Changes in the density of power flow through strong cross-sectional changes are to be avoided.

This idea of the power flow should be supplemented through observation of the following principles:

- The *principle of equal shape stability* means that throughout the entire component, the same stable load is strived for. Economic aspects (costs) can oppose the application of this principle.
- The *principle of the direct and brief transmission of force* refers to the selection of the most direct and shortest path of channelled force (momentum) preferably with torsion/pressure stress in order to keep deformation small and material expenses low through uniform stress distribution. Figure 9.22 describes these relationships in a brace support for a machine frame on the basis of compression stress–strain characteristics of the variants. The instance when either a more rigid or elastic solution is used, depends on the design requirements.

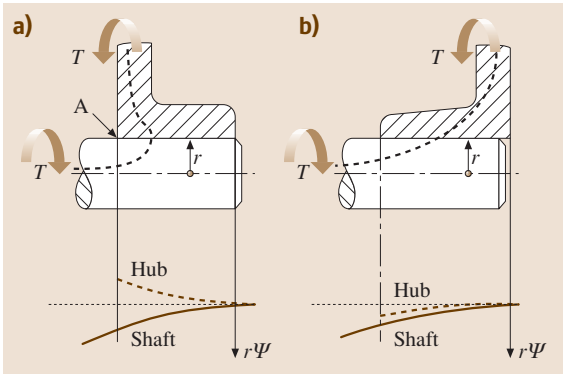

Fig. 9.23 **(a)** Shaft–hub connection with strong *force flow-line deflection*. Torsional deformations of shaft and hub in opposite direction (ψ = angle of twist). **(b)** Shaft–hub connection with gradual *force flow line deflection*. Torsional deformations of shaft and hub in the same direction (after [9.3])

- In joint connections, the *principle of adjusted deformations* designs the components concerned such that when subjected to loads, extensive adaptation of the deformation occurs, through parallel and equal deformation. Figure 9.23 shows the example of a torque-stressed shaft-hub connection (shaft to collar connection) in a favourable and less favourable design. From Fig. 9.24, it is possible to see deformation adjustment possibilities in a crane drive mechanism, without which, off-track running of one of the drives would occur. The cause for this is the different torsion stiffness of the shaft section I_1 (large) and I_2 (less than that of I_1) as shown in Fig. 9.24a. When applying torque, first the left wheel moves, the right wheel stands still and the drive remains obliquely positioned. This deficiency can be overcome through a symmetrical arrangement (Fig. 9.24b) or through the adjustment of the torsion stiffness in both shaft sections (Fig. 9.24c).
- The *principle of balancing force* aims, through compensatory elements or symmetrical arrangement, to limit the auxiliary variables accompanying the main function variables to as small an area as possible so that construction costs and energy losses remain as low as possible (Fig. 9.25).

The *principle of sharing tasks* enables the clear, safe behaviour of these functional agents, better efficiency and increased capacity by assigning components or assemblies, materials or other construction elements to individual subfunctions of a solution concept. This principle of a *differential design* stands in contrast to the usually cheaper variant, *integral design*. The usefulness of the application should be tested on an individual cases basis. By way of example, Fig. 9.25 shows a fixed bearing arrangement, in which radial forces are transferred by a roller bearing and axial forces by a deep groove ball bearing. At high loads, this arrangement is superior to the usual version with only one deep groove ball bearing, which transfers the radial and axial forces.

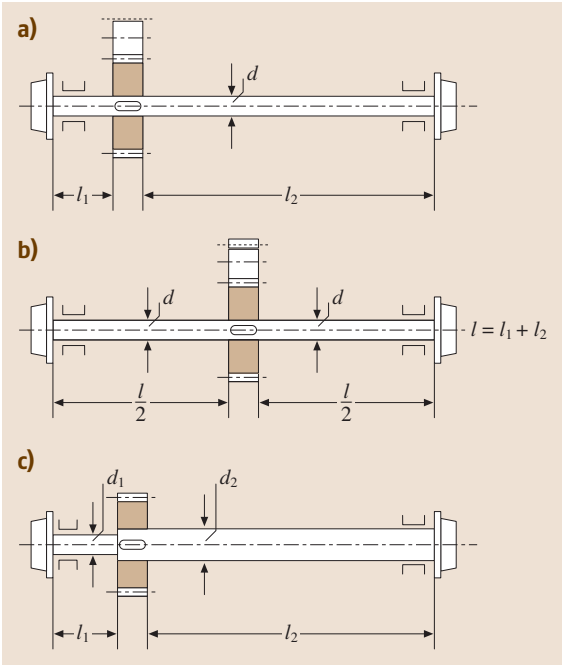

Fig. 9.24a–c Application of the principle of matched – here equal – deformations in crane drives: **(a)** unequal torsional deformation of lengths ℓ_1 and ℓ_2, **(b)** symmetrical layout ensures equal torsional deformation, **(c)** asymmetrical layout with equal torsional deformation due to adaptation of torsional stiffnesses (after [9.3])

The principle of sharing tasks is also applied for distributing load onto several identical mechanical transmission elements, if only one mechanical transmission element exceeds the load limit. Examples of this are split torque multi-channel drives and belt gear with several parallel V-belts.

Through the appropriate selection and arrangement of components to form a construction, the *principle of self-help* leads to effective mutual support, which helps a function to be fulfilled, better, safer and more economically [9.31]. At the same time, a self-strengthening and self-compensating effect can be exploited on a normal

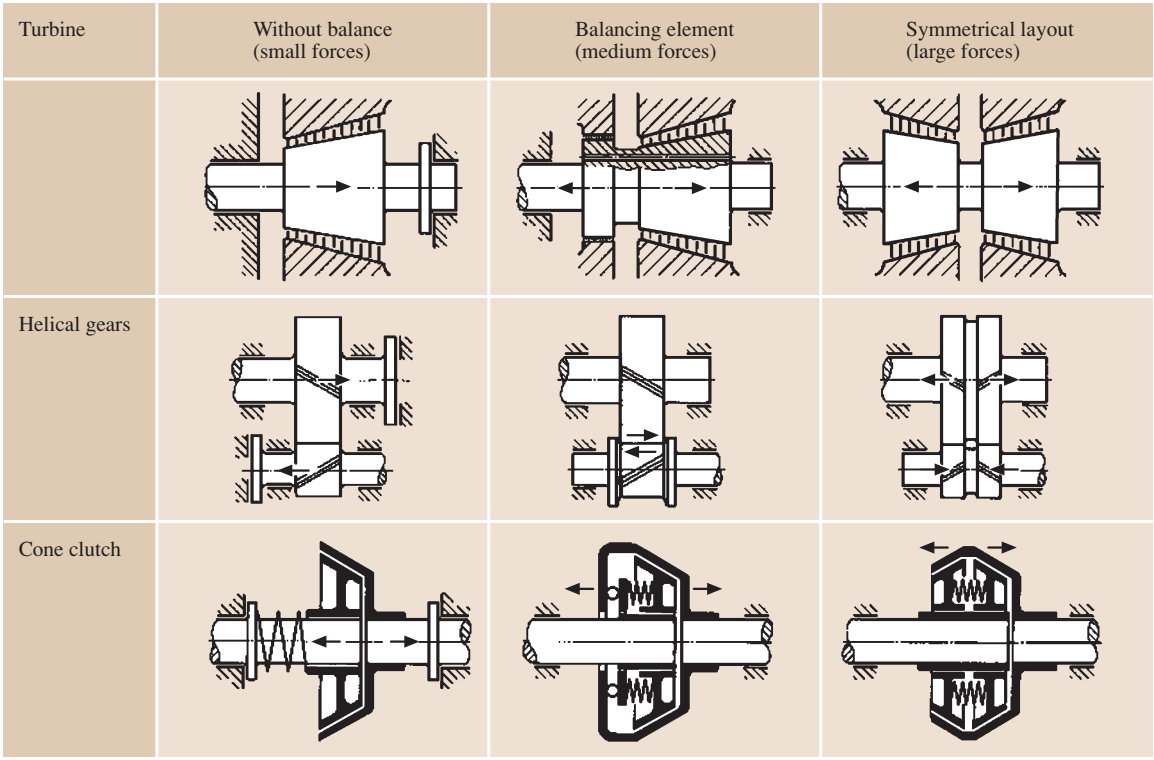

Fig. 9.25 Fundamental solutions for balancing associated forces, illustrated via a turbine, helical gears and cone clutch (after [9.3])

load as well as a self-protecting effect on an overload situation. Figure 9.27 illustrates the self-strengthening solution for a closure in pressure vessels, in which the sealing force of the lid is proportionately increased by the internal pressure of the container.

A self-compensating solution can be found in the example of an incorrectly clamped blade of a jet engine rotor. Through the slanting of the blades, additional

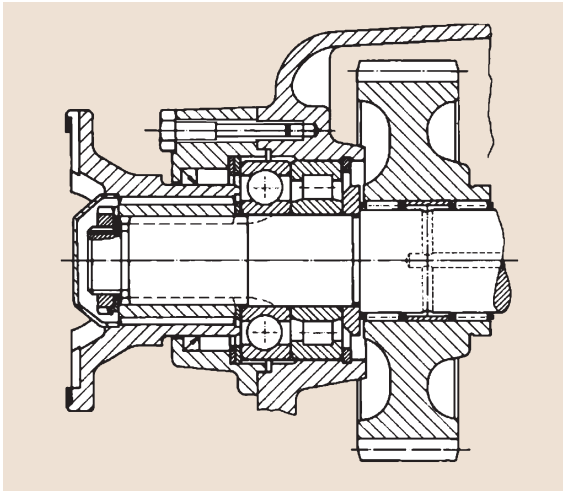

Fig. 9.26 Locating bearing with separate transmission paths for radial and axial forces (after [9.3])

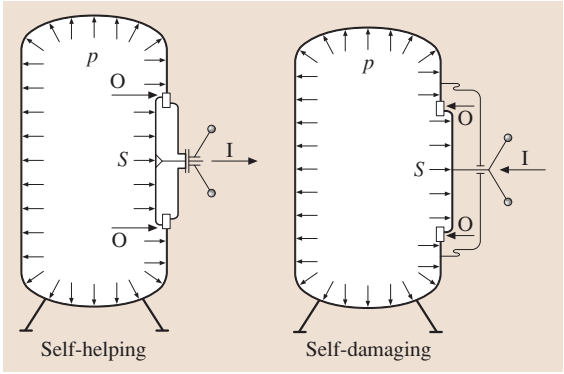

Fig. 9.27 Layout of an inspection cover. I = initial effect; O = overall effect; p = internal pressure (after [9.3])

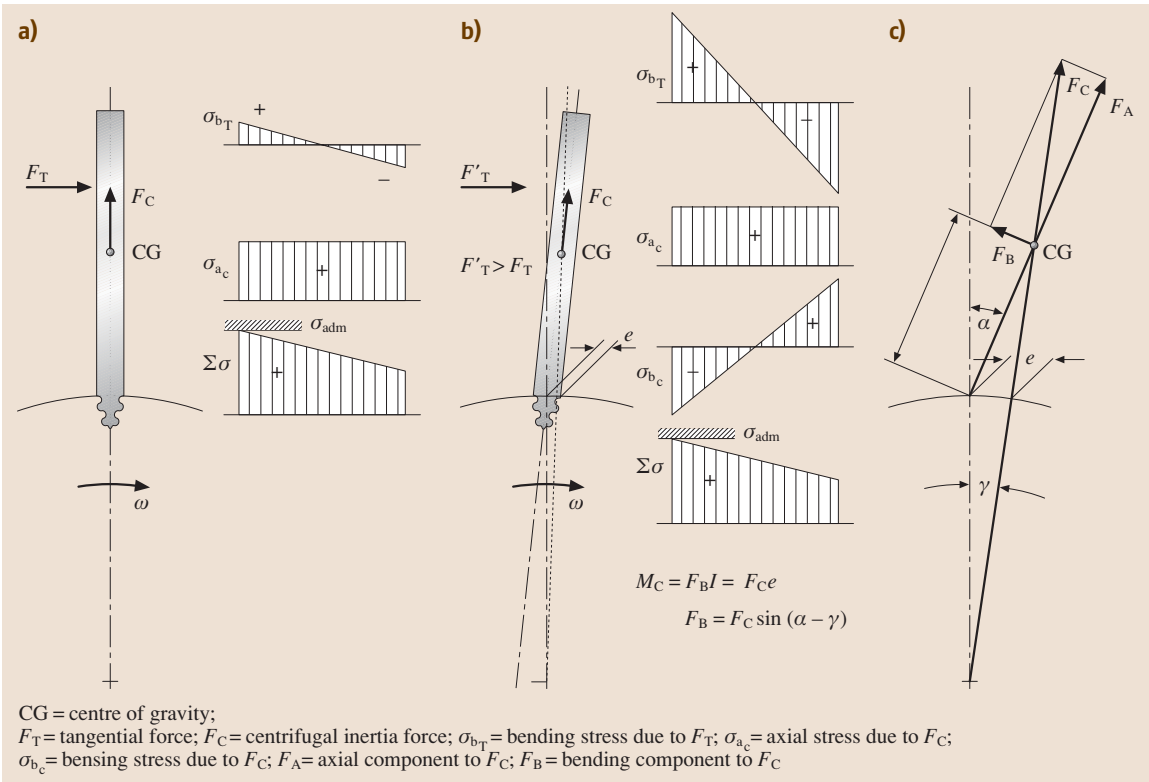

Fig. 9.28a–c Self-compensating solution for turbine blades: **(a)** conventional solution, **(b)** leaning of the blade produces a balancing supplementary effect due to the additional bending stresses produced by the centrifugal inertia force (σ_{b_C}), which oppose the bending stresses caused by the tangential force (σ_{b_T}), **(c)** diagram of forces

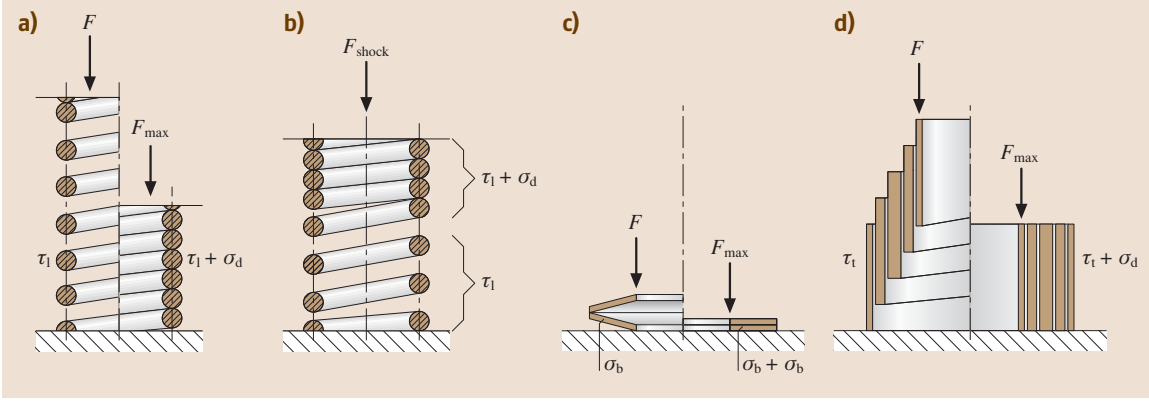

Fig. 9.29a–d Self-protecting solution in springs: **(a)**–**(d)** force transmission path changed, the normal function is suspended or limited in the case of excess loading (after [9.3])

bending stress is generated due to centrifugal force which counteracts and (partly) compensates the bending stress from the tangential force, thus enabling a greater amount of tangential force (= blade force) (Fig. 9.27).

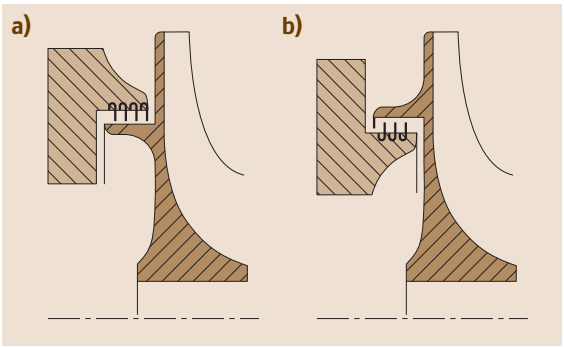

Fig. 9.30a,b Seal in turbocharger (after [9.3])

In restricting functionality, a *self-protecting* solution protects an element from overstress by making a change to the stress type (as Fig. 9.29 shows using springs as an example).

In the event of faults, the *principle of stability* has the aim of evoking a self-neutralizing compensatory effect or at least, an alleviating effect. Figure 9.30 shows this principle by means of a compensation piston seal, which when heated (fault) either starts grinding (unstable solution) or lifts itself away from the anti-effective area (stable solution). Figure 9.30a shows that the friction heat due to rubbing (fault) primarily flows into the inner part i. e. its additional warming, and the resulting expansion reinforces the fault and leads to an unstable behaviour. From Fig. 9.30b, we see that the friction heat due to rubbing (fault) primarily goes into the outer part, i. e. its additional warming and the resulting expansion acts contrary to the fault, reduces it, and leads to stable behaviour.

With the principle of bi-stability, through a deliberate fault, effects are achieved which support and thus help reinforce the fault so that when reaching a borderline state, a significantly new, clearly different state is reached without unwanted intermediate states. As such, the principle also underlies the directness of an effective structure. Figure 9.31 shows the principle of a safety valve, which should quickly move from the closed borderline state to the opened borderline state (through a sudden increase in the pressure area (A_v to A_z) after lifting the valve plate).

More Recommended Design Guidelines. The following design guidelines are recommendations for the designer, which he should note in order to satisfy the general and specific objectives of the task. A detailed description of these design guidelines is found in [9.3]. *Design in accordance with stress* means starting out

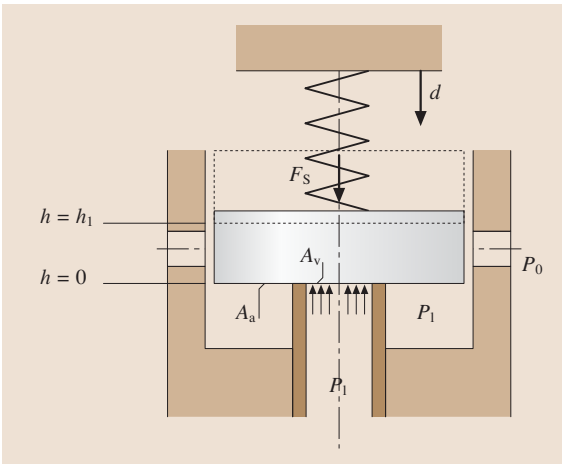

Fig. 9.31 Solution principle for a valve with an unstable opening mechanism: d = precompression of spring; s = stiffness of spring; F_S = spring force; h = lift of valve head; p = pressure on valve; p_ℓ = limiting pressure just sufficient to open the valve; p_i = intermediate pressure upon opening of valve; p' = pressure after opening of valve; p_0 = atmospheric pressure; A_v = surface area of valve opening; A_a = additional surface area.
Valve closed: $F_S = sd > pA_v$, $h = 0$;
Valve just open: $F_S = sdp_\ell A_v$, $h = 0$;
Valve opening fully: $F_S = s(d+h) < pA_v + p_i A_a$, $h = \pm h_1$;
Valve fully open: $F_S = s(d + h_1) = p'(A_v + A_a)$, $h = h_1$ (new equilibrium position) (after [9.3])

with the aim of initially ascertaining all longitudinal and transverse forces touching the component as well as bending and torque moments. This is the basis for calculating existing normal stresses, as tensile, compressed and bending stresses as well as the tangential stresses as shear stresses and torsional stresses. This stress analysis is the basis for determining the existing elastic and/or plastic deformation (strain analysis). In order to identify the level of safety against failure or to make lifetime predictions, these loads are contrasted to the applicable material threshold values for the current case load, observing notching effects as well as surface and variable influences with the help of stability hypotheses.

At the same time, the principle of *equal stability* should be strived for so that all design areas are roughly used to the same extent.

Design in accordance with expansion means thermal and tension-conditioned component expansion, especially relative expansion between the components, as compensated for by adopting channels and through the selection of materials so that no residual stresses,

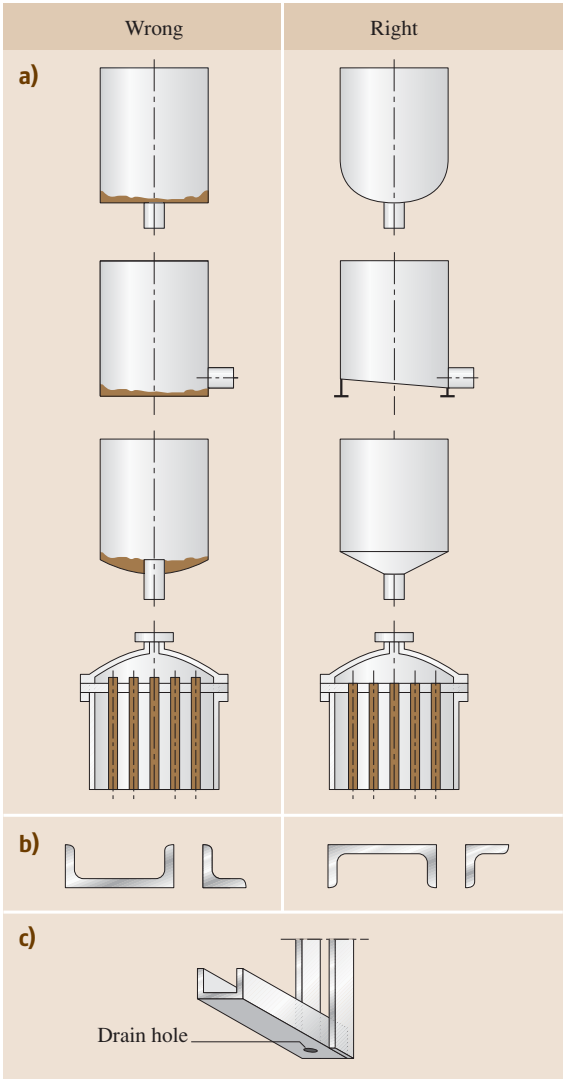

Fig. 9.32a–c Drainage of components susceptible to corrosion: **(a)** design of bases encouraging and impeding corrosion, **(b)** incorrect and correct arrangement of steel sections, **(c)** brackets made of channel section with drainhole (after [9.3])

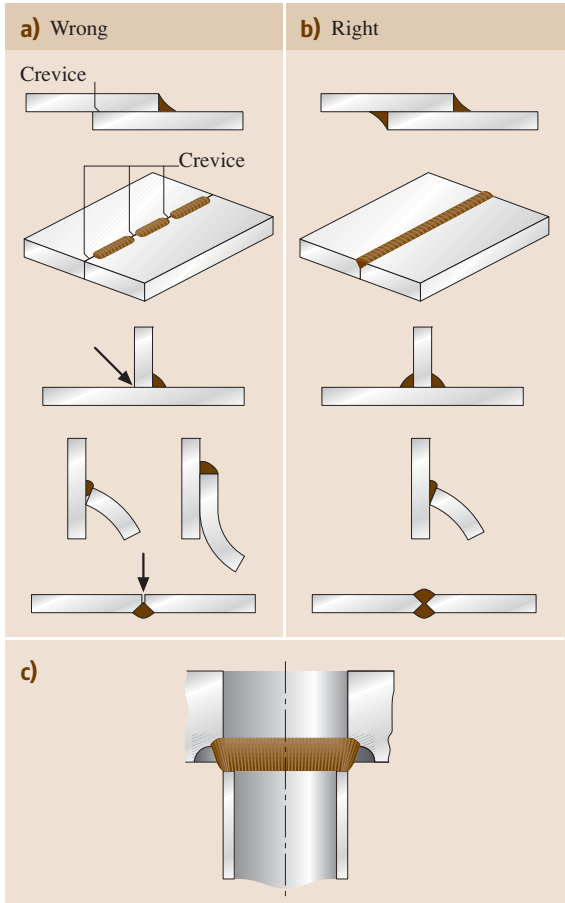

Fig. 9.33a–c Examples of welded joints: **(a)** susceptible to crevice corrosion, **(b)** correct design, **(c)** crevice-free welding of pipes, also improves resistance to stress corrosion cracking (after [9.3])

clamping or other compelling conditions exist, which would reduce the bearing strength of the structures. Channels are to be arranged in the direction of expansion or in the line of symmetry of the thermally or mechanically-conditioned distortion state of the component.

In the case of transient temperature changes, the thermal time constants of adjacent components are to be adapted in order to avoid to relative movements between these (components) [9.3].

Design in accordance with creep means taking into account the time-related plastic deformation of individual materials, especially at higher temperatures or the deformation of synthetic materials through the selection of materials and design, e.g. as much as possible avoiding a reduction in tension (relaxation) in stressed systems (screw connections, compressed connections) using elastic flexibility reserves. The field of tertiary creep is to be avoided through extremes of load and temperature, the selection of materials and stress time testing [9.3].

Design in accordance with corrosion includes avoiding the causes and/or preconditions for the vari-

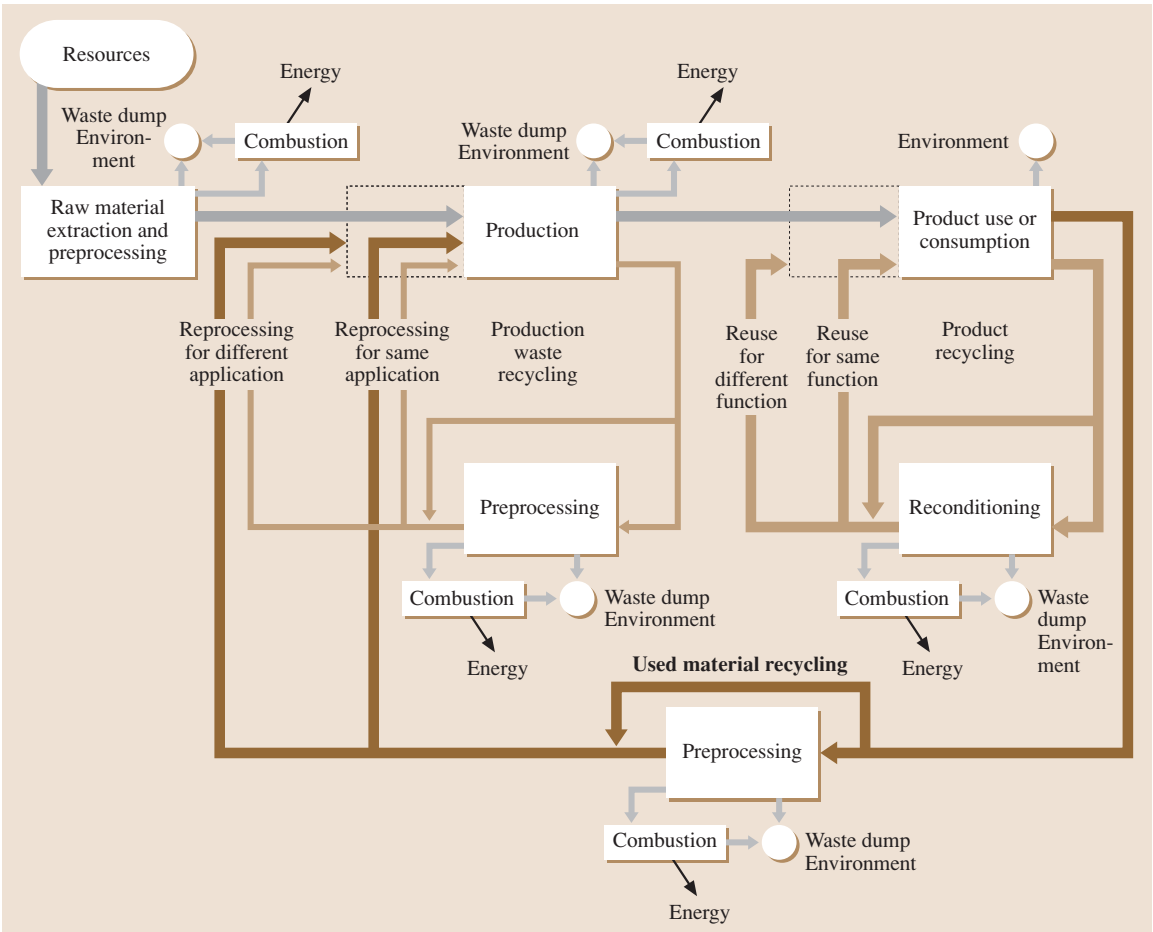

Fig. 9.34 Recycling options (after [9.3])

ous types of corrosion (primary measures) or through the selection of material, coatings or other protective/maintenance measures (secondary measures) which restricts the advancement of corrosion within permissible limits. Figure 9.32 illustrates constructive for avoiding moisture collection points and Fig. 9.33, examples of crevice corrosion.

Design in accordance with wear and tear means adopting the relative movement between parts necessary for the operation with as little wear and tear as possible through tribological measures in the system – material, surface or lubricant. At the same time, composite structures with high-strength boundary layers and design-giving basic materials provide an economic solution [9.32].

Design in accordance with ergonomic considerations includes taking into consideration the key characteristics, abilities and needs of the people to will use the product. In this, biomechanical, physiological and psychological aspects play a role. It is possible to make a differentiation between an active contribution of the person (e.g. in operating the product) and a passive relationship (retroactive and side effects as a consequence of the product) [9.33].

Design in accordance with shape (Industrial Design [9.23, 34]) means to take into consideration the fact that particular utensils not only serve a mere purpose but should also have aesthetic appeal. This is especially true for the look (shape, colour and labelling).

Design in accordance with manufacturing considerations means recognition of the significant influence of construction-related decisions on production costs, production times and manufacturing qualities and to take these into account in the optimizing components [9.3].

In designing parts (pieces) which are convenient to manufacturing processes, the designer has to be aware of the nature of the manufacturing procedures and the specific circumstances of each manufacturing plant (internal or external).

Design in accordance with assembly considerations means to reduce, to simplify, to unify and to automate the necessary assembly operations through an appropriate structure, as well as the design of the joints and joining parts [9.3]. In the design measures to simplify the parts production and the assembly, aspects of the testing process and production monitoring are looked at.

Design in accordance with norms include the norms which are observed for safety, usage and economic reasons and other technical rules which, as recognized engineering rules, serve the interests of manufacturers and users.

Design in accordance with transportation and packing considerations means taking into account standardized packaging and loading units (containers, pallets) for serial production as well as transportation options for large machinery [9.3].

Design in accordance with recycling considerations means knowing the nature of processing and reclamation procedures and supporting their use through assemblies and component design (shape, joints, materials). At the same time, reclamation-friendly constructive measures (facilitated dismantling and reassembling, cleaning, testing and post-processing or exchange) serve the interests of maintenance compatible design (inspection, servicing, repairs). Figure 9.34 shows recycling possibilities for material products, to which constructive measures must be oriented in order to facilitate recycling [9.35–38].

9.2 Basics

The methodical approach to the development and design of technical systems (engineering design) has established itself in virtually all design departments. Teaching specialized knowledge about methodical design is also a fixed component of the curriculum in the teaching of engineering sciences in universities and technical colleges.

There are a large number of approaches to design methodology, which are documented the technical literature. For example, *Ehrlenspiel* [9.1] focuses more on the cost approach to product development. One way of reducing and identifying costs early, according to Ehrlenspiel, is integrated product development. In his method on the other hand, *Roth* [9.2] divides the design process into many smaller steps and places strong emphasis on the incorporation of design catalogues in the solution process. *Pahl* et al. [9.3] worked very actively on the German guidelines VDI2221 [9.21] and VDI2222 [9.39] and subdivided the design process into individual activities, to which detailed methods are assigned. Further methods exist for these purposes, for example from *Koller* [9.6], *Gierse* [9.40], *Hubka* [9.41], *Bock* [9.42] and *Rugenstein* [9.43]. The essential aspect of each of these is the structuring of the task. This takes place, e.g., by drawing up flow diagrams and using methodical structuring aids, e.g., functional structures, efficacy structures or classification diagrams [9.44].

The methodical approach to the development of a technical system is clarified in this chapter using a practical example from the interdisciplinary field of biomedical engineering, based on the methodical method of *Pahl* et al. [9.3].

According to Pahl et al., the design process is divided into four stages:

- Precisely defining the task (problem identification)
- The concept stage
- The design
- Drawing up the final solution (detailed design)

As the example involves an interdisciplinary development project, it is particularly important to draw up only a few, but at the same time all, of the problem or work-related (sub)functions required for adequate structuring of the task and to represent these in a functional structure. It is also necessary to use a generally understood vocabulary. This enables us to ensure that people not yet involved in the process or people who do not have engineering training, e.g., medical experts or biologists can easily obtain an overview. This integration of employees from the individual specialized fields is necessary in order to be able to implement all medical and biological requirements at a high level.

9.3 Precisely Defining the Task

9.3.1 Task

The engineering system to be developed is a test setup for experiments with live human cells. The task (problem) for the designers was drawn up by the responsible medical experts. An extract from this is shown in the following.

For decades it has been known that certain cells in the human immune system are practically incapable of functioning in weightlessness. This can pose a serious problem for long-term stays in space on the International Space Station (ISS), or flights to Mars. The basic mechanism is to be investigated by means of weightlessness experiments with the help of parabolic (ballistic) flights. To this end, experimental equipment is to be designed with which tests on live cells can be performed onboard parabolic flights and in weightlessness. These experiments should also answer the question of whether humans are at all capable of living in weightlessness for any lengthy period. The findings can also be used in therapy for diseases of the immune system. It is necessary to mix the living human cells with an activator liquid and with a stopping liquid after a certain time. All the necessary safety requirements must be observed.

The designer's task consists of precisely defining this problem. This means that they must first draw up a functional engineering description. The aim is to draw up the whole function and all input and output variables for the engineering system to be developed.

9.3.2 Functional Description

The functional engineering description is drawn up by the responsible designer. It is used to clearly define the task or problem the designer has been set. At the same time it provides a basis for discussion with the other team members. In this way it is possible to identify early on whether there are any communication problems. In interdisciplinary projects it is particularly important to integrate the information of the non-engineering science team members into the technical preparations and therefore to create a basis for a methodical approach. It this project it was particularly important for the medical experts/biologists and engineers to speak the *same language*. The functional description is usually verbal. Frequently diagrams or initial sketches are also produced to depict the whole function to be fulfilled transparently. Figure 9.35 shows the outline technology for the test setup to be developed.

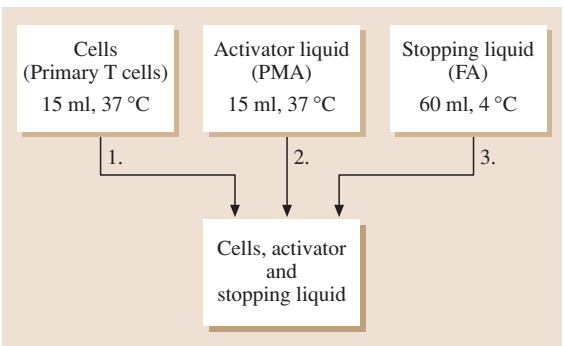

Fig. 9.35 Liquids to be mixed

This rough structuring was based on notes taken during team meetings and a functional structure drawn up by one of the medical–biological team members (Fig. 9.36).

This is already very finely structured. However, it is not drawn up in the usual form used in design methodology [9.3]. Further, such a precise description of a focused possible solution excludes other approaches and solutions in advance. The functional engineering description or the overall function to be fulfilled by the test setup can be described as follows.

A test setup is to be developed that enables three different cell lines to be mixed, to a large extent homogeneously, with certain activator liquids at the start of the weightlessness phase. Just before the end of the weightlessness phase a stopping liquid is to be added to the cell vessels filled with a cell type and an activator liquid.

In order to fulfil the specified medical requirements, combinations of three different cell liquids, three different activator liquids and two stopping liquids (Fig. 9.35) must be realized.

The condition of weightlessness was achieved with the help of parabolic flights. This means that an aircraft flies in a precisely defined parabola and the condition of weightlessness (micro-gravitation) is available for approximately 22–25 s (Fig. 9.37).

A main requirement is the fulfilment of all safety requirements in the test setup. Primarily, that under no circumstances may liquids escape from the test setup during the parabolic flights. Some of the cell lines used are genetically modified tumor cells and immune cells isolated from blood donators, and toxic liquids such as formaldehyde. These could pose a risk to the flight personnel during the weightlessness phase. This means

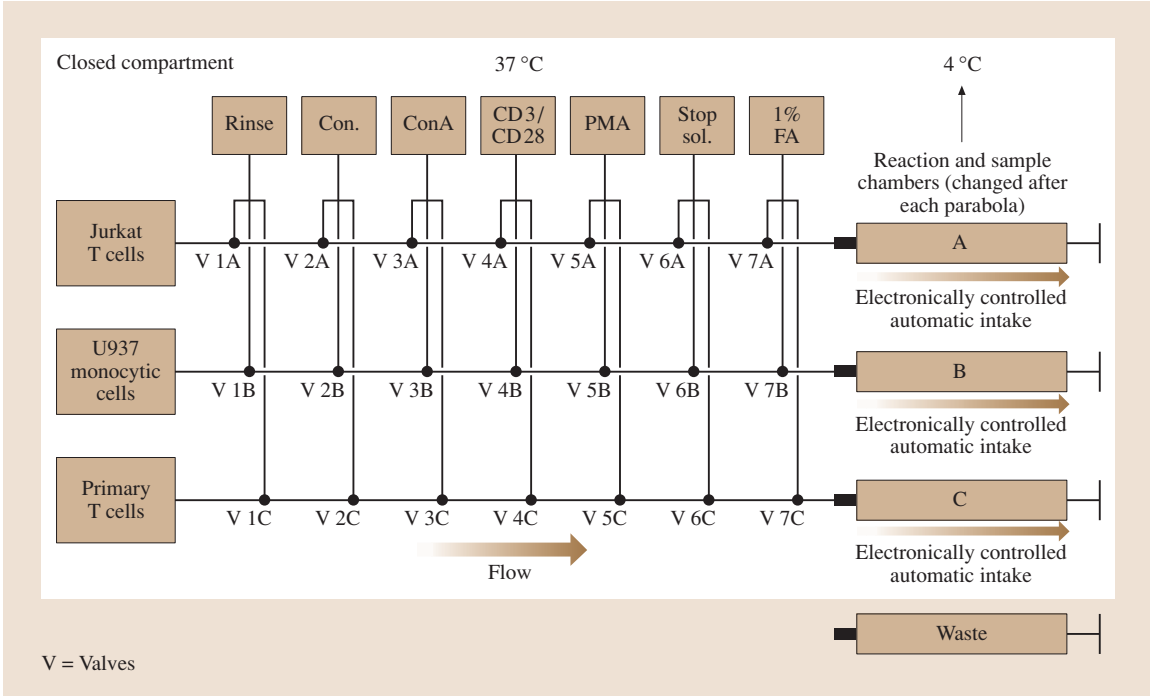

Fig. 9.36 Functional description from a medical point of view

that all parts that come into contact with the media or cell, activator or stopping liquids must be designed with double walls.

A further requirement is that the temperature of the cell and activator liquids must be 37 °C and the temperature of the stopping liquids must be 4 °C (Fig. 9.35).

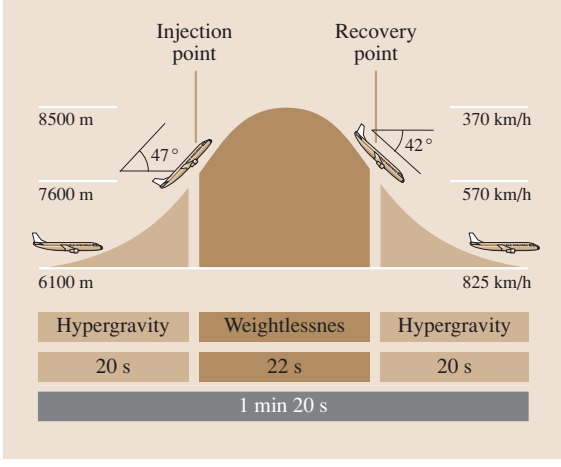

Fig. 9.37 Flight parabola for generating weightlessness (microgravitation) (after [9.45])

Further points included in an initial functional engineering description are:

- Enable fast and easy equipping with liquids
- Realization of the direct safety stage [9.3], i. e., leakproof under the conditions in the aircraft
- Clear functional sequences
- Good miscibility of the liquids during the experiment in the cell culture bag
- Fill under exclusion of air
- To a large extent transparent construction for observation of whether air inclusions exist
- Low weight (mass)
- Small space requirement
- Good cost effectiveness

This initial functional description is the basis for drawing up a requirements list.

9.3.3 Requirements List

When the task or problem is more precisely defined, other individual characteristic values and special requirements are determined. It is necessary to adequately describe all of the requirements set, both qualitatively and quantitatively. In this project this is achieved:

	Product: *Parabolic Flight*		Date: 06.02.06	Sheet 03
	Requirements			Source Responsibility
	No.	Descriptive information	Numerical info/comments	
Overall space required/ connection dimensions/ installation conditions		Aircraft door width	– 1.07 m	
		Aircraft door height	– 1.93 m	
		Cabin length	– 20 m	
		Maximum rack height	– 1,500 mm	
		Fixing points for experimental setup	– Mean rail spacing (y-axis) a) 503 mm b) 1006 mm – Hole diameter for screw M10 = 12 mm – Hole spacing in x direction = n * 25.4 mm > 20 inches (1 inch = 25.4 mm)	
		Maximum load per unit area over 1 m fixing rail length	– 100 kg	
		Rack structure	– Baseplate or frame connected to the seat rail system of the aircraft – There must not be any parts protruding from the baseplate in the direction of the flooring	

Fig. 9.38 Extract from the requirements list

- Through discussions with the other team members (biologists, medical experts)
- Through literature and patent research
- Analysis and evaluation of all applicable rules, regulations, etc. (technical requirements of the aircraft operator) [9.46]

The results of the precise task definition stage are documented in the requirements list. This usually contains the objectives to be realized and the prevailing conditions in the form of requirements and wishes [9.3]. The requirements must always be fulfilled. The wishes listed are to be realized if possible. The boundary between requirements and wishes can often not be clearly defined, especially in interdisciplinary projects. For this reason, such a differentiation was dispensed with for this project. An extract from the requirements list drawn up is shown in Fig. 9.38. At the same time, the requirements list is the legal basis for all further activities, including in this project.

9.4 Conceptual Design

In the conceptual design stage the overall function is structured. The result is a functional structure (Fig. 9.39). This means that the whole system is divided into its subfunctions and their links.

This procedure enables optimum analysis of the whole system. Efficacy principles were then assigned to the subfunctions.

Efficacy principles are usually based on physical effects that enable the function to be fulfilled. These are combined with geometric and material characteristics. In this project, conventional, intuitive and discursive solution-finding methods [9.3, 47] were used to draw suitable action principles. In detail:

- Conventional (e.g., literature or patent) research
- Intuitive (e.g., brainstorming)
- Discursive (e.g., the use of design catalogues)

When suitable efficacy principles have been determined for fulfilling the function, they are assigned to the subfunctions in a classification diagram. In this project the morphological box (Fig. 9.40) was used for this.

The efficacy principles drawn up to fulfil the individual subfunctions must then be purposefully linked to each other. When drawing up the concept for the test setup it was of primary importance that the high safety requirements be fulfilled with all the selected efficacy principles. This results in different efficacy structures. In practice it is usual to draw up a maximum of three efficacy structures. Figure 9.41 shows the path through the morphological box.

The efficacy structures generated are specified in greater detail and further developed to form basic solutions. The individual basic solutions are then assessed. An extract of the assessment (rating) undertaken in this project is shown in Fig. 9.42. The assessment criteria and assessment was carried out by the whole project team.

As a result, a basic solution was released to be drawn up. In general, as in this project, this is the ef-

ficacy structure with the best rating. It forms the basis of the design stage. This is shown in Fig. 9.43a.

The basic solution consists of two separate modules. The first module is the actual working module,

Fig. 9.42 Extract from the assessment list

in which the cells, the activator and stopping liquids and all the necessary units are installed for pumping. This module is divided into three levels/submodules positioned on top of each other. Level 1 contains the pump for the stopping liquids and the cell vessels stored for filling, which is separated from the pump by a wall. Above this is the level for the power supply and controls. The top area contains the pump for the activators and, separated from this by a wall, the cell vessels to be filled are connected. After consulting the medical experts the information was received that three individual cell vessels are filled in parallel. The second module is the cooling module in which all filled cell vessels are stored at 4 °C after the experiment.

An important basis for this design is the joint specification from the medical experts and engineers in the project team that a previously precisely defined quantity of the cell liquid is already located in special cell vessels. The activator and stopping liquids are then pumped into these. The result is a simpler and better solution than the one previously proposed by the medical experts in Fig. 9.36. This arose as a direct consequence of the methodical approach described in Sect. 9.3.2. The new

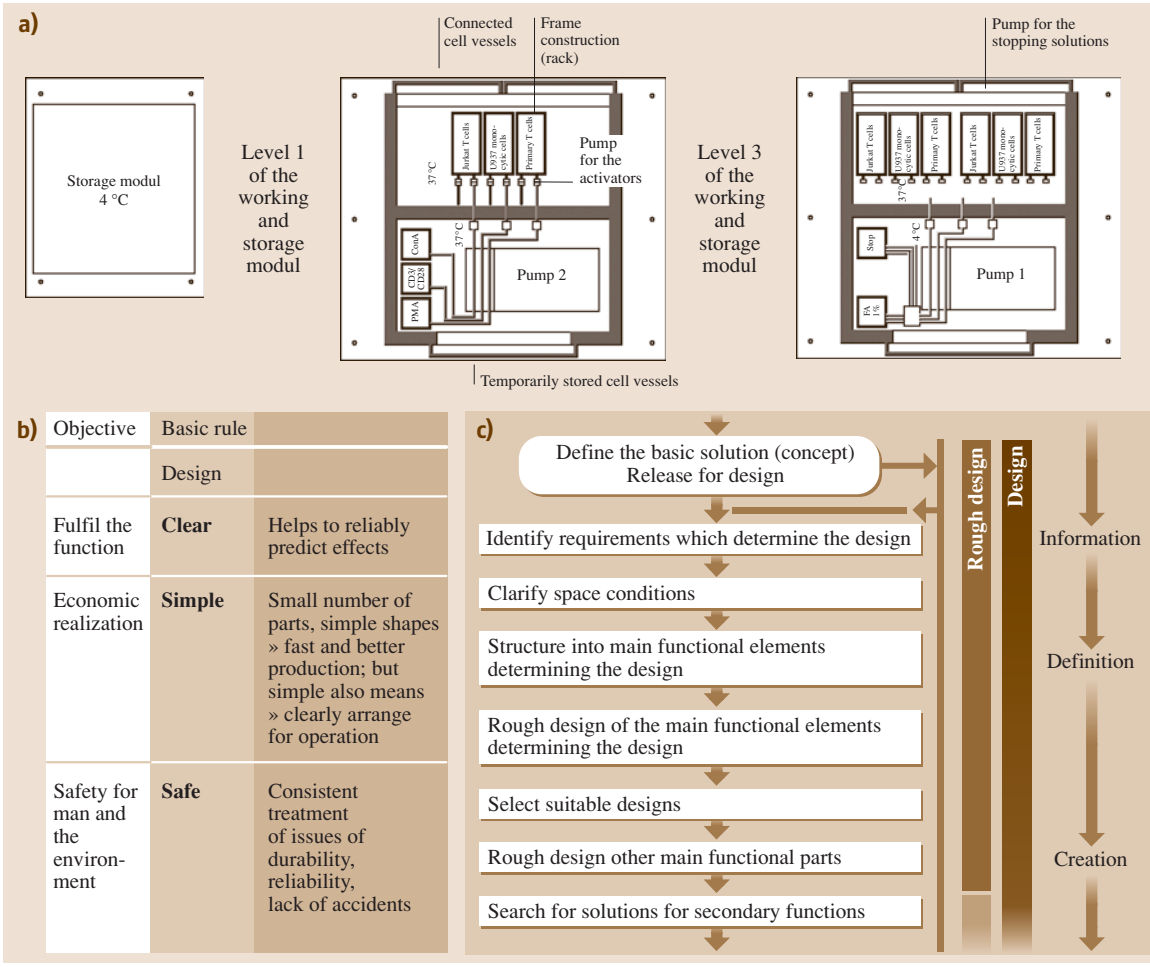

Fig. 9.43a–c Basic solution, released to be drawn up. (c) Extract from the main design activities (after [9.3])

solution prevents the cells themselves from being metered into the installed cell vessels by the pump, which would have generated shear forces that would have had a negative effect on the cells, exposing them to considerable stresses. In addition, it avoids repeated flushing of the pipes/lines for liquid transport. This fact thus minimizes the number of components (pumps, valves, lines) and therefore the costs incurred. In addition the costs for the liquids to be pumped are minimized (less flushing ⇒ less waste). This was an important aspect of *simply* fulfilling the basic design rule. The content is discussed in Sect. 9.5.

9.5 Design

The design stage is divided into:

- Rough design
- Detailed design
- Complete and check

The solution is more precisely defined during the design until a complete structure exists [9.3]. All the technical and economic requirements must be clearly and completely drawn up. The result is the design of the solution option, defining all the geometric, material

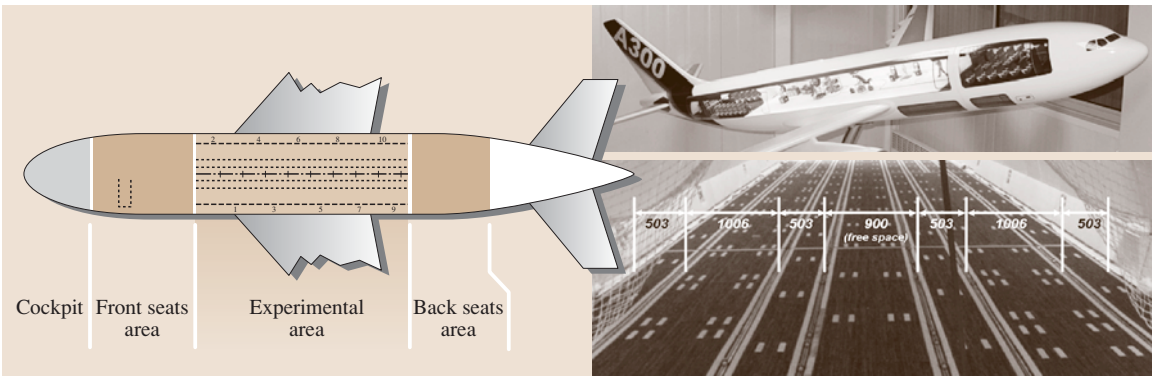

Fig. 9.44 Available (free) space and fixing options in the Airbus A300 of Novespace [9.45]

and condition characteristics. In this stage, the following three basic design rules must be observed: *simple*, *clear* and *safe* [9.3].

Figure 9.44 shows an extract of the main design activities.

The individual activities for developing the test setup for experiments with human cells are described in the following.

9.5.1 Identify Requirements that Determine the Design and Clarify the Spatial Conditions

The decisive requirements are essentially set by the ambient conditions, e.g., available space, effective and allowable stresses and loads, and the requirements set by the work sequence. The main requirements for the test setup to be developed are specified by the information contained in the aircraft operator's user manual. This document provided information on the internal dimensions of the aircraft frame and therefore the maximum effective heights and widths, the type and location of the fixing points, door dimensions for loading, the maximum allowable loads per unit area, details of the power supply, etc. (Fig. 9.44).

Requirements determined by the layout such as the flow directions and handling sequences were specified by the biomedical description of the experiment.

9.5.2 Structuring and Rough Design of the Main Functional Elements Determining the Design and Selection of Suitable Designs

In this activity a roughly structured diagram is drawn up for the main material flow. It names the preliminary main components selected. The main material flow is the pumping of activator and stopping liquids from storage into the cell vessel. Flexible tube pumps and suitable valves and hoses were selected for this task. The pump and valve sizes were chosen on the basis of the time and delivery rate requirements based on the biomedical process variables. Because of these specifications, instead of the originally planned flexible tube pump with a triple head for all activators and the same pump for all stopping liquids, six separate pumps had to be selected to achieve the objective.

Another main functional element was the frame (rack) for the modules. Extruded aluminium sections and accessories, available as a modular system and frequently used for automation engineering, were used in the design. The choice of section size depended on the calculated loads. Figure 9.46 shows the initial design of the working module.

9.5.3 Detailed Design of the Main and Secondary Functional Elements

The design of the main and secondary functional elements is a process that takes place in parallel in everyday design, as both groups may have a strong influence on each other. The pump–valve module (Fig. 9.49) is one of the main functional elements. Its decisive design requirements are those resulting from the biomedical process variables (size of the metered volume) and the boundary conditions resulting from the technical requirements (low mass, small space requirement, etc.)

A secondary functional element is the cell vessel which contains 15 ml of cell liquid at the beginning and into which the activator is injected before weightlessness starts, followed by the stopping solution after

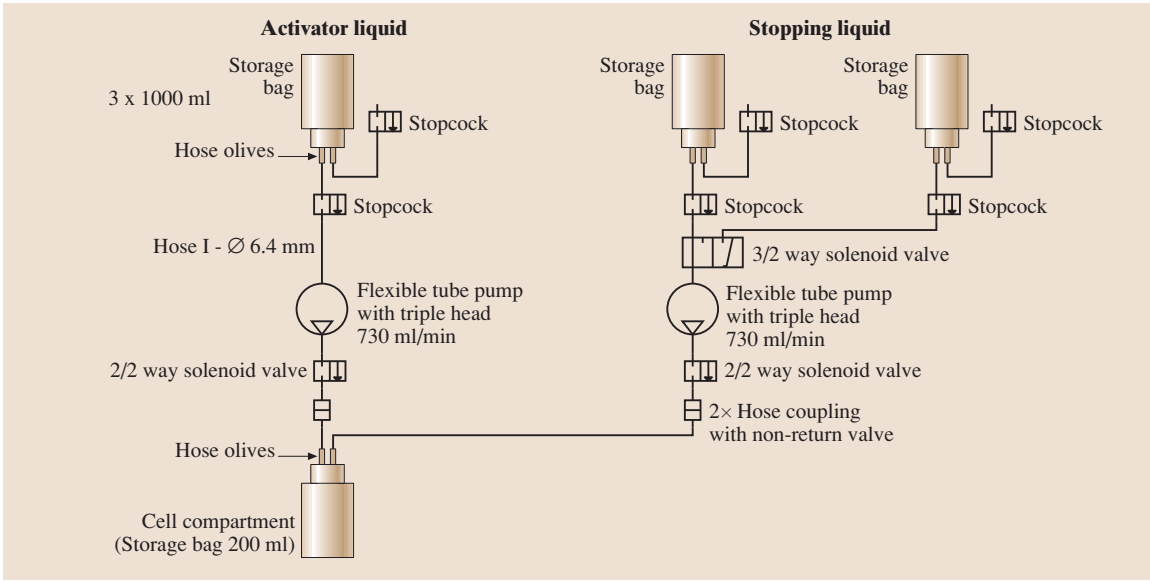

Fig. 9.45 Flow diagram for a cell vessel to be filled

approximately 22–25 seconds. The filling must be able to take place under the exclusion of air and in sterile conditions. Further, due to the safety requirements, this vessel must be designed with a double wall and enable fast removal of the contained liquids after the experiment. For biological and economic reasons the inner part of the vessel should be a one-off (disposable) product and the outer one should be reusable. Due to these requirements, further solutions were conceived and tested (Fig. 9.47).

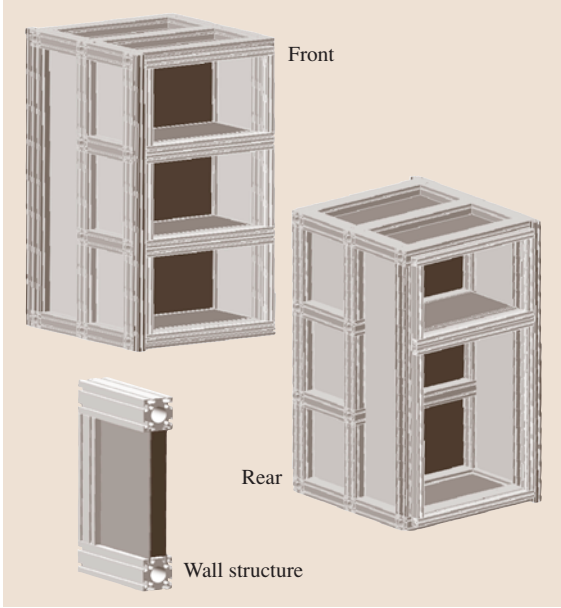

Fig. 9.46 Working module rack: front, rear, wall structure

Option 1 consists of an inner infusion bag integrated into a conventional 1 l plastic bottle. The connections are realized via the hose olives screwed into the bottle lid. Option 2 has a similar structure with a second liquid bag with a screw lid that provides the second wall. In the third solution the outer enclosure is formed by a specially produced plastic enclosure made using a rapid prototyping method.

The first two options have a very favorable price as all the components are production items. However they contain substantial defects in their functional fulfilment (filling under the exclusion of air). The reason for this is that, when the inner infusion bag is screwed in, it irreversibly twists. As a result, clear material flow is not possible, i. e., the basic design rule *clear* was not fulfilled. The third option is the most costly. However, it enables complete functional fulfilment according to the requirements. This is the preferred option and was released for design optimization. The result of the design using a continuous functional test during the optimization phase is shown in Fig. 9.48.

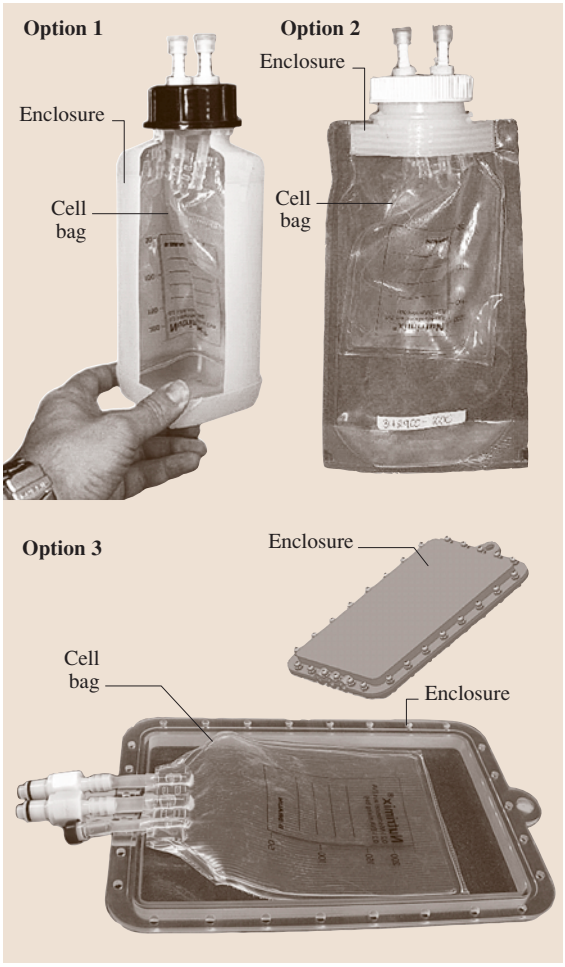

Fig. 9.47 Possible options for the secondary functional element: cell vessel (cell compartment)

9.5.4 Evaluation According to the Technical and Economic Criteria and Specification of the Preliminary Overall Design

During the design and associated continuously performed testing and control process it was found that individual technical requirements such as:

- Compliance with the maximum module dimensions
- Compliance with the maximum mass
- Compliance with the electricity consumption

could not be realized. Deviations from the requirements set in the requirements list were found.

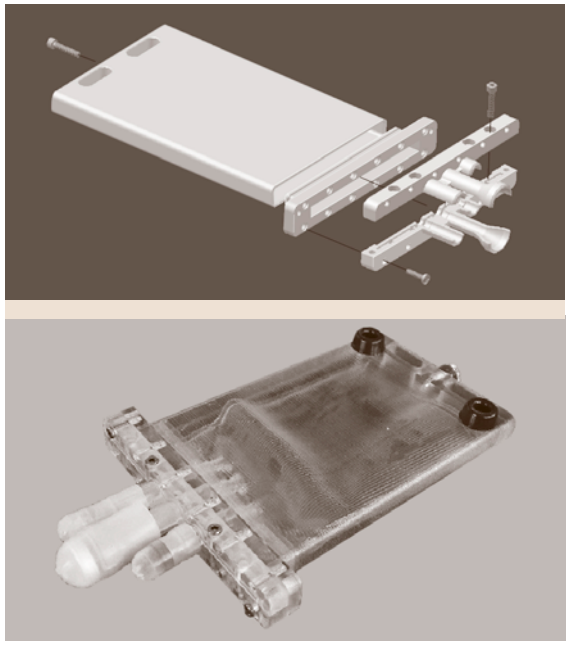

Fig. 9.48 Cell vessel structure

Furthermore, in this phase of the development work the functional fulfilment was checked. No deviations from the requirements list were found. The

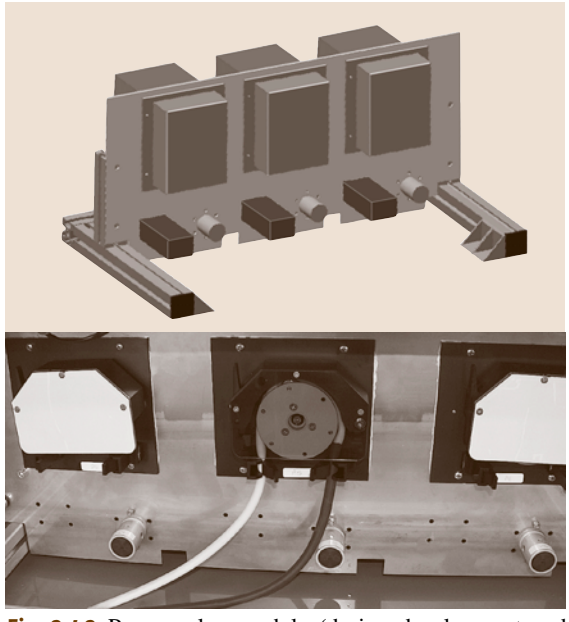

Fig. 9.49 Pump–valve module (during development and assembly)

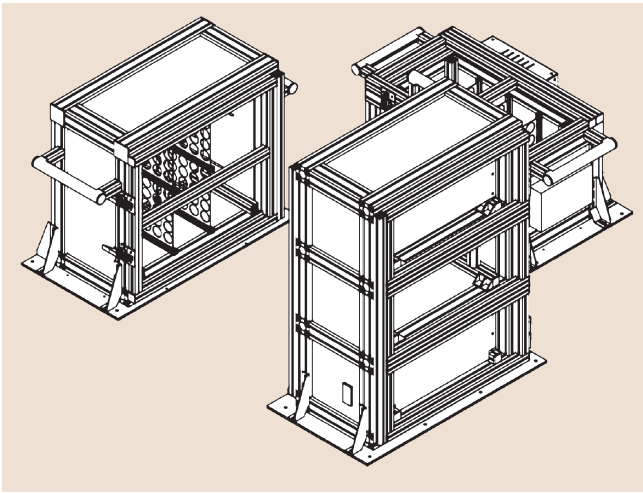

Fig. 9.50 Design for the experiment modules

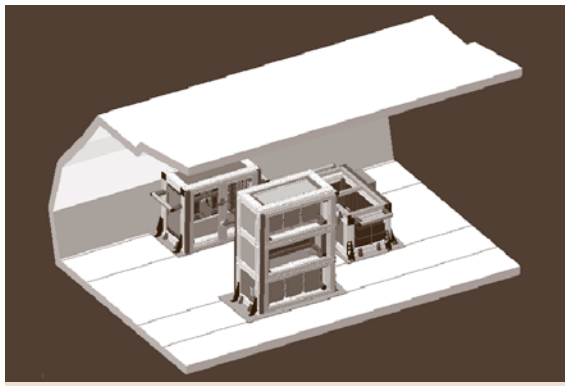

Fig. 9.51 Experiment modules

specified delivery rates of the pumps were fulfilled. The temperature ranges to be realized were achieved and the whole operational sequence was clear.

With respect to the economic criteria to be realized, there were also no deviations from the requirements list. All the specifications, such as material costs or production and assembly costs, were met.

A second design was drawn up based on the deviations from the requirements list. This design consisted of three separate modules (Fig. 9.50).

Module 1: The heating module for storing the cell compartments at 37 °C (incubator) before the experiment

Module 2: The actual working module, in which the cell vessels are filled

Module 3: The cooling module for storing the cell vessels after the experiment (4 °C)

This design was able to fulfil all of the technical and economic requirements and was released for further design work.

In the final phase of the design stage it is necessary to adapt the solution to existing standards and regulations. The individual components are assigned binding materials. During this phase, among other things, the drawings relevant for production are completed and the product documentation is produced. Figure 9.51 shows the result of the development.

9.5.5 Subsequent Consideration, Error Analysis, and Improvement

The main activities during the design phase according to [9.3] include the item: *checking for errors and disrupting effects*. This is a meaningful and necessary activity during design to prevent abortive development. However, systematic error analysis was only possible to a limited extent for the developed modules. Unlike other projects, in which empirical values already exist, process sequences are easy to follow or tests, or preliminary trials performed in parallel with the development process help to check for errors or faults, the analyses carried out for the experiment modules described here were to a large extent based on assumptions. During the development phase it was not possible to realize the condition of microgravitation for testing of the modules of the test setup. For this reason it was important to document and analyze the sequence and function of the modules during the parabolic flights. This was the only way to specifically enable error corrections and improvements. Several examples of modifications to the modules are listed in the following:

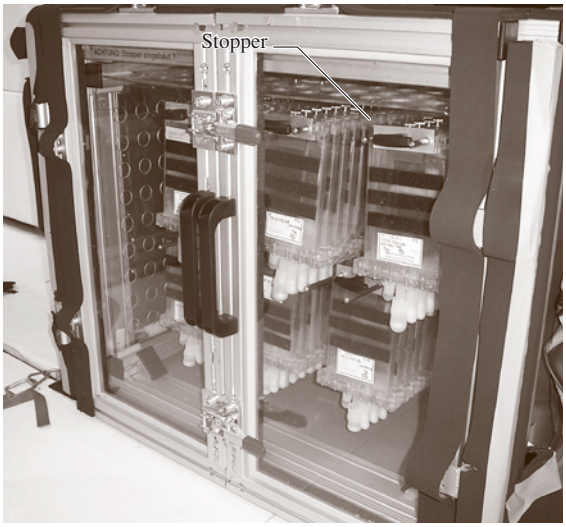

Fig. 9.52 Stopper in the heat module

- Most of the hoses from the medium replaced with rigid pipes
- Integration of safety sensors to identify the presence of the vessels to be filled before injection starts
- Replacing the manually opened venting valves in the cell vessels with automatically opening valves
- Improving the fixing (stoppers) of the cell vessels in the heating and cooling module

These modifications will be realized for subsequent flights.

The development and design of engineering systems according to methodical aspects based on information from the literature [9.1–3] is a useful procedure. The guidelines of design methodology were also applied in this interdisciplinary development project together with its tools, such as the requirements list, functional structure and morphological box, to name just a few. During the design phase of the product development process it was important to comply with the basic design rules: *simple*, *clear* and *safe* [9.3]. Several items that clearly show the realization of these three criteria are:

1. Simple:
   - Use of a module system for the rack design.
   - Only 15% of the required components are specially made (turned or milled parts).
2. Clear:
   - The liquid flow path is clear and does not lead to indefinable conditions.
3. Safe:
   - Redundant arrangement of parts absorbing forces and
   - Fixing of moving parts (cell vessels)

Primary importance was placed on realizing the direct safety requirements during the development activity. This task was successfully solved.

However, unlike the theoretical principles, practical experience shows that, especially during the conceptual and design phases, the experience and intuition of the designer are increasingly used to find the solution and systematic development is consciously dispensed with. This is not due to the fact that taught theoretical procedures are not generally practical, but to the increasing time and cost pressure for the development. It is often not possible for the designer to define several options for all main and secondary functions or to produce designs for the overall and part solutions and still produce a solution on schedule and within the cost framework. Here there is a risk that technically and economically better solutions are overlooked. One example from the project above is the fixing mechanisms (stoppers, Fig. 9.52) for limiting the sixth degree of movement for fixing the cell vessels in the working and heating module. Several optional solutions were not determined for this secondary functional element in advance, but instead the *first best* solution was used. In the technical test evaluations after the flights the operating personnel complained that due to the high stresses during parabolic flight these stoppers were difficult to undo and refasten. This solution had worked, but not optimally and will be changed for the next series of flights.

9.6 Design and Manufacturing for the Environment

The environment can be envisioned as interacting with human society in two ways: as a *source* of natural resources, and as a *sink* for emissions and wastes. The environmental problems addressed here are all related to overuse of both sources and sinks. Overuse of sources shows up as depletion and the reduced quantity and quality of resources. Overuse of sinks shows up as unbalancing of the harmony of previously natural pro-

Table 9.3 List of environmental concerns and links to manufacturing processes

Environmental concerns	Linkage to manufacturing processes
1. Global climate change	Greenhouse gas (GHG) emissions from direct and indirect energy use, landfill gases, etc.
2. Human organism damage	Emission of toxins, carcinogens, etc. including use of heavy metals, acids, solvents, coal burning
3. Water availability and quality	Water usage and discharges, e.g., cooling and cleaning use in particular
4. Depletion of fossil fuel resources	Electricity and direct fossil fuel usage, e.g., power and heating requirements, reducing agents
5. Loss of biodiversity	Land use, water usage, acid deposition, thermal pollution
6. Stratospheric ozone depletion	Emissions of chlorofluorocarbons (CFCs), hydrochlorofluorocarbon (HCFCs), halons, nitrous oxides, e.g., cooling requirements, refrigerants, cleaning methods, use of fluorine compounds
7. Land use patterns	Land appropriated for mining, growing of biomaterials, manufacturing, waste disposal
8. Depletion of non-fossil fuel resources	Materials usage and waste
9. Acid disposition	Sulfur and NO_x emissions from smelting and fossil fuels, acid leaching and cleaning

cesses. Often the change in balance takes years to detect and can be influenced by a variety of factors, making isolation and identification of the problems difficult and sometimes controversial. Nevertheless, over time many of these problems have been identified. They include ozone depletion, global warming, acidification, and eutrophication, among others. Corrective action often involves changes in the types and ways we use materials and energy for the production, use, and disposal of products. Table 9.3 lists commonly agreed environmental concerns and aspects of production, consumer use, and disposal that contribute to these concerns.

Table 9.3 clearly conveys the message that many of our environmental problems are directly related to materials usage, including energetic materials. In particular, note that several prominent concerns listed in Table 9.3 are directly related to our use of fossil fuels to generate energy. These include: CO_2 and NO_x emissions from the combustion of all fossil fuels, and SO_x and several heavy metals including As, Cd, Cr, and Hg, which are deposited onto land from the combustion of coal [9.48, 49]. In fact, at least four out of nine of the concerns listed above are related to fossil fuel use, including numbers 1, 2, 4, and 9. Because of this overriding importance, we will pay particular attention to tracking energy usage in the life cycle of products.

9.6.1 Life Cycle Format for Product Evaluation

A very important aspect of environmental analysis simply involves *connecting the dots*, in other words, showing the interconnectivity of human activities, and in particular, material flows. Few people contemplate where resources come from, or where they go after they are used, yet this is essential for life cycle analysis. With a life cycle accounting scheme one can then properly *burden* each product or activity with its environmental load. This information, in turn, can be used to answer the question, *is the utility gained from this product or activity worth the associated environmental load*? Although conceptually simple, this task is, in fact, quite complex. The major complexities are:

1. Establishing system boundaries
2. Obtaining accurate data
3. Representing the data with concise descriptors that appropriately assign responsibility
4. Properly valuing the results

Our approach will be to represent the product using material flow diagrams that capture the major inputs and outputs. In general, we will not attempt to relate these inputs and outputs to specific levels of environmental harm but only to identify them as *environmental loads*, known to cause harm, and which are excellent targets for technical improvement. When specific amounts of inputs used or outputs emitted are given, this type of analysis is called a life cycle inventory (LCI). The full life cycle analysis (LCA) includes LCI plus a connection between the loads produced and associated harm caused and often a ranking value among the different types of harm. Some LCA methods use these ranking values to generate a single number result. This can greatly ease decision-making, but requires agreement

with all of the implied value tradeoffs, something that is often difficult to accomplish.

Before proceeding further, it is important to more clearly establish the idea of a product life cycle. This is generally conceived as a materials flow process that starts with the extraction of raw materials from the Earth and ends with the disposal of the waste products back to the Earth. The general stages of this linear *once-through* cycle are:

1. Material extraction
2. Primary processing and refining
3. Manufacturing
4. Product distribution
5. Use
6. Final disposition

This sequence follows the principal product material flow, but of course there are multiple cross flows (consider the materials used by products, e.g., paper in printers and gasoline in automobiles) as well as back flows, such as product reuse, component remanufacturing, and material recycling. Figure 9.53 illustrates these flows in a general way, indicating cross flows both from nature and society as well as the major recycling flows. Society can then be represented by a vast array of these networks, interconnected but ultimately all originating from and leading to the ground – the Earth. This thought experiment clearly suggests the complexity of our problem. In practice this task is simplified by clearly defining the system boundaries and the objectives of the life cycle study. Problems can arise when the system considered is too large due to the interconnectivity of materials systems, and when the system considered is too small due to truncation. Matrix inversion methods, identical to those used in economic input–output analysis [9.50], along with high-level summary statistics have been called upon to help with the first problem [9.51, 52], while experience, iteration, and hybrid approaches are used to address the second [9.53, 54].

The commonest practice among LCA practitioners is based on developing process flow diagrams similar to Fig. 9.53 for the product, and tracing the major input and output paths to Earth. This requires data such as a bill of materials and lists of manufacturing processes, common use scenarios, distribution channels, and end-of-life characteristics for the product. The output is then a long list of material and energy inputs as well as emissions to the environment. These lists can easily include hundreds of materials, which then require some simplification and aggregation for interpretation. In this chapter, we will use a simplified format suggested by *Graedel* in his book on streamlined life cycle analysis (SLCA) [9.55]. This involves examining each stage of the life cycle and identifying major impacts and opportunities for improvement in five categories:

1. Materials choice
2. Energy use
3. Solid residues
4. Liquid residues
5. Gaseous residues

Graedel then suggests scoring each stage of the life cycle for each of the five categories with a numerical score from 0 (the worst) to 4 (the best). These scores are given relative to best practice for the product under consideration. In general, a score of 0 is reserved for a blatantly poor and/or uninformed practice that raises significant environmental concern, while a score of 4

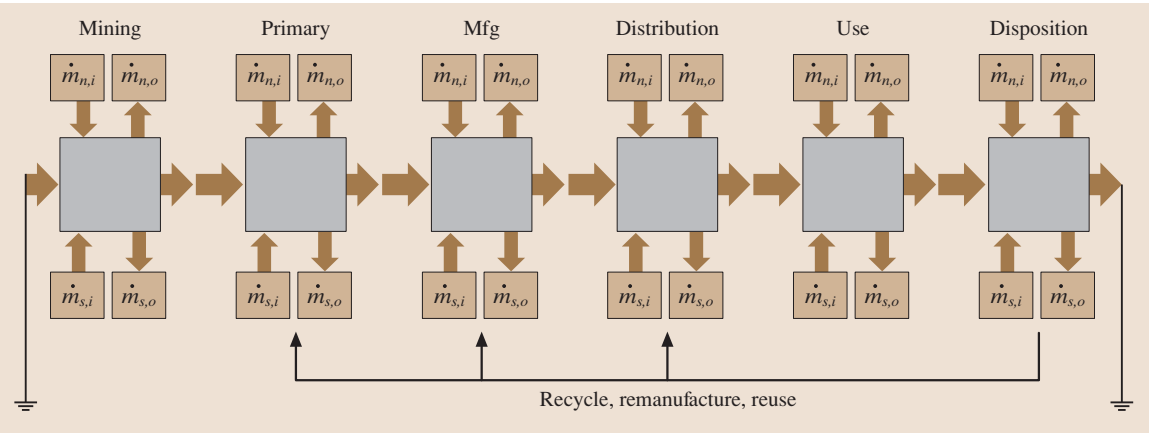

Fig. 9.53 Product life cycle material flows (m_n represent exchanges with nature, m_s represent exchanges with society)

Table 9.4 The environmentally responsible product assessment matrix [9.55]

Life cycle stage	Environmental stressor				
	Materials choice	Energy use	Solid residues	Liquid residues	Gaseous residues
Premanufacture	11	12	13	14	15
Product manufacture	21	22	23	24	25
Product delivery	31	32	33	34	35
Product use	41	42	43	44	45
Refurbishment, recycling, disposal	51	52	53	54	55

(The numbers are the indices for the matrix element M_{ij})

indicates excellent environmental performance with no known serious concerns. A perfect product would thus obtain a score of 100. Graedel gives more detailed guidance on how to score each element of the 5×5 matrix, as shown in Table 9.4, which represents the product.

9.6.2 Life Cycle Stages for a Product

In this section we will identify some of the major environmental issues that appear in each of the five stages of a product life cycle. The scoring of products for SLCA depends on the extent to which the designer and manufacturer make an effort to avoid these problems and substitute alternative materials and technology when possible.

Premanufacture: Materials Extraction and Primary Processing

Many of the environmental impacts associated with materials selection appear to occur in the very early stages of the material life cycle. This can be surmised by looking at United States national statistics for energy use, pollutants, and hazardous materials by various industrial sectors. For example, in Fig. 9.54, some of the manufacturing industries are broken down by standard industrial categories [standard industrial classification (SIC) codes] in terms of CO_2 and toxic materials per value of shipments. The primary processing of chemicals, petroleum and coal, and primary metals, have significantly larger environmental loads than other manufacturing sectors such as plastics and rubber, fabricated metals, machinery, electronics, and transportation. While not shown in Fig. 9.54, the metal mining industry would also show up prominently on this list. For example, toxic material releases for US metal mining in 1998 were equal to 145% of the toxic material releases from all of the manufacturing industries in the United States combined (including primary processing) [9.56].

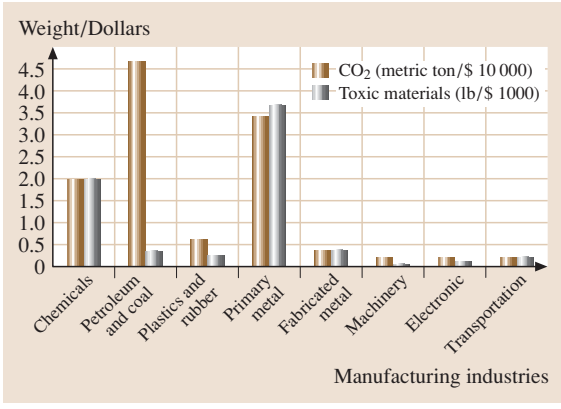

Fig. 9.54 CO_2 and toxic materials for several manufacturing industries

These large normalized impacts can be explained in two ways: relatively large emissions and relatively low prices. Primary processing industries handle very large quantities of materials, introducing many opportunities for economies of scale. At the same time, this high materials usage leads to high waste and emissions levels. For example, mining is very material intensive, producing ore waste-to-metals ratios that range from about 3:1 for iron and aluminum, to 10 000:1 for gold. In addition, many metals exist as, or occur in companion with, metallic sulfides. Once these materials are exposed to the surface they can oxidize into sulfates and sulfuric acid runoff, which can cause significant damage by acid mine drainage. Many of the commonest metals can lead to acid mine drainage, including copper, iron, nickel, lead, and zinc. In addition, some of the early processes can use other hazardous materials. If these materials escape, widespread environmental damage can occur. For example, the leaching of gold employs toxic cyanide compounds.

Table 9.5 Typical energy requirements for some common materials [9.57]

Material	Energy cost (MJ/kg)	Made or extracted from
Aluminum	227–342	Bauxite
Copper	60–125	Sulfide ore
Glass	18–35	Sand, etc.
Iron	20–25	Iron ore
Nickel	230–70	Ore concentrate
Paper	25–50	Standing timber
Polyethylene	87–115	Crude oil
Polystyrene	62–108	Crude oil
Polyvinylchloride	85–107	Crude oil
Silicon	230–235	Silica
Steel	20–50	Iron
Titanium	900–940	Ore concentrate
Wood	3–7	Standing timber

Table 9.6 Toxicity ratings for some of the elements [9.49]

Toxicity rating	Example elements
High toxicity	Beryllium, arsenic, cadmium, mercury, lead,
Moderate toxicity	Lithium, boron, chromium, cobalt, nickel, copper, bismuth
Low toxicity	Aluminum, silicon, titanium, iron, zinc, bromine, silver, tin, tungsten, gold,

Similarly, primary materials processing can be both materials and energy intensive. For example, the production of 1 kg of aluminum requires on the order of 12 kg of input materials and 290 MJ of energy [9.57]. The energy for this production plus other processing effects, in turn, leads to about 15 kg of CO_2 equivalent for every kg of aluminum produced [9.58]. Table 9.5 gives the energy requirements for some materials. Note that aluminum is in the high range of these materials, on the order of silicon but substantially less than titanium. The substitution of recycled materials can greatly reduce this energy requirement. Conversely the requirement for ultrahigh purity can greatly increase this requirement. For example, the recycled energy requirement versus *virgin* material is only about 5% for aluminum and 30% for steel [9.59], while the energy requirements for wafer-grade silicon used in the semiconductor industry is about 33 times that of commercial grade [9.60]. Hence, the mere act of selecting materials can in itself define a large part of the environmental footprint for a product. *Graedel* and *Allenby* suggest several other criteria to consider when selecting materials, including toxicity and abundance [9.49]. The ratings for some elements are given below in Tables 9.6 and 9.7.

Manufacturing Processes

As a group, manufacturing processes appear to be quite benign compared to materials extraction and primary processing, as indicated in Fig. 9.54. However, manufacturing processes often set many of the requirements for primary processing outputs. For example, processes with higher scrap rates require more energy in primary processing. Alternatively, processes that can use large quantities of recycled materials will have greatly reduced primary energy needs. This concept can be illustrated more rigorously by writing an equation for the embodied energy content for a hypothetical manufacturing process that uses E_m energy per kilogram of product produced. It has become common to discuss the energy "used up" in a process, but by the first law of thermodynamics we know that the energy is not actually lost. Rather, it is made unavailable. A more accurate thermodynamic quantity, *exergy* can be used up, and is more precisely what we mean in our discussion of *energy used*. Let the waste fractions be: α to ground, γ to recycle, and β to *prompt scrap* (recycled within the factory). This process uses a fraction ϕ of primary material with

Table 9.7 Classes of supply for some of the elements [9.49]

Worldwide supply	Example elements
Infinite supply	Bromine, calcium, chlorine, krypton, magnesium, silicon
Ample supply	Aluminum (gallium), carbon, iron, potassium, sulfur, titanium
Adequate supply	Lithium, phosphorus
Potentially limited supply	Cobalt[a], chromium[b], nickel[a], lead (arsenic, bismuth), platinum[b], zirconium
Potentially highly limited supply	Silver, gold, copper, mercury, tin, zinc (cadmium)

[a] Supply is adequate, but virtually all from South Africa and Zimbabwe. This geographical distribution makes supplies potentially subject to cartel control.
[b] Maintenance of supplies will require mining seafloor nodules. Note that materials in parentheses are co-mined with the parent material listed in front.

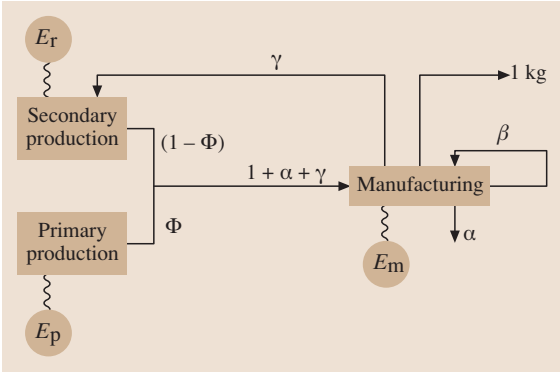

Fig. 9.55 System energy requirements for a manufacturing process

embodied energy E_p and a fraction $(1-\phi)$ of recycled material with embodied energy E_r, where in general $E_r \leq E_p$. From this, the sum of the energy requirement E_s, to produce one kilogram of product is (Fig. 9.55)

$$E_s = (\phi E_p + (1-\phi)E_r)(1+\alpha+\gamma) + E_m(1+\alpha+\beta+\gamma)\,. \quad (9.1)$$

Hence, even though it may be that $E_m \ll E_p$, (9.1) illustrates the long reach of the manufacturing process and its influence both up and down the product life cycle. As an example, consider the differences between machining and casting a part. While it might be true that $E_{m\,casting} > E_{m\,machining}$, generally speaking $\phi_{machining} \gg \phi_{casting}$. Furthermore, the waste for machining, particular α and γ, which show up in the first part of (9.1), can be quite large. In contrast, for large casting operations, most metal waste shows up in β, which does not occur in the first term. Hence in some situations, and quite counterintuitively, casting may be a more environmentally benign process than machining. Of course, this statement is based only on embodied energy usage and ignores other possible emissions.

Generally speaking however, while primary processing adds energy of order 100 MJ/kg (E_p) to any product, manufacturing adds energy of order 10 MJ/kg (E_m) [9.61,62]. The real role of manufacturing is that it draws in materials and energy not directly incorporated into the product and then expels them, often as wastes or emissions to the environment.

In addition to fossil fuel usage, a second environmentally important class of materials used in manufacture is cleaning fluids and coatings. Manufacturing often involves the cleaning and preparation of surfaces. Of particular concern are many of the solvents that are used to remove cutting fluids, lubricants, and other materials from the surface of the parts. In order to avoid the use of hazardous materials, many manufactures have replaced organics with water-based and mechanical cleaning methods [9.63].

Product Delivery

Product delivery involves two important types of environmental loads: transportation and packaging. The transportation of products around the world provides jobs and opportunities for many, but at the same time constitutes a major component of energy usage and related emissions. Furthermore, the geographical separation of product use from manufacturing can create significant barriers for the recycling of some materials.

Packaging waste is particularly egregious because of the large amounts of materials with only a very short intended lifetime. Furthermore, the customer gets the opportunity to experience this waste first hand.

Product Use

It is probably true that the vast majority of consumer appliances, electrical products, vehicles, lawn equipment, power tools, etc. – in short anything that has a power cord or runs on gasoline – has its largest or second largest impact during the use phase. Products with power cords draw energy from the utility station, which, in the US, have an average efficiency of about 35% and still burn 50% coal. These two facts alone often completely dominate the environmental impact of some products. Furthermore, powered devices can consume still other materials, e.g., paper and ink in printers, coffee in espresso machines, water in refrigerators with electric ice makers, etc. By and large, these automated appliances are considered desirable conveniences, but automated usage often, and unintentionally, leads to automated waste too.

Disposition

Most products in the USA end up in landfills, some are incinerated, and a few are recycled. In general, US landfill access has been significantly diminishing, particularly in the highly populated northeast. Many states have been closing landfills faster than they are opening new ones. Some states have moratoriums on new landfill development, and many ship their waste out of state. Furthermore, lined landfill sites for the collection of hazardous materials are highly restricted, leading to very high transportation and disposal costs for hazardous substances.

While incineration is not very popular in the USA, particularly in well-to-do communities, it is very much

an active option for a significant portion of the municipal solid waste (MSW) generated. Incineration can be combined with an electrical generation facility to produce power. Furthermore, the emissions can be scrubbed for various emissions. Nevertheless, it is difficult to tightly control the incoming waste stream and hence a wide variety of emissions, some not anticipated, can occur. In addition, it is well known that municipal incinerators are one of the top producers of dioxins in the USA, which are extremely expensive to scrub [9.64, 65]. Dioxins are a group of chemicals that have been found to be highly persistent, toxic, and carcinogenic.

A number of products are widely recycled in the USA. These include automobiles, tires (as a fuel to generate energy), newspapers, aluminum cans and, to a lesser extent, mixed paper and high-density polyethylene (HDPE) and polyethylene terephthalate (PET) bottles.

9.6.3 Product Examples: Automobiles and Computers

LCA, LCI, and SLCA can all help identify where major opportunities for environmental improvement occur for a product. The results depend on the product characteristics and the environmental loads of concern. Often our attention goes to those loads with the highest environmental profile. For example, in the life of a paper cup the use stage is short and the disposal can be benign, hence our attention goes immediately to the papermaking process, which has a variety of issues, many associated with the pulp bleaching process for kraft paper making, and possibly to the distribution stage, if the cups are transported a long distance. Another example, the disposable diaper, focuses attention on the waste disposal problem, while the reusable cloth diaper focuses attention on the energy-intensive washing cycle. Other products can be more complex, with major issues in several life cycle stages. Here we review life cycle issues for automobiles and computers.

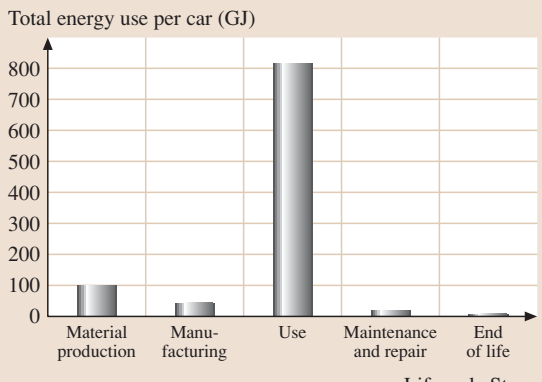

Fig. 9.56 Total energy use by life cycle stage for an automobile (after [9.66])

Table 9.8 Characteristics of generic automobiles [9.55]

Characteristics	ca. 1950s automobile	ca. 1990s automobile
Material (kg)		
Plastics	0	101
Aluminum	0	68
Copper	25	22
Lead	23	15
Zinc	25	10
Iron	220	207
Steels	1290	793
Glass	54	38
Rubber	85	61
Fluids	96	81
Other	83	38
Total weight (kg)	1901	1434
Fuel efficiency (miles/gallon)	15	27
Exhaust catalyst	No	Yes
Air conditioning	CFC-12	HFC-134a

Automobiles

The automobile has been subject to numerous studies concerning its environmental load [9.55, 66–71]. This discussion focuses on the automobile as a product. Other issues related to the automobile, for example how it has shaped our lifestyles and land use patterns, while very important, are not included in this discussion. As one can imagine, given the tens of thousands of parts, and the complexity of consumer behavior, vehicle types, and driving conditions, this is an enormous task. Yet, in spite of all of this complexity, the results have been quite consistent. By far the most important place to look for opportunities for environmental improvement is in the vehicle use stage. It is during this approximately 10 year period where the average vehicle, with a fuel efficiency of about 10 km/l (23.8 miles/gallon), burns about 14 metric tons of gasoline while traveling about 120 000 miles. Furthermore, due to the stoichiometry of the combustion process, this fuel consumption translates into some 40 metric tons of CO_2. When other aspects of the life cycle are included (the energy to make

Table 9.9 Premanufacturing ratings [9.55]

Element designation		Element value & explanation: 1950s automobile		Element value & explanation: 1990s automobile	
Materials choice	1, 1	2	Few hazardous materials are used, but most materials are virgin	3	Few hazardous materials are used, and much recycled material, Pb in battery in closed recycle loop
Energy use	1, 2	2	Virgin material shipping is energy intensive	3	Virgin material shipping is energy intensive
Solid residue	1, 3	3	Iron and copper ore mining generate substantial solid residues	3	Metal mining generates solid residues
Liquid residue	1, 4	3	Resource extraction generates moderate amounts of liquid residues	3	Resource extraction generates moderate amounts of liquid residues
Gas residue	1, 5	2	Ore smelting generates significant amounts of gaseous residues.	3	Ore processing generates moderate amounts of gaseous residues

Table 9.10 Product manufacture ratings [9.55]

Element designation		Element value & explanation: 1950s automobile		Element value & explanation: 1990s automobile	
Materials choice	2, 1	0	Chlorinated solvents, cyanide	3	Good materials choices, except for lead solder waste
Energy use	2, 2	1	Energy use during manufacture is high	3	Energy use during manufacture is fairly high
Solid residue	2, 3	2	Lots of metal scrap and packaging scrap produced	3	Some metal scrap and packaging scrap produced
Liquid residue	2, 4	2	Substantial liquid residues from cleaning and painting	3	Some liquid residues from cleaning and painting
Gas residue	2, 5	1	Volatile hydrocarbons emitted from paint shop	3	Small amounts of volatile hydrocarbons emitted

Table 9.11 Product delivery ratings [9.55]

Element designation		Element value & explanation: 1950s automobile		Element value & explanation: 1990s automobile	
Materials choice	3, 1	3	Sparse, recyclable materials used during packaging and shipping	3	Sparse, recyclable materials used during packaging and shipping
Energy use	3, 2	2	Over-the-road truck shipping is energy intensive	3	Long-distance land and sea shipping is energy intensive
Solid residue	3, 3	3	Small amounts of packaging during shipment could be further minimized	3	Small amounts of packaging during shipment could be further minimized
Liquid residue	3, 4	4	Negligible amounts of liquids are generated by packaging and shipping	4	Negligible amounts of liquids are generated by packaging and shipping
Gas residue	3, 5	2	Substantial fluxes of greenhouse gases are produced during shipment.	3	Moderate fluxes of greenhouse gases are produced during shipment

the fuel, etc.) and other greenhouse gases are converted into their CO_2 equivalent, the resulting equivalent CO_2 emissions over the life time of the vehicle are about 94 metric tons or 9.4 t/year. Other emissions during the use stage are also high, including NO_x, volatile organic compounds (VOCs), which contribute to ground-level ozone and smog, and other hazardous materials at lower levels. Other areas of concern are painting and cleaning during manufacturing, leaks and emissions during use and maintenance, and remaining quantities of unrecyclable materials: plastics, glass, foam, rubber, etc. The total energy use by stage, shown in Fig. 9.56, indicates that energy use during material production and manufacturing are also significant [9.66].

A general assessment of how the environmental performance of the automobile has changed over the years can be found in Graedel, who performed an SLCA to compare a 1950s automobile to one from the 1990s [9.55]. The assumed characteristics of the cars are given in Table 9.8. Their ratings for each of the five impact categories in each of the five life cycle stages are given in Tables 9.9–9.13. The final matrix values are summarized in Tables 9.14, 9.15, and plotted as a target plot in Fig. 9.57.

Computers

The study of the environmental footprint for computers is an interesting contrast to automobiles. While auto-

Table 9.12 Product use ratings [9.55]

Element designation		Element value & explanation: 1950s automobile		Element value & explanation: 1990s automobile	
Materials choice	4,1	1	Petroleum is a resource in limited supply	1	Petroleum is a resource in limited supply
Energy use	4,2	0	Fossil fuel energy use is very large	2	Fossil fuel energy use is large
Solid residue	4,3	1	Significant residues of tires, defective or obsolete parts	3	Modest residues of tires, defective or obsolete parts
Liquid residue	4,4	1	Fluid systems are very leaky	3	Fluid systems are somewhat dissipative
Gas residue	4,5	0	No exhaust gas scrubbing; high emissions	2	CO_2, lead (in some locales)

Table 9.13 Refurbishment/recycling/disposal ratings [9.55]

Element designation		Element value & explanation: 1950s automobile		Element value & explanation: 1990s automobile	
Materials choice	5, 1	3	Most materials used are recyclable	3	Most materials recyclable; plastics, glass, foam not recycled; sodium azide presents difficulty
Energy use	5, 2	2	Moderate energy use required to disassemble and recycle materials	2	Moderate energy use required to disassemble and recycle materials
Solid residue	5, 3	2	A number of components are difficult to recycle	3	Some components are difficult to recycle
Liquid residue	5, 4	3	Liquid residues from recycling are minimal	3	Liquid residues from recycling are minimal
Gas residue	5, 5	1	Recycling commonly involves open burning of residues	2	Recycling involves some open burning of residues

mobiles use mostly conventional materials and many standard manufacturing processes, the microchips in computers use much more-specialized materials and rapidly changing process technology. The result is that the complete life cycle of the computer has not been filled in to the extent that the automobile has. This is clearly illustrated in the important paper by *Williams*, *Ayres*, and *Heller* [9.60], which illustrated that there is far less agreement on the magnitudes of the environmental impacts associated with microchip fabrication.

Nevertheless the available data indicate that microelectronics fabrication is very materials and energy

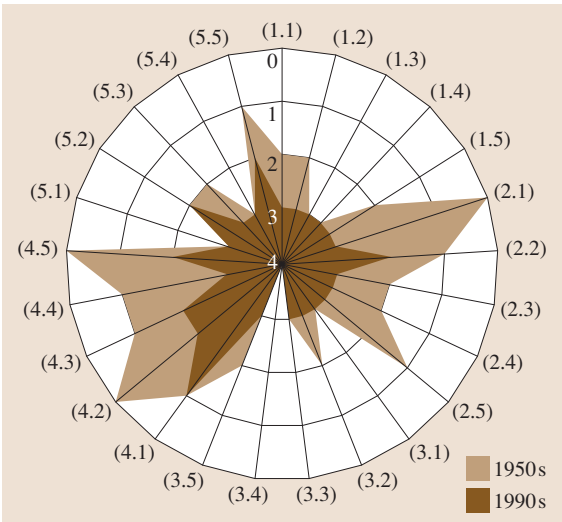

Fig. 9.57 Target plot of the environmental impact of generic automobiles for the 1950s and 1990s, see text (after [9.55])

intensive, in fact orders of magnitude more so than, for example, automobile manufacturing. In particular, approximately 1.7 kg of materials (including fuel) are needed to make a 2 g microchip. This certainly undermines some claims that microelectronics represent a form of dematerialization. Some of the chief findings of Williams et al. are summarized in Table 9.16.

At the same time, it is important to keep in mind that a computer is made up of much more than microchips, and the life cycle includes more than the fabrication stage. An approximate bill of materials for a desktop computer and cathode ray rube (CRT) monitor are given in Table 9.17. In this context the microchips and their constituents hardly show up. In fact many of the materials used in a computer are rather conventional. However, there are some materials of concern. Lead is present in both the central processing unit (CPU) and the monitor, cadmium (not listed) may be present in the batteries, mercury can be used in some switches

Table 9.16 Chief findings for microelectronics fabrication for a dynamic random-access memory (DRAM) chip [9.60]

Mass of 32 MB DRAM chip	2 g

and is used in laptop displays, and there is growing concern, particularly in Europe, over brominated flame retardants, which are used in the plastics.

Currently, there is active work to develop a complete life cycle analysis available for computers. An earlier study looked at energy, waste, hazardous materials and water used in the life cycle of a computer workstation [9.55,73], and more-recent information particularly on the fabrication, use, and end of life stages for a personal computer is given by *Kuehr* and *Williams* [9.72]. Computers seem to raise concerns at all stages of life. The premanufacture and manufacturing stages are very material and energy intensive due primarily to the high material purity needed for the microelectronics fabrication. Distribution can be a concern due to the large amount of packing materials and the long dis-

Table 9.18 Streamlined life cycle analysis: desktop computer display and CPU. Premanufacturing

i, *j*	Environmental stressor	Score
1, 1	Material choice Few recycled materials are used. Many toxic chemicals are used, including Pb in CRT and PWB, Cd in some batteries, Hg in some switches, and brominated flame retardants in plastics.	0
1, 2	Energy use Extra-high-grade materials for microchip very energy intensive. Other high-energy materials include virgin aluminum, copper, CRT glass.	1
1, 3	Solid residues Many materials are from virgin ores, creating substantial waste residues. Si wafer chain is only 9% efficient.	1
1, 4	Liquid residues Some metals from virgin ores can cause acid mine drainage.	2
1, 5	Gaseous residues Very high energy use and other materials use lead to substantial emissions of toxic, smog-producing, and greenhouse gases into the environment.	1

Table 9.19 Streamlined life cycle analysis: desktop computer display and CPU. Product manufacture

i, *j*	Environmental stressor	Score
2, 1	Material choice Manufacturing uses restricted and toxic materials (see 1,1) plus cleaning solvents.	1
2, 2	Energy use Energy use in production is very high for ICs and PWB and moderate to high for conventional materials. If we examine energy use during the manufacture of individual parts of the computer: microchip (0), printed circuit board (1), cathode ray tube (2), LCD (0), other bulk material (3)	1
2, 3	Solid residues There are large solid residues for chemical processes, such as CVD, PVP and plating, e.g., printed circuit boards yield 12 kg of waste for each kilogram of finished product. Also high performance requirements often result in low yields.	1
2, 4	Liquid residues Large quantities of waste liquid chemicals, e.g., approximately 500 kg of waste liquid chemicals for each kilogram of product including plating solutions and cleaning fluids. Very high volumes of water are also used.	1
2, 5	Gaseous residues Manufacturing energy use and processes lead to substantial emissions of toxic, smogproducing, and greenhouse gases into the environment.	1

Table 9.20 Streamlined life cycle analysis: desktop computer display and CPU. Product packaging and transport

i, *j*	Environmental stressor	Score
3, 1	Material choice Several materials, large quantities, minimal recycling activity.	3
3, 2	Energy use Long distances traveled. Large volumes of materials.	2
3, 3	Solid residues Waste volumes are large, no arrangements to take back product packaging after use.	2
3, 4	Liquid residues Little or no liquid residue is generated during packaging, transportation, or installation.	4
3, 5	Gaseous residues Gaseous emissions are released by transport vehicles.	2

tances some products need to travel. The use phase can be very energy intensive. For example, data given by *Kawamoto* [9.74] and *Cole* [9.75] sets the residential annual energy use for a desktop computer and monitor at about 380 MJ/year. In a commercial/industrial setting where the computer monitor may be on con-

Table 9.21 Streamlined life cycle analysis: desktop computer display and CPU. Product use

i, *j*	Environmental stressor	Score
4, 1	Material choice Power from electrical grid uses 50% coal.	2
4, 2	Energy use High to very high energy usage.	1
4, 3	Solid residues Little direct solid residues (excluding printing functions) but power uses coal, resulting in mining residues.	3
4, 4	Liquid residues Little direct liquid residues (excluding printing function) but coal mining yields liquid residues.	3
4, 5	Gaseous residues No emissions are directly associated with the use of computers. However, gaseous emissions are associated with energy production for use of computers.	1
Does not include printing		

Table 9.22 Streamlined life cycle analysis: desktop computer display and CPU. Refurbishment/recycling/disposal ratings

i, *j*	Environmental stressor	Score
5, 1	Material choice Product contains significant quantities of lead and brominated flame retardants and may contain mercury and cadmium. Often these are not clearly identifiable or easily removable. Many materials are not recycled.	1
5, 2	Energy use The product is not designed for energy efficiency in recycling, or for high-level reuse of materials. Also, the transport of recycling is energy intensive because of weight/volume and location of suitable facilities.	1
5, 3	Solid residues Dissimilar materials are joined together is ways that are difficult to reverse and the product overall is difficult to disassemble. Little recycling. Short life cycle of computers compounds these problems.	1
5, 4	Liquid residues Product contains no operating liquids and minimal cleaning agents are necessary for reconditioning (not including printing functions).	3
5, 5	Gaseous residues Roasting of printed wiring boards (PWBs) to recycle metals leads to emissions.	2

Table 9.23 Streamlined life cycle analysis: desktop computer display and CPU. Environmentally responsible product assessment for the computer display and CPU

Life stage	Materials	Energy	Solid	Liquid	Gaseous	Total
Premanufacture	0	1	1	2	1	**5/20**
Product manufacture	1	1	1	1	1	**5/20**
Product delivery	3	2	2	4	2	**13/20**
Product use	2	1	3	3	1	**10/20**
Recycling	1	1	1	3	2	**8/20**
Total	**7/20**	**6/20**	**8/20**	**13/20**	**7/20**	**41/100**

tinuously, the estimate is 1500 MJ/year. For a 3 year lifetime, this is more than half of the energy used in production. The end-of-life issues are several; there are several *materials of concern* as mentioned earlier, and the shear volume of retired computer and electronics represents a significant solid waste/recycling challenge. Currently only a very small percentage of computers are recycled [about 11%, as estimated by the Environmental Protection Agency (EPA)]. Using the materials lists given in Table 9.17 and the information cited in the references reviewed here [9.55, 60, 72–76] we have developed a baseline SCLA for a 1990s desktop computer and CRT display. The results are given in Tables 9.18–9.23. A target plot is given in Fig. 9.58.

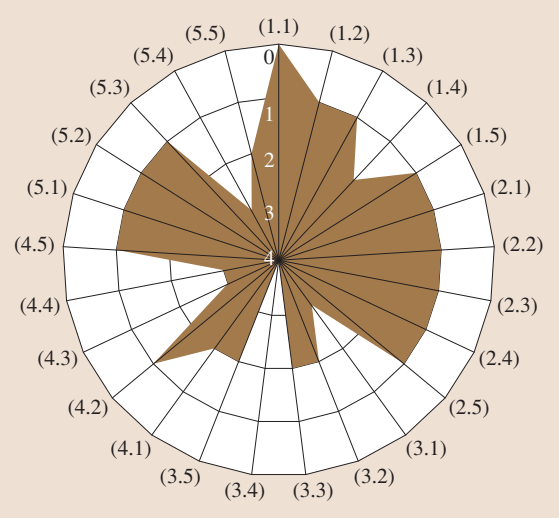

Fig. 9.58 Target plot of the environmental impacts of an early-1990s desktop computer and CRT display, see text (after [9.55])

Using Life Cycle Information for Product and Process Improvement

One of the primary reasons for developing life cycle environmental information is to identify opportunities for improvement. Streamlined life cycle analysis (SLCA) as developed in the two preceding sections is particularly good at this because it provides an overview with an emphasis on high-profile issues. The automobile example illustrates important environmental improvements from the 1950s to the 1990s, at the same time indicating several remaining challenges, particularly related to fossil fuel usage.

The SLCA given for the 1990s desktop computer is intended as a baseline for identifying critical areas for improvement, which are many. In comparison, the current laptop computer would score much more favorably. Important improvements would include:

1. A drastic reduction in the total weight of materials used
2. Elimination of significant amount of lead found in the CRT (although small amounts of mercury are needed for the laptop display)
3. Significantly reduced packing materials
4. Significantly lower energy required in usage

The SLCA methodology presented here is a compact way to learn about a complex problem, however, once a significant target for environmental improvement has been identified by SLCA, a more quantitative life cycle inventory for the material(s) of concern would be warranted. This would allow a much more precise evaluation of potential improvements; for example, Fig. 9.56 shows the total energy used for a generic family automobile in the late 1990s. An LCI study would then connect each of these energy requirements to the energy technology used and the corresponding emissions. For example while the use phase burns gasoline in an internal combustion engine, the material production and manufacturing phases use a mixture of mostly coal along with natural gas, oil, and even nuclear (from the electricity grid). Hence connecting the energy requirements to the fuel cycles would lead to specific contributions of each type of pollutant of interest. For example, energy from electricity in the USA comes from 50% coal, 20% nuclear, 18% natural gas, 7% hydroelectric, 3% oil, and 2% renewables. The corresponding emissions per electricity used are: 633 kg CO_2/MWh, 2.75 kg SO_2/MWh, 1.35 kg NO_x/MWh, and 12.3 gmercury/GWh, where MWh is a megawatt-hour, and GWh is a gigawatt-hour [9.77].

A full-blown life cycle analysis (LCA) would include weightings of the different pollutants based on human value judgments. For example, the LCA software Simapro from the Netherlands employs a weighting scheme called the *Eco-indicator* that reflects the value judgments of Europeans concerning the various environmental issues that concern them. Obviously such schemes could vary widely depending upon local concerns.

Before leaving this section it is worth noting that, because SLCA yields numerical scores for products, it might be tempting to compare different types of products. This is possible but must be done with caution. In the first place the SLCA methodology developed by Graedel and Allenby was intended as a relative indicator for a particular product type. Therefore the methodology would have to be modified. A second problem is that dissimilar products can have vastly different utilities for the users. Hence the comparison may seem nonsensical to some. Nevertheless some comparisons can be useful. For example, Williams has pointed out that the fossil fuel used during the entire life cycle of the production and use for a computer is almost identical to that of a refrigerator even though the computer only lasts about one quarter of the time (2.5 years versus 10 years) and the refrigerator is on all of the time [9.76]. The obvious implication is that much more could be done to improve the energy efficiency of computers.

Table 9.24 Energy efficiency guidelines [9.49, 78, 79]

Action	Reason
Do SLCA/LCI/LCA for product	Identify energy usage
Encourage use of clean renewable energy sources	Reduce harmful by-products and preserve resources
Choose the least harmful source or energy Note for fossil fuels the cleanest is natural gas followed by oil products, and then coal	Reduce harmful by-products
Have subsystems power down when not in use	Reduce energy usage and fossil fuel consumption
Permit users to turn off systems in part or whole	Reduce energy usage and fossil fuel consumption
Avoid high-energy materials	Reduce energy and preserves resources
Avoid high-energy processes	Reduce energy
Specify best-in-class energy efficiency components	Reduce energy usage and fossil fuel consumption
Insulate and/or use waste heat	Reduce losses/increases efficiency

9.6.4 Design for the Environment (DFE)

Design for the environment, like design for manufacturing or design for assembly, is a set of guidelines to help designers meet particular design goals. Often these guidelines are reduced to simple rules that aid understanding. However, behind these rules are observations and models that capture how the product can be expected to perform as the result of certain design decisions.

To a certain extent this whole chapter has been aimed at understanding how products and product decisions result in environmental loads. There can be, however, different environmental goals. For example, designing an automobile for lower fuel consumption may lead to using structural composite materials for weight reduction, whereas designing for recyclability would probably lead to the use of metals for the structural components. In this section we outline some of the generally agreed upon guidelines for two important environmental goals: reduced hydrocarbon fuel consumption and increased recyclability. These are summarized in Tables 9.24 and 9.25.

9.6.5 System-Level Observations

In this section we have presented an overview of engineering actions to lessen the impact of materials use, manufacturing, and design decisions on the environment. One of the goals of this section has been to identify the connections between a product life cycle and the associated environmental loads. To do this we have frequently normalized the environmentally sensitive parameters such as energy requirements or emissions by some measure of useful output such as the weight of the output, the economic activity, or, in some

Table 9.25 Recyclability guidelines [9.49, 78, 80]

Rating	Description or action	Reason or comment
Good	Product is reusable/remanufacturable	Extends life of product
Good	Materials in part are recyclable with a clearly defined technology and infrastructure	Most metals, some plastics in particular: PET & HDPE
Good	No toxic materials, or if present, clearly labeled and easy to remove	Avoid Pb, Hg, Cd
Good	Allow easy removal of materials, avoid adhesives and joining methods which cannot be reversed	Facilitates separation and sorting
Less good	Material is technically feasible to recycle but infrastructure to support recycling is not available	Most thermoplastics, some glass
Less good	Material is organic – can be used for energy recovery but cannot be recycled	thermoplastics, rubber, wood products
Avoid	Avoid mixtures which cause contamination, and painting and coatings which are difficult to remove	e.g., polyvinylchloride (PVC) in PET, Cu in steel, painted plastics
Avoid	Material has no known or very limited technology for recycling	Heated glass, fiberglass, thermoset plastics, composite materials

cases, just by the product itself. This scheme helps assign responsibility and allows us to track progress by enabling comparisons.

At the same time, however, by measuring the environmental load too narrowly there is a danger of missing the overall trend. One way of making this point is by writing the environmental impact in terms of several normalized parameters. For example, consider

$$\text{impact} = \text{population}\,\frac{\text{wealth}}{\text{person}}\,\frac{\text{impact}}{\text{wealth}}\,. \qquad (9.2)$$

This is a mathematical identity, known as the IPAT equation, which associates impact I, with three important elements: P for population, A for affluence, and T for technology. Our focus has been on the last term – impact/wealth (or impact/product etc.). Many variations on the IPAT equation are possible, for example $A =$ products/person, $T =$ impact/product, etc. It is the collection of the terms on the right-hand side that give the impact. Hence, a technology improvement could be offset by increases in population and/or wealth/person. This is unfortunate, but appears not to be in the domain of the engineer. If this was all there was to the story, the IPAT equation would be a neat way to subdivide responsibility. The implication is that, if engineers can improve the technology term, then they have done their job. The actual picture unfortunately is much more complicated, as technology improvements do not only improve the environment but also play an important role in stimulating the economy. In fact, relatively recent economic growth theories, pioneered by Nobel laureate *Robert Solow*, now give primary importance to technology change [9.81, 82]. Hence the very act of improving the performance of a product could, and often does, stimulate increased production and consumption of the product. Some versions of this effect are called the *rebound effect* or *Jevon's paradox*, after the 19th century economist who noted that more-efficient production and use of a resource (coal in his case), stimulated more consumption of the resource, not less [9.83].

In a similar vein, one could observe that taken as a whole labor-saving technological progress in developed countries has not led to less employment (but it has led to increased income). The general rule is that people respond to incentives, and all the incentives in a market economy point toward increasing investment and output rather than decreasing employment or resource use [9.82].

If society wants to reduce resource use, or emissions, or toxic waste, etc., it will need to provide the incentives, most likely through policy instruments, to do this. There are many successful examples to illustrate this point. The USA has reduced emissions of lead and sulfur dioxide, it has reduced the energy consumed by refrigerators, and the world has stabilized the levels of ozone in the upper atmosphere through implementation of the 1976 Montreal Protocol. Hence, the engineering actions described in this chapter should be taken in conjunction with a wider incentive and policy system that will preserve the engineering efficiency gains.

9.7 Failure Mode and Effect Analysis for Capital Goods

Failure mode and effect analysis (FMEA) [9.84, 85] is a method to recognize and eliminate mistakes or causes of faults during the product design process and in particular in the earliest stages.

This method was developed in 1963 by the National Aeronautics and Space Agency (NASA) within the Apollo mission to design products without design failures. This is especially important when products cannot be repaired easily, e.g., satellites or spaceships. The method was adopted later by the aviation industry, the automotive industry, in medicine and nuclear technology as well as by the armaments industry [9.85, 86]. Today this method is increasingly used in all fields of the development process of consumer and capital goods [9.84, 87–89].

With regard to the rework of the initially developed and applied approach see [9.89, 90].

9.7.1 General Innovations for the Application of FMEA

The complexity of many products due to their mechatronic character but also because of the simultaneously applied engineering concepts complicates the distinction between the three traditional types of FMEA: system FMEA, design FMEA, and process FMEA (Fig. 9.59). In addition many FMEA sessions mix all three fields [9.90].

Instead of this distinction a continuous form of FMEA therefore has to be implemented, which

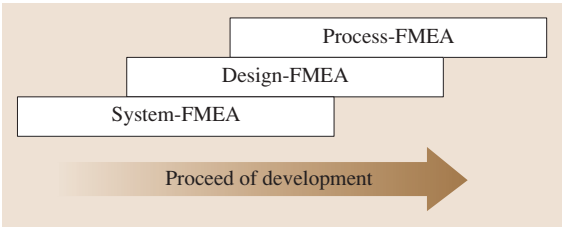

Fig. 9.59 FMEA separated in subprocesses (traditional form)

becomes more detailed with increasing knowledge through the product development process. As the design of a product proceeds and product knowledge grows, the danger of errors increases as does the need for their recognition and elimination. This leads to the concept of a continuous FMEA process (Fig. 9.60).

Such continuity produces the best results if the group of people involved stays the same. In practice, it turns out that it is already reasonable to apply competence in manufacturing or quality control in FMEA at the concept stage. This does not contradict the demand that specialists have to be consulted for specific questions. An additional benefit is gained from all team members becoming acquainted with the product.

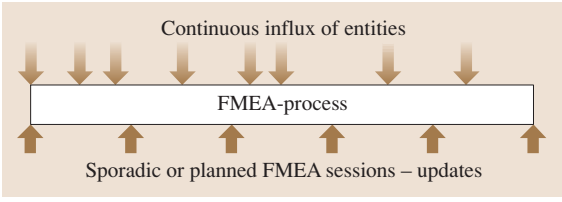

Fig. 9.60 FMEA as a continuous process

In general the early stages of the product development process and the stages during and after market launch are not covered by traditional FMEA. The early phases of the product development process (idea generation and market assessment) include many sources of errors that influence the success or failure (not only technically) of a new product.

The traditional form of FMEA does not take the costs of possible damage as well as the costs of avoiding this damage into account. To decide on appropriate trouble-shooting actions it is important to gain an economic understanding of FMEA and its consequences.

The new form, based on the original FMEA form but now including the economic point of view, is schematized and formalized in Fig. 9.61.

9.7.2 General Rules to Carry Out FMEA

The observation of FMEA sessions in companies shows that a clear separation into the three fields of system, design, and process is not performed, nor is it reasonable. This is because each failure affects the system, the design, and the process FMEA.

Since the system FMEA is carried out before the design FMEA this new influence into the system and his effects is not considered anymore. Only a completed process FMEA will discover the actual source of error, for example an unsuitable die-casting machine. Again the influence of the elimination of this failure mechanism is no longer considered in the system and design FMEAs.

Company project	**Failure mode and effect analysis – FMEA** Project- and lifecycle – FMEA									Name of functions / working principles / assemblies Ident-No.						
	Generating department:									Generated by: Date:						
Failurelocation Ident-No. Entity	Type of failure	Impact of failure	Cause of failure	Present status Means of control	A	B	E	K	RPZ	Remedial action	Improved status Realized action	A	B	E	K*	RPZ*
1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17

Fig. 9.61 FMEA form with additional columns K and K^* to consider the cost influences for decision-making

For these reasons it is not reasonable to separate the three individual FMEA methods. It is more reasonable to carry them out simultaneously in order to benefit from synergy within the group.

The Prerequisites at the Beginning of a FMEA

The following prerequisites must be met absolutely at the beginning of an FMEA process:

1. FMEA participants that are competent and confirmed in their continuity [9.91, 92]. The definition of the *risk priority number* (RPZ) numbers (see Sect. 9.7.3) is done subjectively and thus randomly. Therefore the selection of the FMEA participants has to be done carefully in order to take into account different views and issues and to obtain a realistic RPZ. This problem is similar to that of the evaluation process [9.91, 92].
2. The product idea is defined and understood by all FMEA participants.
3. The market performance process of a new product is available.
4. A clear list of demands (requirements), tested for interrelations [9.93].
5. A use analysis [9.94].
6. A functional analysis, if possible as a functional diagram.
7. Heuristic context within the product development process. The methods involved between the individual components and units as well as external (referring to the usage of a product) and internal (working principles, effects and regularities) functions (Fig. 9.62) cannot be correctly represented in conventional forms, which will result in incorrect decisions.
8. Complete documentation of the state of development.

Improvement of Error Recognition

(Formal) FMEA with conventional forms [9.84] is in principle incomplete since a suitable inspection of completeness is not given. This takes effect on the methodic context and on the other hand on the accidental error recognition. Some ways of improving error recognition rates are

1. The experience of the FMEA participants
2. Integration of other specialists
3. Knowledge of or becoming acquainted with the product to be analyzed
4. Integration of customer-oriented departments and the customers themselves

	Examples		
Action	Operate	View	Hear
Function	Amplify	Shine	Ring
Principle	Hydraulic	Electric	Acoustic
Effect, physical principle	Static pressure	Ohm's law	Sound wave
Formula	$P_2 = P_1(A_2/A_1)$	$U = R\,I$	$E = J/(f\lambda)$

Fig. 9.62 Heuristic context within the product development process; the five stages of solution finding in the concept stage

5. Collection and analysis of mistakes and experiences recorded in databases
6. Study of the history of a product (test reports, complaint reports, etc.)
7. Concurrent application of heuristic support tools (e.g., *Goldfire*, Invention Machine, Boston)

Inclusion of all Secondary Fields of Development

The FMEA refers only to hardware, not to documentation, services, software logistics, test programs, manufacturing method, production plants, and machines. Measurement and checking facilities, experimental setups, and devices are not covered by any FMEA, although many errors could occur here. This situation only can be improved by including these new fields.

9.7.3 Procedure

The localization of risks concerning the lifetime of a product, starting from the first design concept to product use, is in principle always the same procedure, regardless of the product size. The principle and pro-

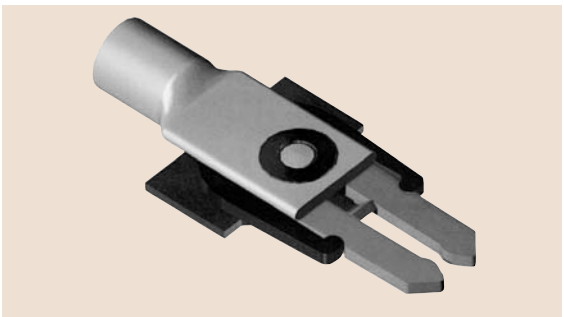

Fig. 9.63 Small product: plug-in contact (source: ABB, Baden)

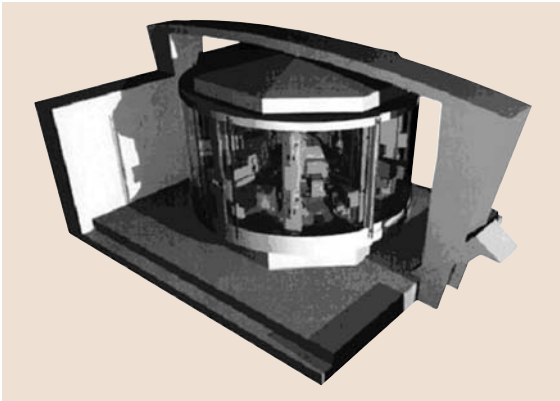

Fig. 9.64 Large product: machine tool (source: A. Breiing, MIKRON, Biel)

cedure is identical for a small product like a plug-in contact (Fig. 9.63) or a large technical system like a machine tool (Fig. 9.64).

Description of the project

Nomination of the FMEA moderator. The nomination is done with the agreement of the responsible project manager.

Formation of an FMEA team. The formation of the team (Table 9.26) is done by the project manager with the agreement of the FMEA moderator. Important is the visualization of the team members (Table 9.26). The departments should contribute at least one participant as a continuous FMEA team member.

Structuring of functions. The basis of FMEA is functional analysis of the investigated product. This implicates the specification of functional modules or submodules, for example as a hierarchical functional diagram (Fig. 9.65) or as a process-orientated diagram (Fig. 9.66).

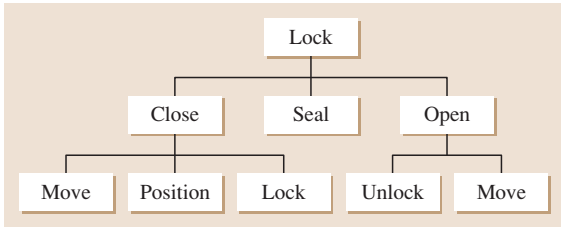

Fig. 9.65 Example of a hierarchical functional structure of an autoclave door [9.95]

Filling out the FMEA Form (Fig. 9.61).

Column 1. This column consists of all aspects of possible sources of error, as shown in Table 9.27. Since in the early stages of product development, in particular during idea generation and during the determination of the market performance profile, sources of error can already be detected, the corresponding entities have to be entered in this column (first block). Sources of error can also be detected in the development phase (second block), during market launch (third block), and in particular during the usage phase up to product disposal (fourth block).

Columns 2–4. These columns require an analysis of all possible potential failures, for example:

Possible errors in the planning stage.

- The idea of a new product cannot be realized due to physical, chemical, biological, ethical, legal or cultural constraints or restrictions
- The product idea is already realized by competitors
- The product idea is already protected by the competitors with patents, petty patents, and/or design patents
- There is no market potential and/or no market gap available
- The time is not ripe
- No foe image available or not relevant enough (for military development)

Table 9.26 Visualization of the team members

No.	Faculty/customer	Name, company
1	Project management	
2	Design, construction, and calculation	
3	Manufacturing preparation	
4	Manufacturing	
5	Quality control, simultaneously presentation of FMEA	
6	Purchase department	
7	Sales department	
8	Customer support (inauguration, maintenance, repair)	

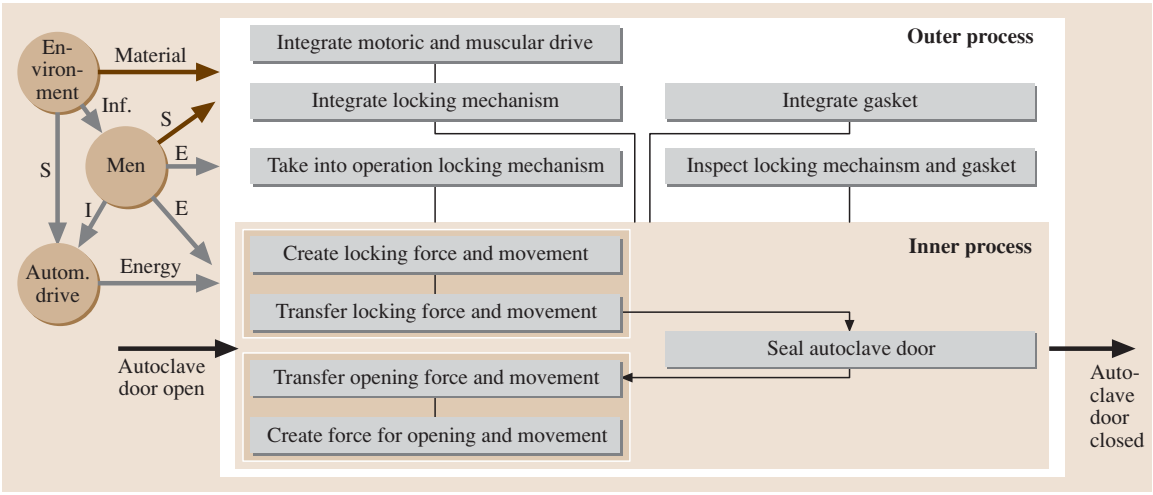

Fig. 9.66 Example of a process functional structure of an autoclave door [9.95], generated from Fig. 9.64

Table 9.27 FMEA form with entities over the complete life cycle of a product (an example)

Company **Project**	**Failure mode and effect analysis (FMEA)**			
Failure location Identification number Entity	Impact of failure	Type of failure	Failure cause	Means of control
1	2	3	4	5
Idea Market analysis Cost planning Time scheduling Strategy				
Inner functions Outer functions Module Assembly Component Manufacturing process				
Storage Transport Mounting Initiation				
Implementing Operation Controlling Maintenance Repair Recycling or liquidation				

- Rare resources
- No sustainable environment

Possible errors in the development process.
- Internal functions from a function analysis (hierarchical and/or process functional structure)
- External functions from a use analysis
- Assembly of the product structure
- Assembly/disassembly:
  - Assembly/disassembly operation
  - Assembly/disassembly regulations
  - Utilities (e.g., oil for the removal of bearings)
  - Assembly/disassembly devices
  - Control and/or measuring devices (e.g., torque spanner)
  - Additional means (e.g. hoisting devices)
- Components from the product structure and/or parts list
- Manufacturing:
  - Manufacturing processes (e.g., lapping)
  - Manufacturing operations (for manual manufacturing, e.g., deburring)
  - Manufacturing regulations
  - Manufacturing means and devices (e.g., drilling patterns)
  - Auxiliary manufacturing requirements (e.g., coolant)
  - Control and measuring devices (e.g., calipers)

The *outer function* takes into account the human being in his incompleteness as users during the product life. This must be included into the FMEA. The user is a component of the system; (s)he influences all processes, starting from idea generation, through development and usage until the end of the product life. The user causes failures and errors at all stages. With the integration of the available use analysis (Table 9.28) that covers all stages of a product's life [9.94] possible sources of error during assembly, maintenance, and repair are also considered (Table 9.27, fourth block).

In order to register these potential sources of error systematically the FMEA is expanded by the integration of the use analysis. These entities can be taken from the tabular recording of the man–machine interfaces.

Moreover each part, assembly, and product needs the following documentation:

Possible errors within the technical documentation. Check the:
- Manufacturing documents (drawings and lists)
- Documents for assembly/disassembly (e.g., instruction sheets)
- Calculation documents, such as:
  - Load assumptions
  - Verification of strength
  - Verification of deformation
  - Verification of stability (e.g., buckling, bending, stability)
- Balances such as:
  - Balance of performance
  - Balance of weight
  - Position of the centers of gravity
  - Balance of the moments of inertia
  - Balance of temperature
  - Balance of coolant
- Documents such as:
  - Manufacturing documents
  - Instruction sheets
  - Instructions for maintenance and service
  - Spare-part catalogue

Possible errors during market launch.
- Storage:
  - Activities
  - Apparatus (e.g., bearing block)
  - Racks, halls, stacks (e.g., storage rooms with air conditioning)
- Transport:
  - Activities
  - Apparatus (e.g., lifting gear)
  - Means of transportation (e.g., overhead crane)
- Mounting:
  - Activities
  - Mounting regulations and instructions
  - Apparatus (e.g., lifting gear)
  - Measuring and test equipment (e.g., theodolite)
- Initial operation:
  - Activities and tests in accordance with:
    - Instruction manual (Chapter *Initial setup*)
    - Checklist
    - Users' handbook
    - Maintenance instruction

Possible errors in the use stage and in decommissioning.
- Initial operation:
  - Activities in accordance with:
    - Instruction manual (Chapter *Initial setup*)
    - Checklist

Table 9.28 Use analysis of a nutcracker

No.	Subfunction first order	Man–product relationship: needed activities	Man–machine interface	Affiliated requirement	Required functions resp. possible carriers of function

    - Logistics documents (e.g., global workshop catalogue)

Column 5. Here the status of currently used measures for the prevention of failures and test procedures is entered. These entries are used to reduce the causes of failure in column 4 and to detect possible sources of error.

Columns 6–10. These columns are used to calculate the risk priority number (RPZ).

To decide on actions for trouble-shooting it is very important to obtain an economic perspective on FMEA and its consequences. In the case of extension of the FMEA by integrating a cost calculation, the form includes an additional column K for the costs. The factor K stands for the probable costs in the case of an error occurring.

The value of column 10 has to be calculated by

$$\mathrm{RPZ} = A \cdot B \cdot E \cdot K \,, \tag{9.3}$$

where: A = probability of a failure incidence

Unlikely	1
Very low	2
Low	3
Medium	4
High	5
Very high	6

B = consequences for the customer

Consequences not noticeable	1
Inconsiderable inconvenience for the customer	2
Small inconvenience for the customer	3
Inconvenience for the customer	4
Irritation of the customer	5
Possible loss of the customer	6

E = probability of failure detection

Very high	1
High	2
Medium	3
Low	4
Very low	5
Unlikely	6

K = probability costs in the case of a fulfilled error

No or negligible increase of costs	1
Little additional costs	2
Medium additional costs	3
High additional costs	4
Extremely high additional costs	5
Nonbudgeted costs	6

Instead of the absolute measure of 1–6 a range of values from 1–10 can also be chosen. This is only reasonable if detailed knowledge is available, for example within an FMEA at the end of the product development process.

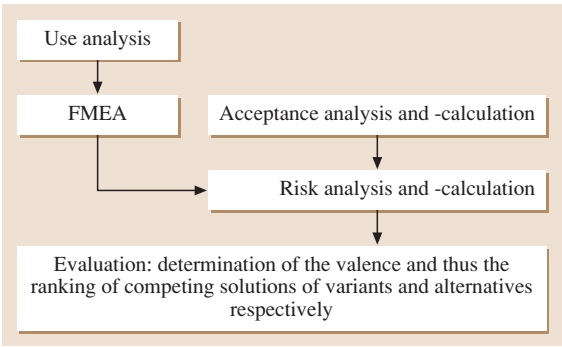

Fig. 9.67 Relationship between acceptance, risk and evaluation

A verbal description of the RPZ is:

Unacceptable high	1296–10 000
Medium	256–1295
Low	1–255

In practice RPZ failure values lower than 81 resp. 625 are not used to remove a failure as it is not profitable to do so.

Column 11. In this column the actions for trouble-shooting are entered.

Columns 12–17. Supposing that the recommended actions for trouble-shooting from column 11 are realized the actions are described in columns 12 and the RPZ* value is calculated again in columns 13–17. The factor K^* stands for the probable costs of the measure required to avoid or minimize a probable error. Both K and K^* have the same range of risk factors. The measure is accepted if the RPZ* is below the level described in the above.

The value of column 17 is calculated by

$$\mathrm{RPZ}^* = A \cdot B \cdot E \cdot K^* \,. \tag{9.4}$$

In practice failure values RPZ* that are lower than 81 resp. 625 are not used to remove a failure as it is not profitable to do so. The verbal description of RPZ* is like that of RPZ.

If RPZ* is higher than RPZ then the measure to avoid or to minimize a probable error has to be considered critically.

9.7.4 Further Use of FMEA Results

Within the concept and sketching phases several competing solutions or alternatives are available. In order to identify the best solution a ranking procedure is carried out. If the criterion *risk* is already part of this ranking procedure it is reasonable to use the sum of the RPZ or RPZ* values of each solution.

The relationship between acceptance, risk, and weighting is shown in Fig. 9.67.

10. Piston Machines

Vince Piacenti, Helmut Tschoeke, Jon H. Van Gerpen

Piston machines are the most used power and work machines in the mechanical engineering industry. The piston machines are divided in so-called reciprocating and rotary piston machines. With the first one a reciprocating motion is transformed to a rotary motion in the case of the power machine and conversely in the case of the working machine. Today rotary piston machines are almost exclusively used as work machines. Important innovations and intensive researches are practiced particularly for the use of the piston machines as an internal combustion engine. Therefore the mixture formation and the combustion process, with their consequences in terms of emission and fuel-consumption are int the center of attention.

10.1 Foundations of Piston Machines

10.1.1 Definitions

Piston machines employ a moving displacer (also called a piston) to convert a medium's potential energy into kinetic energy or vice versa, i. e., they use the movement of the displacer to increase the energy content of the medium. This occurs in a working chamber that can be altered by the displacer motion.

In piston machines, the moving displacer effects both the charge cycle (filling and draining of the medium) and the work cycle (expansion and compression). The characteristic mode of operation for piston machines is a self-contained working chamber that varies periodically due the piston's movement.

Piston machines can be classified according to their method of operation, the piston motion and the medium used (Fig. 10.1). When piston machines are classified according to their method of operation then power and work machines are differentiated.

A power machine converts a medium's potential energy into mechanical energy. Power machines include engines (pneumatic engine, hydraulic motor) and thermal machines (steam engines, combustion engines). Work machines on the other hand utilize mechanical energy to increase the energy of the medium being

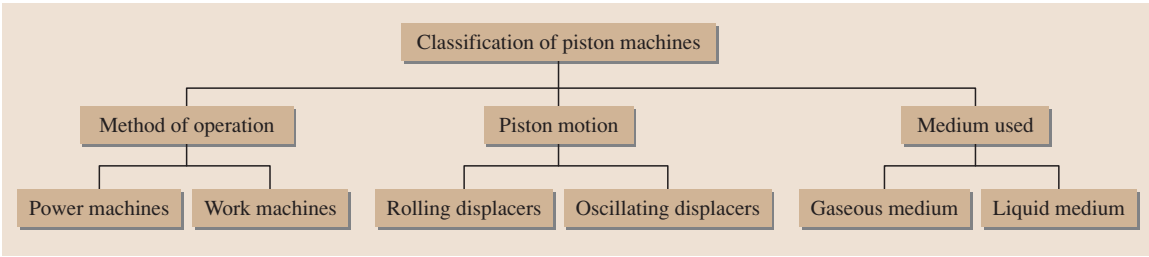

Fig. 10.1 Classification of piston machines (after [10.1])

conveyed. Work machines include compressors and pumps.

Rotating and oscillating displacer motions are other potential classification.

In addition, piston machines can be classified according to the medium used, which can be gaseous or liquid.

Reciprocating Machines

When a piston machine's oscillating displacer executes a linear motion, it is called a reciprocating machine (Fig. 10.2). A cylindrical displacer that moves between two end positions, top and bottom dead center (TDC and BDC), is characteristic. The working chamber is calculated from the piston diameter and the distance between the two dead centers, the so-called stroke s (see *Working Chamber* below), and is therefore also referred to as the displacement.

Rotary Piston Machines

Machines of this type are characterized by a rotating displacer. The medium can flow axially or radially to the piston axis. An axial direction of flow is found, for instance, in screw-type compressors, screw pumps or eccentric screw pumps. Rotary piston compressors, Roots blowers and gear pumps are examples in which the medium flows radially to the piston axis. In Wankel engines (Fig. 10.3), however, the medium flows axially as well as radially, depending on the design.

Cylinder Configuration

Differently configuring the interrelation of the cylinders makes it possible to produce various types of piston machines.

The inline and V configuration in particular and the boxer variant to a lesser degree are choices for combustion engines. The V design is compact and produces high output per unit volume. Its compact design makes manufacturing it more complex and expensive though. Moreover, accessibility is impaired, as a result of which

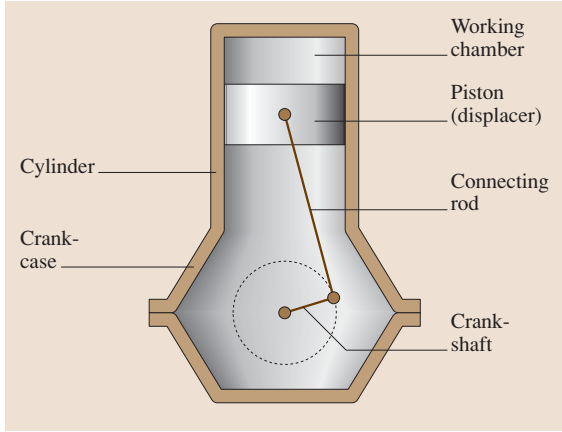

Fig. 10.2 Reciprocating machine

the time and effort required for maintenance increase along with maintenance costs. The advantages of the boxer engine are its overall length and height, though at the expense of width. The W configuration is frequently employed for piston compressors, yet relatively infrequently for combustion engines. The radial configuration is considered obsolete. It was used early on for

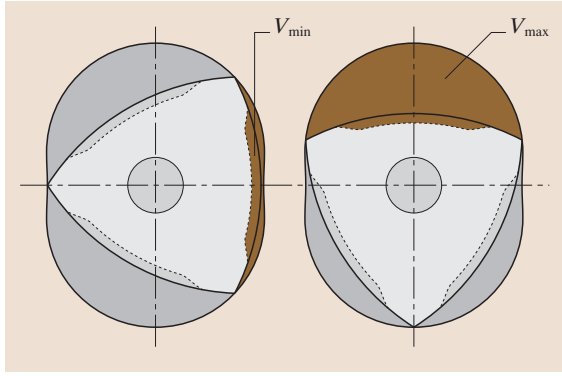

Fig. 10.3 Wankel engine as an example of a rotary piston machine (after [10.2])

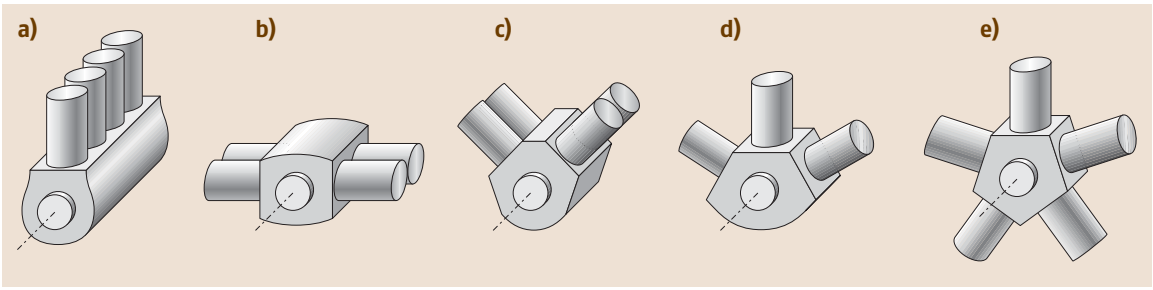

Fig. 10.4a–e Cylinder configurations (after [10.1]) **(a)** in-line machine **(b)** opposed-cylinder machine **(c)** V machine **(d)** W machine **(e)** radial machine

aircraft engines because of the good air cooling resulting from the design and the minimal axial extension.

A multi-cylinder design helps increase machine performance for combustion engines. In compressors, multistage compression is achieved by additionally using varying piston diameters. Increasing the number of cylinders boosts running smoothness. A larger number of cylinders adversely affects production and maintenance costs. Moreover, a more-complex design increases susceptibility to failure. Cylinder configuration, unit size, and the stiffness of the crankshaft can limit the number of cylinders.

Working Chamber

The displacer's movement causes the actual working chamber volume V_a to vary between the volume limits V_{min} and V_{max}. V_{min} can be a design-related clearance volume V_S or, in the case of combustion engines, a compression volume V_c contingent on the working process. Thus $V_{min} \leq V_a \leq V_{max}$ applies.

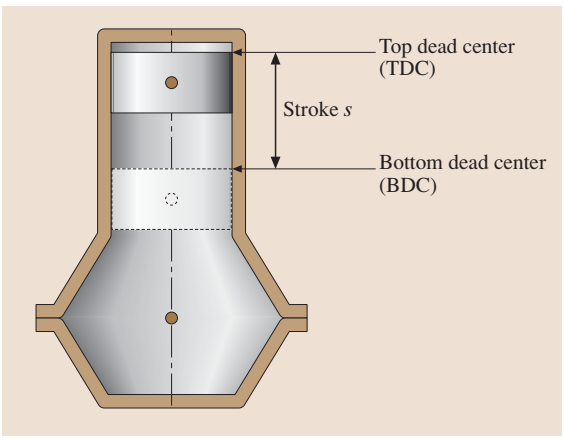

Fig. 10.5 The stroke s corresponds to the distance between top and bottom dead center

In a reciprocating machine, the maximum piston displacement V_A or swept volume V_h corresponds to the volume resulting from the product of the piston surface A_p and the stroke s (10.1). The stroke corresponds to the distance that the piston covers between the top and bottom dead centers (Fig. 10.5)

$$V_A = V_h = A_p s = s \cdot \pi \cdot D^2/4 \,. \qquad (10.1)$$

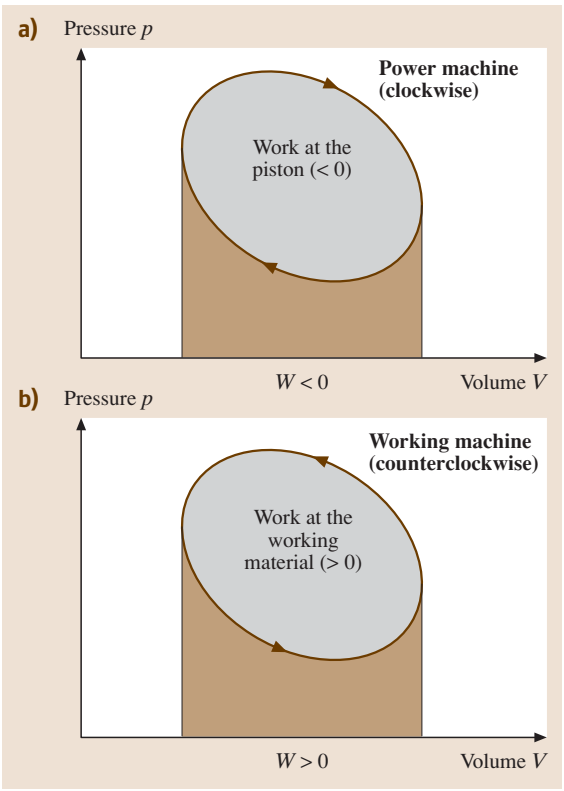

Fig. 10.6 p–V diagrams of power and work machines (after [10.3])

Defining a cylinder's volume (corresponding to the maximum volume) requires the incorporation of the minimum volume

$$V_{cyl} = V_{max} = V_h + V_{min} \,. \tag{10.2}$$

For machines with a multi-cylinder design, the total piston swept volume V_H follows from the number of cylinders z and the swept piston volume V_h

$$V_H = zV_h = zA_p s \,. \tag{10.3}$$

Using (10.2), the total working chamber of a combustion engine is calculated as

$$V_{working\text{-}chamber} = (V_h + V_{min}) \,. \tag{10.4}$$

10.1.2 Ideal and Real Piston Machines

The Ideal Combustion Cycle

A cycle is a succession of a material's changes of state until it returns to its initial state. The cycle serves as the foundation for evaluating the thermodynamics of processes.

The p–V diagram is used to represent the development of cycles (Fig. 10.6). Its enclosed area corresponds to the cycle work W.

Figure 10.6 is a general representation of the development of the cycles of a power and a work machine. The different direction of rotation of each process and the resultant sign of the cycle work are characteristic here. Since the work done by the machine's piston can be utilized (effective work), it is defined negatively, while the work expended on the working material is defined positively. The cycle work is calculated from the total of both values and corresponds to the area within the circle

$$W = W_{at\text{-}the\text{-}piston} + W_{at\text{-}the\text{-}working\text{-}material} \,, \tag{10.5}$$

$$W = \oint V\mathrm{d}p = -\oint p\mathrm{d}V \,. \tag{10.6}$$

A clockwise cycle profile with negative cycle work results for the power machine, while a counterclockwise cycle profile with positive cycle work results for the work machine.

Three examples of cycles based on the Carnot process (Chap. 4) are described below and are referred to as reference cycles. They are subject to the following premises:

1. State changes are infinitely slow.
2. The working chamber is adiabatically and hermetically sealed.

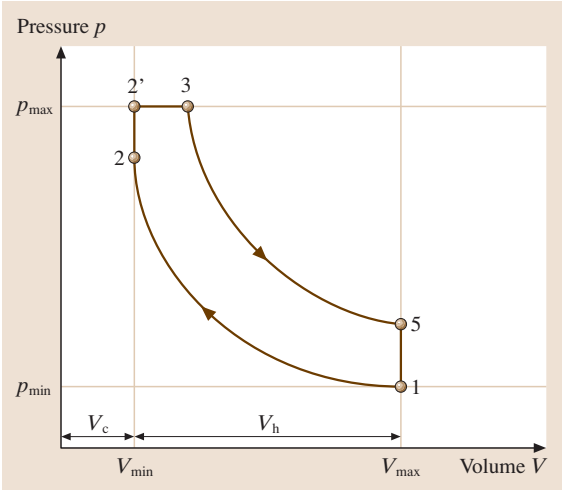

Fig. 10.7 p–V diagram of a combustion engine (Seiliger process) (after [10.4])

3. Fluid is exchanged without any change in the state variables (mass, pressure, temperature).

Combustion Engines. The Seiliger process constitutes a reference process for diesel engines. Adiabatic compression causes the pressure to rise until it is slightly below the maximum cylinder pressure. The internal combustion of a fuel mass is followed by an isochoric and isobaric input of heat, as a result of which the maximum cylinder pressure is reached. This is followed by an isentropic expansion up to the initial volume. The

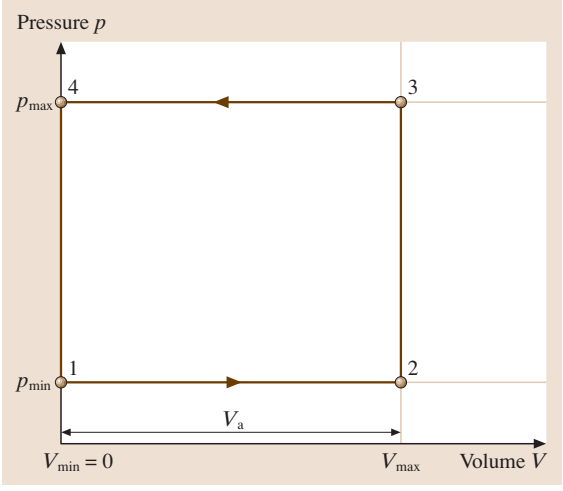

Fig. 10.8 p–V diagram of a positive displacement pump (after [10.4])

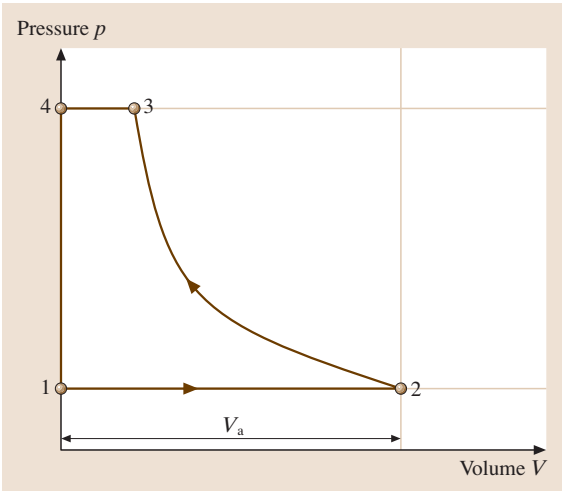

Fig. 10.9 p–V diagram of a positive displacement compressor (after [10.4])

initial state has been reached again when the heat extraction is isochoric.

Positive Displacement Pump. In an initial step, the working chamber is filled with an incompressible fluid. When the maximum volume V_{max} is reached, the pressure climbs isochorically to the maximum pressure p_{max}. The fluid is expelled at the maximum pressure. When the working chamber has been completely discharged, the pressure falls isochorically, returning to the initial state.

Positive Displacement Compressor. Analogous to the positive displacement pump, the working chamber is filled isobarically with a fluid up to the volume limit. When the positive displacement compressor's cycle is ideal, the low compression work causes the pressure to rise isothermally. When the maximum pressure has been reached, the fluid becomes isobaric and is expelled isochorically until it has been completely discharged.

Real Machines

While lossless state changes are assumed for an ideal combustion cycle, losses in the real machine occur as irreversible subcycles when the state changes. Infinitely slow (quasistatic) state changes would be needed to prevent irreversible cycles.

Deviations from the ideal cycle occurring in real machines are caused by:

1. Wall heat losses, i. e., heat exchange with the system boundaries (e.g., with the working chamber's walls and the piston)

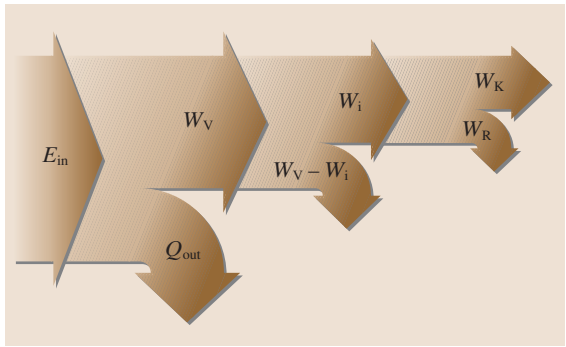

Fig. 10.10 Schematic diagram of a real power machine's losses (combustion engine)

2. Irreversibilities when states change; changing material values during the cycle
3. Losses when energy is transferred (e.g., friction in the machine, flow losses)
4. Leaks because the working chamber is not absolutely sealed

Efficiency

The aforementioned deviations are expressed by the efficiency, which represents the relationship between utility and effort. For heat engines, the total effort corresponds to the total quantity of input heat, while the utility is the outcome of an energy conversion process.

Power Machine. Figure 10.10 is a schematic diagram of a real power machine's losses.

Heat exchange with the system boundaries represents the greatest percentage loss of input energy. The relationship between the cycle energy of an ideal power machine's reference cycle and the input energy is expressed with the efficiency of the reference cycle and referred to as the efficiency of the ideal machine

$$\eta_v = W_v / E_{in} \, . \tag{10.7}$$

The irreversibilities of a cycle's state changes cause further losses. The related efficiency specifies the indicated cycle's approximation of the reference cycle and is referred to as a cycle's efficiency

$$\eta_g = W_i / W_v \, . \tag{10.8}$$

The work against friction W_R subsumes the losses occurring during the transfer of energy. The relationship between the effective work or the useful work that can be extracted at the clutch W_K and the indicated work is referred to as the mechanical efficiency

$$\eta_m = W_K / W_i \, . \tag{10.9}$$

Consequently, a real power machine's coupling efficiency is calculated from the efficiency chain

$$\eta_K = \eta_v \eta_g \eta_m = (W_v/E_{in})(W_i/W_v)(W_K/W_i) = W_K/E_{in} . \quad (10.10)$$

This efficiency represents all losses occurring in the power machine, which leads to the output useful work (clutch work) W_K.

Work Machine. Analogous to the power machine, Fig. 10.11 is a schematic diagram of a real work machine's losses.

The following relationships likewise apply to the mechanical efficiency

$$\eta_m = W_i/W_K , \quad (10.11)$$

internal efficiency

$$\eta_g = W_V/W_i \quad (10.12)$$

and system efficiency

$$\eta_A = E_{benefit}/W_V . \quad (10.13)$$

Consequently, a work machine's total efficiency is calculated from the chain of efficiencies

$$\eta = \eta_m \eta_g \eta_A = (W_i/W_K)(W_V/W_i)(E_{benefit}/W_V) = E_{benefit}/W_K . \quad (10.14)$$

Specific Energy

The relationship between the piston machine's output energy W_e and the corresponding piston swept volume is referred to as the volume-specific energy w_e

$$w_e = W_e/V_H . \quad (10.15)$$

In combustion engines, the unit of the volume-specific energy w_e is denoted as kJ/dm^3. Work machines' mass-specific energy w' is obtained from the relationship of the requisite work energy W_a and the mass of the fluid delivered per working cycle m_f. It is specified, for instance, in kJ/kg

$$w' = W_a/m_f . \quad (10.16)$$

The more losses that occur in the work machine, the more energy is needed to deliver the same amount of fluid. Consequently, the mass-specific work also increases as losses occur.

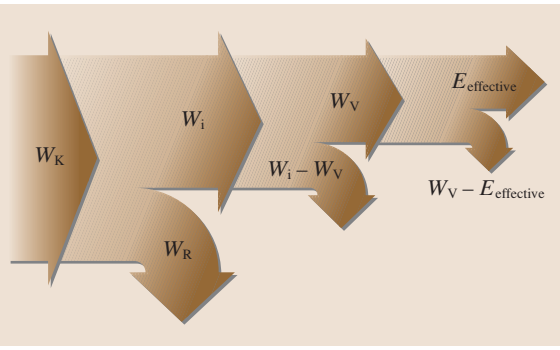

Fig. 10.11 Schematic diagram of a real work machine's losses

Power

A machine's power corresponds to the energy output (power machine) or input (work machine) per unit time.

$$P = \frac{W}{t} . \quad (10.17)$$

Moreover, the power can be calculated using the product of the torque M_d and angular velocity ω

$$P = M_d \omega = M_d 2\,\pi n , \quad (10.18)$$

where ω is the angular velocity and n is the engine speed or with the aid of the cycle energy W_K

$$P = \frac{W_K}{t_{ASP}} = W_K f_{ASP} , \quad (10.19)$$

where $t_{ASP} = i/2n$ is the time for one working cycle and $f_{ASP} = 1/t_{ASP}$ is the working cycle frequency; i is the number of cycles or piston strokes per working cycle. Expressing this using the mass flow $\dot{m}$ and the mass delivered per working cycle m_{ASP} leads to

$$P = \frac{W_K}{m_{ASP}} \dot{m} . \quad (10.20)$$

10.1.3 Reciprocating Machines

Types of Transmissions

Different types of transmissions transmit energy between piston and crankshaft, e.g., crankshaft drive, swash plate drive, cam drive and eccentric drive. The simple engineering and dimensioning of a reciprocating machine's important parameters (e.g., stroke and compression) are the reason why a crankshaft drive is frequently used as the transmission.

The connecting rod transmits energy between the piston and crankshaft (Fig. 10.2). In the process, the piston's oscillating motion is converted into the crankshaft's rotating motion in order to improve the further transmission of energy. Accordingly, the motion is transformed conversely when energy is transmitted from the crankshaft to the piston. The crankshaft drive can be constructed as a plunger piston or crosshead version. The crosshead serves to relieve the piston from

the lateral piston force, particularly in large piston machines.

Kinematics

The piston executes a motion characterized by accelerations and decelerations between the two dead centers. The piston's linear, irregular motion at the crankshaft is converted by the connecting rod into a rotating motion with constant angular velocity. The instantaneous distance covered by the piston, related to the top dead center, is designated the piston travel x (Fig. 10.12). The maximum piston travel, i. e., the distance between the two dead centers, is defined as the stroke s. This corresponds to twice the distance between crankshaft journal and shaft journal (crank radius r).

Piston travel can be specified as a function of the piston angle α

$$x = l + r - (l\cos\beta + r\cos\alpha)\,. \tag{10.21}$$

By substituting the connection rod angular travel β with α by using the relation

$$l\sin\beta = r\sin\alpha \tag{10.22}$$

and the connecting rod ratio

$$\lambda = r/l\,, \tag{10.23}$$

the formula for piston travel is obtained as

$$x = r(1-\cos\alpha) + l(1-\sqrt{1-\lambda^2\sin^2\alpha})\,, \tag{10.24}$$

where $\sin\beta = \lambda\sin\alpha$ and $\cos\beta = \sqrt{1-\lambda^2\sin^2\alpha}$.

Expanding the expression under the root into a Taylor polynomial produces a complex equation. In practice, only the first two orders of the Taylor polynomial are applied since they already yield sufficiently precise results for the piston travel x

$$x \approx r\left(1-\cos\alpha + \frac{\lambda}{2}\sin^2\alpha\right)\,. \tag{10.25}$$

Piston speed can be stated as an average or instantaneous speed.

The average piston speed is calculated based on the simple relation between distance covered and the necessary time expended. Twice the piston stroke is covered during one revolution. This yields the formula for the average piston speed

$$c_\mathrm{m} = \frac{2s}{\frac{1}{n}} = 2sn\,. \tag{10.26}$$

The following numerical value equation is also frequently applied

$$c_\mathrm{m} = \frac{sn}{30}\,. \tag{10.27}$$

The unit of revolution has to be specified in 1/min or min^{-1} and rpm respectively in order to obtain the average piston speed in m/s.

If the actual piston speed v is required, piston travel must be differentiated with respect to the time t, remembering that piston travel is only a function of the piston angle

$$v = \frac{\mathrm{d}s}{\mathrm{d}t} = \frac{\mathrm{d}s}{\mathrm{d}\alpha}\frac{\mathrm{d}\alpha}{\mathrm{d}t}\,, \tag{10.28}$$

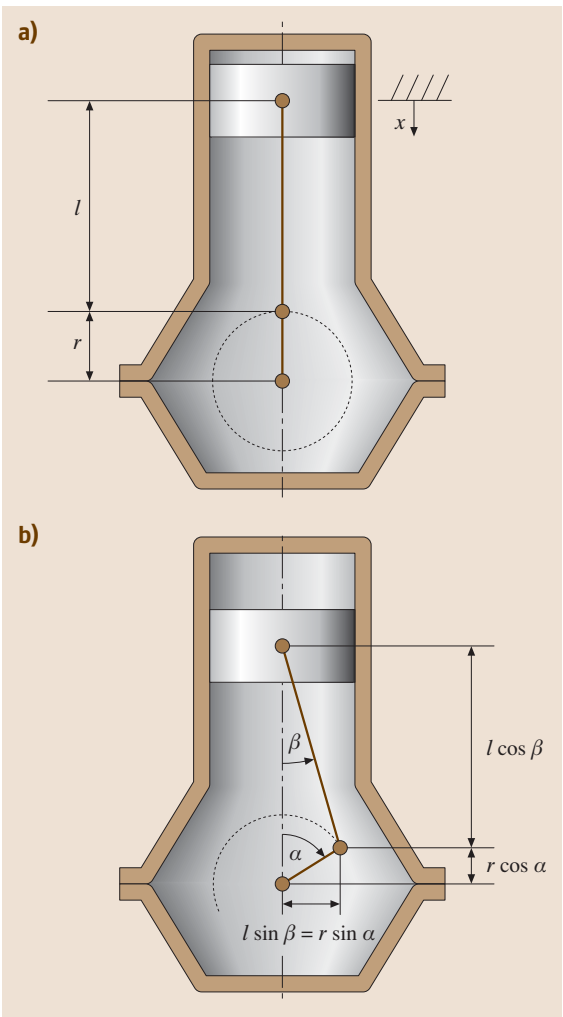

Fig. 10.12 Piston travel x and crankshaft drive geometry

where $d\alpha/dt$ is the crankshaft angular velocity ω.

Differentiating (10.25) yields an approximate equation for the piston speed:

$$v \approx \omega r \left[\sin\alpha + \frac{\lambda}{2} \sin(2\alpha) \right] . \tag{10.29}$$

Analogous to the piston speed, an approximate value can be derived for the piston acceleration

$$a \approx \omega^2 r [\cos\alpha + \lambda \cos(2\alpha)] . \tag{10.30}$$

Equations (10.25), (10.29) and (10.30) do not yield any precise results when speeds are high (e.g., racing engines). The exact piston travel and the corresponding derivatives for speed and acceleration would have to be used for this application.

Forces

Fluid Forces. The state change of the fluid enclosed in the working chamber induced by the oscillating motion of the displacer causes a force that is dependent on the piston surface A_K and the fluid pressure p_F exerted on the piston. Allowing for the atmospheric pressure p_0, the fluid force F_F of a single-action piston is calculated with the following equation

$$F_F = A_K (p_F - p_0) . \tag{10.31}$$

An equal force acts on the cylinder cover. The bolted connections, e.g., between the cylinder cover and the housing, create a closed linkage so that the forces in the machine balance (Fig. 10.13).

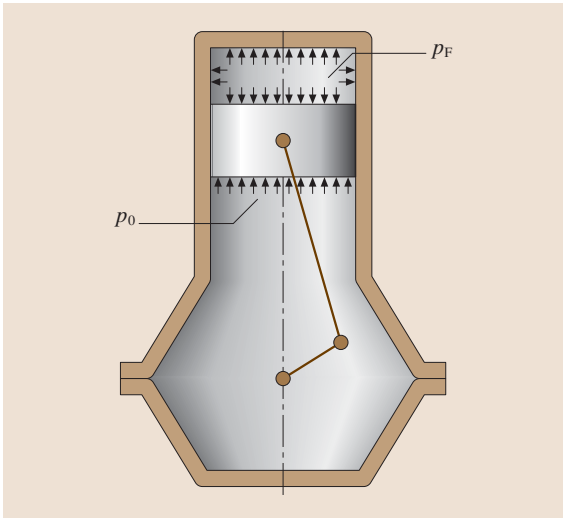

Fig. 10.13 Pressures on the piston

Inertial Forces. The irregular motions of the translationally moving structural parts cause periodic inertial forces to arise, which act as oscillators. The centripetal acceleration generates rotary inertial forces on the connecting rod and crankshaft suspensions. Therefore they have to be balanced. This can be easily and completely done for rotary piston machines, but only partially or with considerable effort for reciprocating machines. The inertial forces are classified as rotating and oscillating based on the different types of motion of the transmission components.

The rotating inertial forces F_{mr} are calculated with the formula

$$F_{mr} = m_r r \omega^2 . \tag{10.32}$$

The rotating masses m_r are concentrated in the crankshaft journal at the distance r from the center of rotation and consist of the masses of the crankshaft journal m_z, the crankshaft web (converted to the crank radius), and the rotating portion of the connecting rod (10.36).

The oscillating and rotating motion of the connecting rod cause the mass to be distributed to two points

$$m_{Pl} = m_{Plo} + m_{Plr} , \tag{10.33}$$

where m_{Pl} is the connecting rod mass, m_{Plo} is the oscillating mass fraction, m_{Plr} is the rotating mass fraction, a and b are the distances to the connecting rod center, and l is the distance between the two connecting rod eyes.

The mass m_{Plo} is located in the piston pin and is only involved in the oscillating motion, while m_{Plr} on the crankshaft journal executes a purely rotary motion. Since the distances from the center and the total moment of inertia are maintained, the masses are calculated based on

$$m_{Plo} = \frac{m_{Pl} a}{l} \tag{10.34a}$$

and

$$m_{Plr} = \frac{m_{Pl} b}{l} . \tag{10.34b}$$

As a result, a substitute connecting rod is obtained, the dynamic behavior of which is approximately comparable with a real connecting rod.

Since the center of the web masses m_W does not lie at the center of the crankshaft axis, the masses must be converted to the crank radius. Using the distance x between the center of the web masses and the crankshaft axis as well as the crank radius, the reduced mass m_{WE} is calculated as

$$m_{WE} = m_W \frac{x}{r} . \tag{10.35}$$

Taking the preceding observations and allowing for two web masses, the following result ensues for the rotating inertial forces of the reciprocating machine

$$F_{mr} = (m_Z + m_{Plr} + 2m_{WE})r\omega^2. \quad (10.36)$$

The irregular piston motion generates oscillating inertial forces F_{mo} as a function of the piston acceleration a

$$F_{mo} = m_o a\ , \quad (10.37)$$

where $m_o = m_K + m_{Plo}$ are the oscillating masses.

Taking the piston acceleration (10.30), the following ensues for the oscillating inertial force

$$F_{mo} \approx m_o\omega^2 r[\cos\alpha + \lambda\cos(2\alpha)]\ . \quad (10.38)$$

It is divided into oscillating inertial forces of first and second order (I and II)

$$F_{moI} = m_o\omega^2 r\cos\alpha = F_I\cos\alpha\ , \quad (10.39a)$$

$$F_{moII} = m_o\omega^2 r\lambda\cos(2\alpha) = F_{II}\cos(2\alpha)\ . \quad (10.39b)$$

The frequency of the first-order forces of inertia corresponds to the crankshaft speed, while the second-order forces of inertia change as the crankshaft speed doubles.

The influence of the stroke/connecting rod ratio λ (10.23) makes the amplitude of the second-order forces of inertia less than that of the first order. The extreme values for F_{moI} are in the top and bottom dead center, i. e., at $\alpha = 0°$ and $\alpha = 180°$. Since the frequency of F_{moII} is doubled, the maximum amplitudes are at $\alpha = 0, 90, 180$ and $270°$. This yields the following for the oscillating inertial forces at top dead center

$$F_{mo} = F_{moI} + F_{moII} \quad (10.40)$$

and the following at bottom dead center

$$F_{mo} = F_{moI} - F_{moII}\ . \quad (10.41)$$

Since there is no closed linkage, the oscillating inertial forces cause the crankcase to oscillate and thus exerts a load on the external engine suspension.

Forces on the Transmission. The piston force F_K consists of the fluid force F_F and the oscillating inertial force F_{os}. It is broken down into a lateral force F_N and a connecting rod force F_S as follows (Fig. 10.15)

$$F_N = F_K\tan\beta\ , \quad (10.42a)$$

$$F_S = \frac{F_K}{\cos\beta}\ . \quad (10.42b)$$

The cylinder wall absorbs the normal force. The connecting rod force divides at the crankshaft journal into a radial and a tangential component (F_R and F_T)

$$F_R = F_S\cos(\alpha+\beta) = F_K\frac{\cos(\alpha+\beta)}{\cos\beta}\ , \quad (10.43a)$$

$$F_T = F_S\sin(\alpha+\beta) = F_K\frac{\sin(\alpha+\beta)}{\cos\beta}\ . \quad (10.43b)$$

The tangential force and the crank radius produce the torque

$$M_d = F_T r\ . \quad (10.44)$$

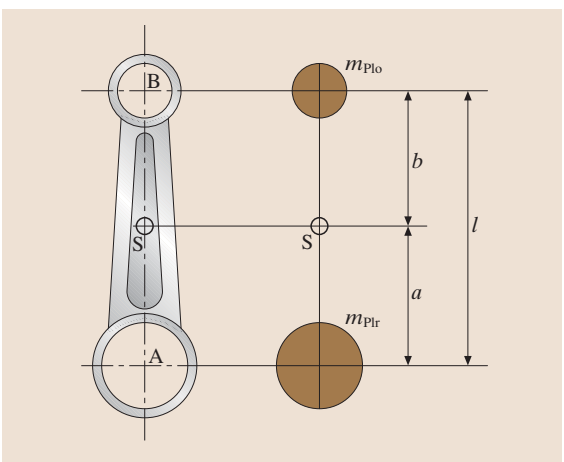

Fig. 10.14 Distribution of the connecting rod mass (after [10.5])

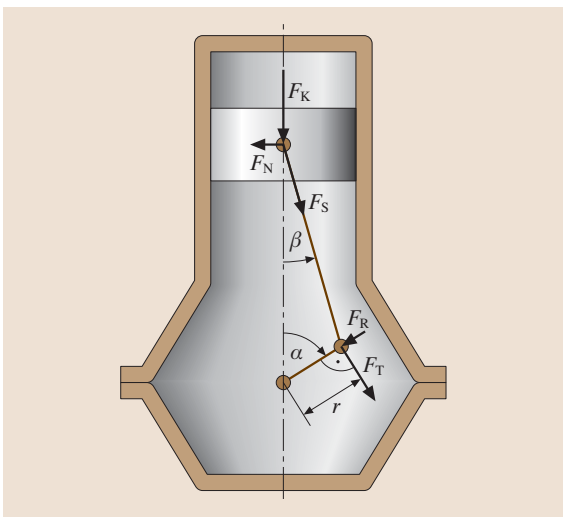

Fig. 10.15 Forces on the transmission

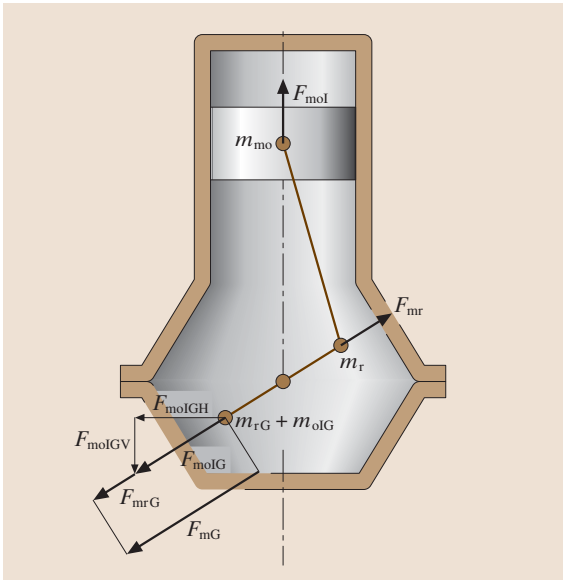

Fig. 10.16 Counterweight and forces

The direction of the force F_T corresponds to the direction of rotation. The normal force generates the corresponding reaction torque, which acts as a tilting moment on the housing and must be absorbed by the housing suspension.

Mass Balancing

The periodically varying inertial forces and moments of the transmission's moving points can cause oscillations, which have an effect on the engine suspension and substructures. This load can be counteracted by balancing masses at the crankshaft webs. The configuration of this mass balancing depends on the number and arrangement of the cylinders as well as the distribution of the crank throw.

Inertial Force Balancing on Single-Cylinder Machines. Only rotating and oscillating inertial forces, but no moments of inertia, occur on a single-cylinder machine since the plane of symmetry lies in the cylinder axis.

The rotating inertial forces can be balanced relatively easily and completely by two counterweights m_{rG} on the crankshaft (Fig. 10.16). These are offset by 180° with respect to the crankshaft journal and are calculated from the rotating mass m_r and the corresponding distances from the center of rotation as

$$m_{rG} = 0.5 m_r \frac{r}{r_G}\,, \tag{10.45}$$

where r is the crank radius and r_G is the distance of the counterweights from the center of rotation.

The distribution of the balancing masses to individual counterweights with the mass m_{rG} is incorporated to prevent an additional moment.

To balance the oscillating inertial forces, (10.38) is applied and broken down into first- and second-order forces of inertia. The change of the first-order forces of inertia corresponds to the frequency of the crankshaft speed and consequently can be partially balanced by counterweights on the crankshaft.

Second-order forces of inertia change twice as fast. Therefore they cannot be balanced by counterweights on the crankshaft.

The oscillating inertial forces act in the direction of the cylinder axis. Hence, only the perpendicular force components of the rotating counterweights can be used as mass balancing. The horizontal force components also generated represent an interfering force. The following equation is used to calculate the counterweights

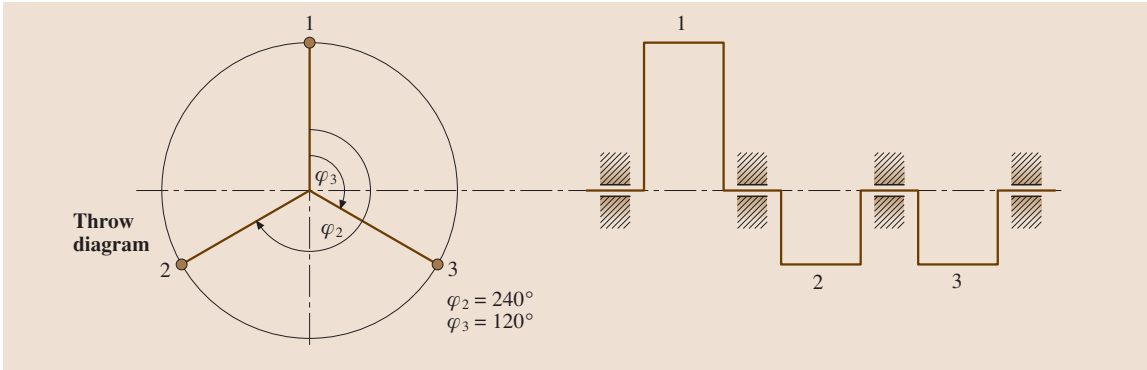

Fig. 10.17 Cross and longitudinal sections of a three-cylinder crankshaft (after [10.3])

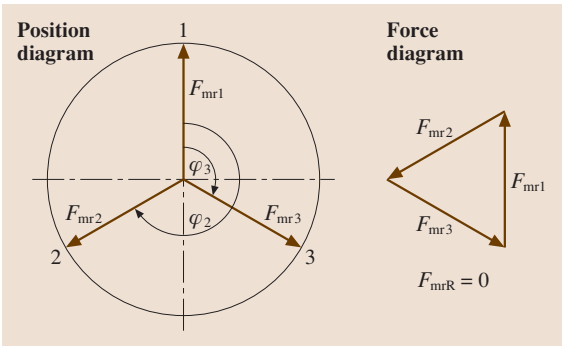

Fig. 10.18 Determination of the resultants from the rotating inertial forces (after [10.3])

m_{oIG} per web to balance the first-order forces of inertia

$$m_{oIG} = 0.5 m_o \varphi \frac{r}{r_G} , \qquad (10.46)$$

where φ represents the proportion of the first-order forces of inertia being balanced. This prevents the influence of the interfering horizontal force components from becoming too great.

Mass Balancing on Multi-Cylinder Machines. To balance masses for multi-cylinder engines, the inertial forces are calculated for every cylinder and consolidated in a resultant. The aim of mass balancing is to compensate the inertial forces reciprocally and to keep the resultants as small as possible.

Furthermore, the concentrated loads not engaging in the center of mass cause additional moments of inertia. These are also consolidated into resultants.

The radial and axial arrangement of the crank throw strongly influence the value of the resultants. When designing the crankshaft, attention has to be paid to balancing the concentrated loads. One simple way to do this is by projecting the crankshaft radially and axially. Cross and longitudinal sections of the crankshaft are drawn (Fig. 10.17). The cross section (the left-hand image in Fig. 10.17) is called a throw diagram because of its shape. Along the longitudinal section (the right-hand image in Fig. 10.17) of the crankshaft, the crank throws are numbered from left to right and subsequently transferred to the throw diagram.

Resultants from the Rotating Inertial Forces. The rotating inertial forces calculated with (10.32) are transferred in parallel to a common cross-sectional plane. By adding the vectors, the individual forces are consolidated into a resultant F_{mrR} (Fig. 10.18).

The resultant rotates with the crankshaft speed and has a constant value. Hence it does not have to be determined anew for other crankshaft positions, but only rotated by the corresponding angle (Fig. 10.18).

Resultants from the First-Order Forces of Inertia. The specific instantaneous value in the cylinder axis is calculated by projection onto these and the total first-order inertial forces in the direction of the cylinder axis is determined by adding their vectors. The maximum value of the first-order forces of inertia is calculated with

$$F_{moI\_max} = m_o \omega^2 r . \qquad (10.47)$$

A simpler approach is often used in practice. The maximum values are likewise applied in the direction of the crank arm. Adding these forces yields a resultant of the maximum values $F_{moI\_max\,R}$ that is projected onto the cylinder axis. The force calculated in this way is the resultant of the first-order forces of inertia F_{moIR} (Fig. 10.19).

The resultant of the maximum values rotates together with the crankshaft as it rotates. In the corresponding crank position, it must be projected

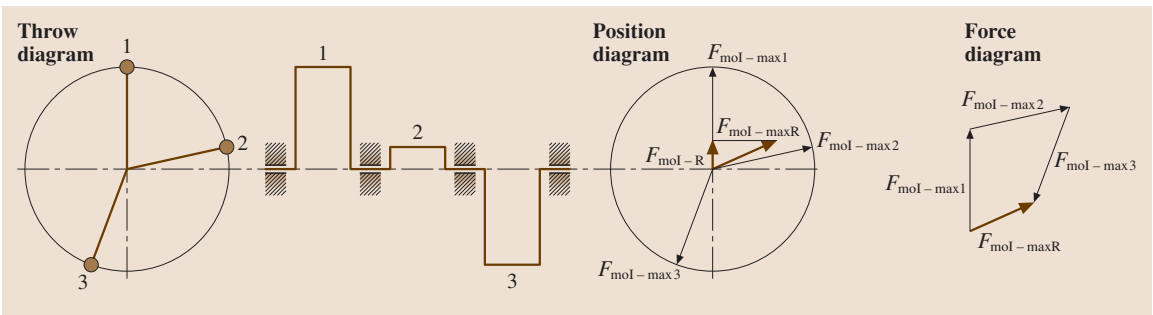

Fig. 10.19 Determination of the resultants from the first-order forces of inertia (after [10.6])

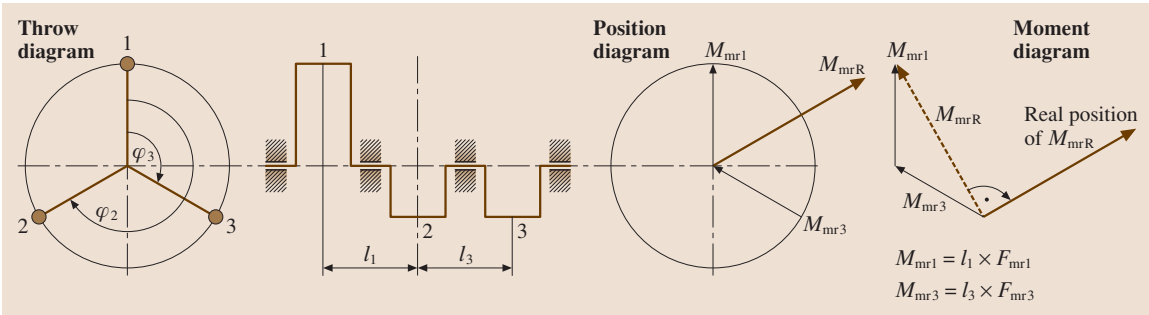

Fig. 10.20 Determination of the resultant moment of inertia from the rotating inertial forces (after [10.6])

anew onto the cylinder axis in order to obtain the corresponding resultant of the first-order forces of inertia.

Resultants from the Second-Order Forces of Inertia. The resultant of the second-order forces is calculated in the same way as the resultant from the first-order forces of inertia. However, the second-order forces of inertia change their value as the crankshaft's angle of rotation doubles. Therefore they cannot be applied in the direction of the crank arms. Rather, they have to be drawn at twice the angle. A force plan is again used to calculate the resultant of the maximum values, which is subsequently transferred to the position diagram. Projection onto the cylinder axis yields the resultant of the second-order forces of inertia.

The rotation of the resultant of the maximum values has to be entered on the site plan at twice the crankshaft angle. The resultant sought is calculated by projection onto the cylinder axis.

Resultant Moment of Inertia. The inertial forces in multi-cylinder engines act at a specific distance to the machine's center of gravity and cause moments of inertia. Since their precise determination is extremely involved, a simplified assumption places the center of gravity in the longitudinal section in the crankshaft axis (e.g., the second cylinder's axis in a three-cylinder machine; see the longitudinal crankshaft section in Fig. 10.20). The resulting error is negligible in most cases.

The moment vectors are applied corresponding to the crank arms taken from the throw diagram in the site plan. The direction of the vectors is determined as follows. The vectors in the longitudinal section to the left of the reference point point outward, while the vectors to the right of the reference point point toward the center of the throw diagram.

The value of the resultant moment of inertia is obtained by adding the vectors in the moment diagram. The vector is given its correct position by rotating it clockwise by 90°.

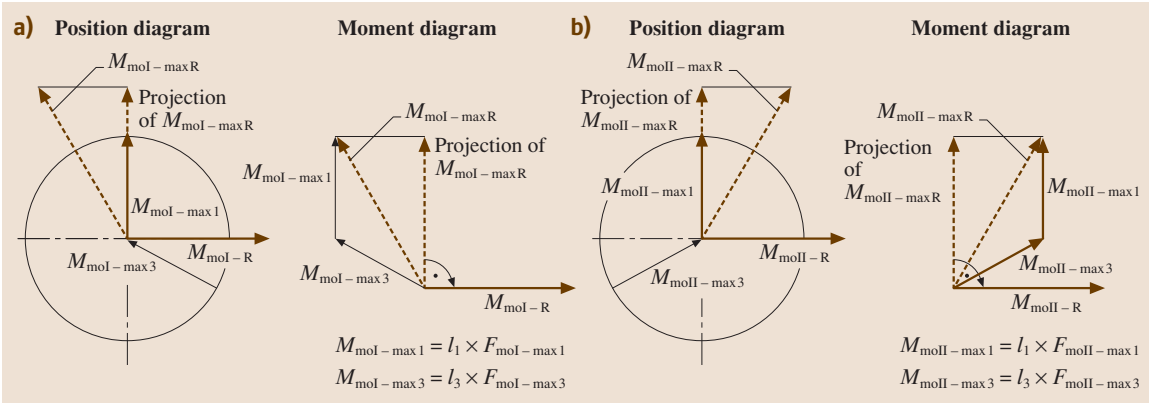

Fig. 10.21a,b Determination of the resultant moment of inertia from the oscillating **(a)** first- and **(b)** second-order inertial forces (after [10.6])

A similar approach is employed to determine the resultant first-order moment of inertia. However, the resultant of the maximum values of the moments is projected onto the cylinder axis and then rotated clockwise by 90° (left-hand position and moment diagram in Fig. 10.21).

When the resultant second-order moment of inertia is calculated, the moment vectors must be entered at twice the crank angle (see the right-hand position and moment diagram in Fig. 10.21). Just as with the resultant first-order moment of inertia, the resultant of the maximum values is projected onto the cylinder axis and rotated by 90°.

10.1.4 Selected Elements of Reciprocating Machines

Crankshaft Drive

The crankshaft drive can be constructed in a plunger piston or crosshead design. The crosshead relieves the piston from lateral piston force, especially in large piston machines (Fig. 10.22).

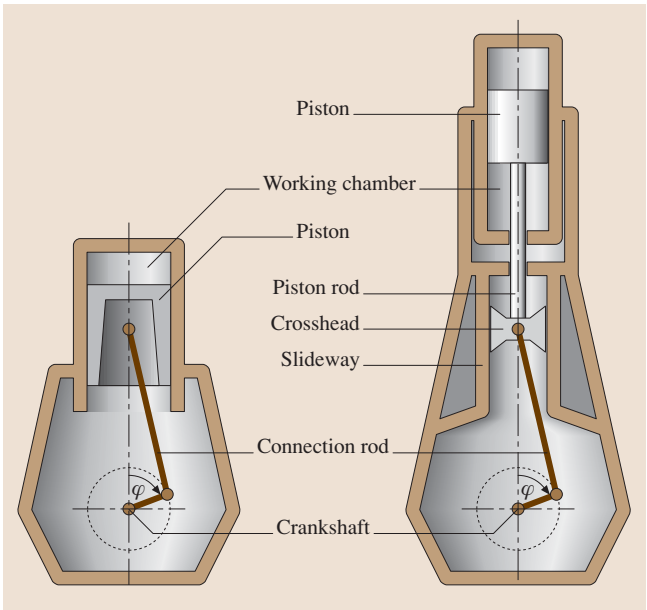

Fig. 10.22 Plunger piston and crosshead crankshaft drive (after [10.6])

Crankshaft

The crankshaft shown in Fig. 10.23 has a shaft journal (1) running in bearings connected by webs (3) to the crankshaft journal. Counterweights (4) on the webs balance the rotating inertial forces. As a rule, the crankshaft is suspended by $z+1$ main bearings, where z is the number of cylinders.

The crankshaft is under stress from forces and bending and torsional moments. The webs are dimensioned accordingly to handle the high stresses.

Different methods are used to manufacture crankshaft blanks. A difference is principally made between cast and forged crankshafts. Cast crankshafts weigh 10% less than forged ones because of the low density of the nodular graphite cast iron frequently used. Giving cast crankshafts a hollow design can boost this even more. A significant disadvantage of cast over forged crankshafts is the low elastic modulus of penetration and associated lower stiffness. In Europe, the market share of cast-iron car and truck crankshafts that are not highly stressed is 60% [10.7].

The most important forging methods can be classified as open die forging and closed die forging. While hammer forging is only used for prototypes and custom-made pieces, closed die forged crankshafts are primarily used in cars and trucks in conjunction with large lot sizes.

If the size of the crankshaft being produced exceeds the production possibilities of forging and casting, the shaft and crankshaft journal are directly connected to one another by the webs. These so-called multi-piece crankshafts are primarily used in the manufacture of large diesel engines.

Forged and cast crankshafts are subjected to different post-processing in order to increase a crankshaft's component strength. Apart from inductive hardening to increase the bearing journal's resistance to wear, rolling the radii in the transition bearing journal and web and nitriding build up residual compressive stresses in the journal and radii zone. As a result, the fatigue strength can be increased considerably in these highly stressed zones.

Connecting Rod

The connecting rod transmits forces between the piston and crankshaft journal. It is not only under stress from tension and compressive forces but is also subjected to bending by the respective inertial forces. This necessitates a design that is both rigid and light, especially in high-speed combustion engines.

The connecting rod (Fig. 10.24) consists of a shank and two conrod eyes, which act to connect the piston and the crankshaft. It is cast, die forged or sintered. Heat-treated steel as well as gray cast iron, malleable iron and light metals are used as materials. Fracture separations, also called cracks, separate (straight or

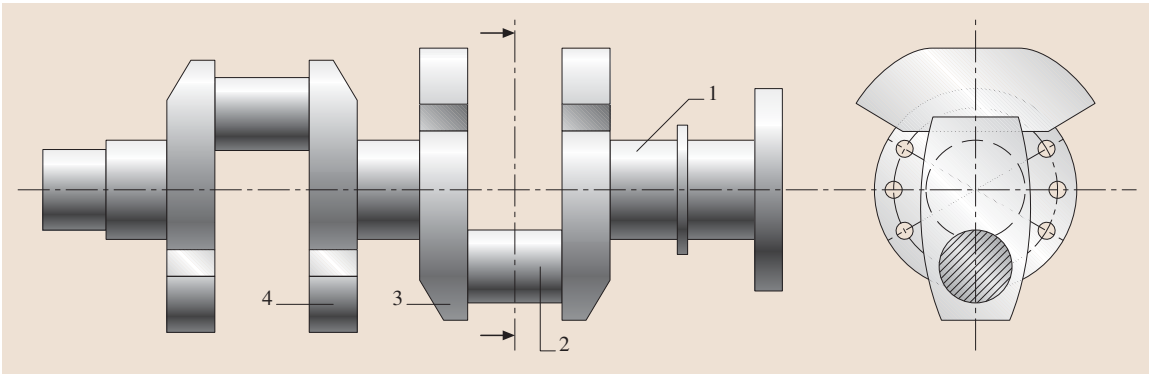

Fig. 10.23 Elements of a crankshaft (after [10.4])

obliquely) the bottom (large) small-end bearing. Anti-fatigue bolts hold the halves of the large conrod eye together.

Piston

The piston's job is to transmit fluid forces to the connecting rod or connecting rod forces to the fluid (Fig. 10.25).

In addition, the piston seals the working chamber by means of piston rings. The number of piston rings is dependent on the pressure difference between the upper surface and the bottom surface. In combustion engines, for example, the piston rings dissipate the heat generated in the pistons, which piston cooling can subsequently pass to the motor oil.

Hence, having high resistance to wear and resistance to heat as well being able to conduct heat and being lightweight are the most important requirements on a piston.

This is why pistons are usually made of light alloys and less often gray cast iron (smaller pistons). Low piston weight has a positive effect on the oscillating inertial forces. Steel and cast steel are only used for the top part of multi-piece pistons or for plunger pistons.

Lubrication

The lubrication of piston machines serves the functions:

- Forming a stable lubricating film between the structural parts
- Reducing friction
- Reducing wear in the machine
- Cooling and cleaning bearings and sliding surfaces
- Forming a seal between the piston ring and cylinder wall

Pressure circulation lubrication is primarily used. The oil is delivered by a pump that is powered by a piston machine or electrically powered. It is purified, cooled and subsequently pumped into the main oil gallery. From there, it reaches the lubricating points such as the crankshaft, valve gear and piston.

Cooling

The heat losses occurring on the walls of the working chamber necessitate cooling of the corresponding components. The heat flow dissipated is dependent on the surface, the heat transfer coefficients and the temperature difference. Water and air are mainly used as coolants and prevent overheating of the components and lubricant as well as power losses caused by filling losses. However, water's better cooling effect increases the complexity of designing as well as manufacturing of the machine. Water-cooled machines are given a cooling jacket through which water is pumped. In the case of air cooling, the design of

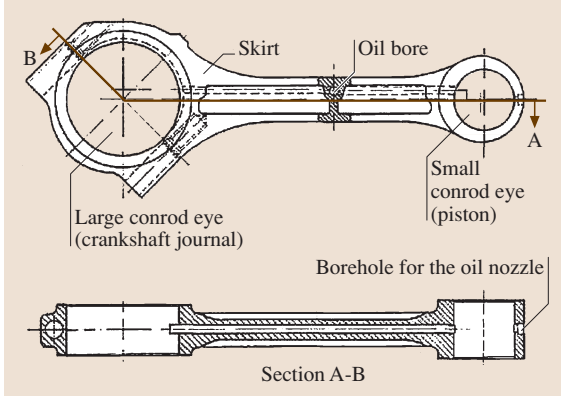

Fig. 10.24 Connecting rod design (after [10.6])

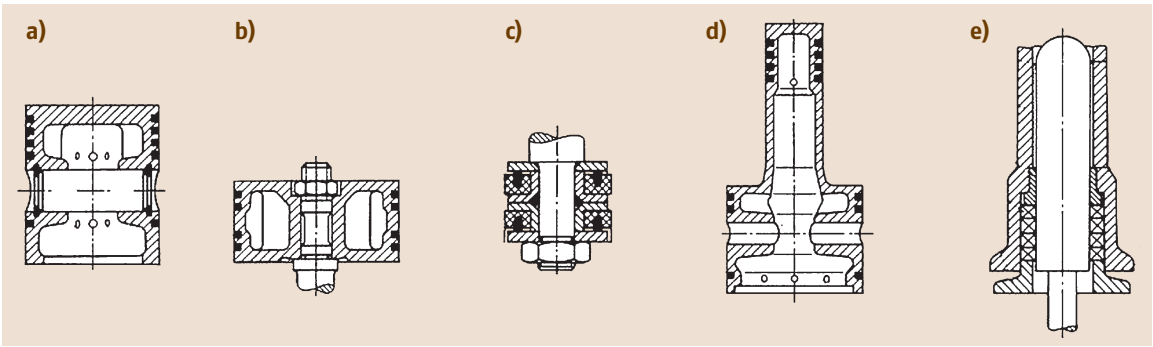

Fig. 10.25a–e Piston variants (after [10.4]). **(a)** Plunger, **(b)**, **(c)** disc pistons, **(d)** stepped piston, **(e)** plunger piston

the fins enlarges the surface of the components being cooled.

Suspension

As a rule, a split bearing is used for the suspension in reciprocating machines because of the offset shape of the crankshaft. Exceptions are multi-piece crankshafts or small and medium-sized piston compressors in which antifriction bearings, among others, can be used.

Their simple design and the small space required in the crankcase, their ability to absorb impacts and vibrations as well as their low mass is increasingly leading to friction bearings with hydrodynamic lubrication being used in reciprocating machines.

Apart from great strength, the materials used must also have optimal tribological properties. Hence, friction bearings are usually designed with a harder matrix (e.g., CuSn, AlCu) into which a soft, low-melting-point material (e.g., Pb, Sn) is incorporated.

The suspension's reliability is crucially important for guaranteeing a piston machine's operation. Hence, optimal engineering utilizes improved bearing materials and state-of-the-art calculation methods.

10.2 Positive Displacement Pumps

10.2.1 Types and Applications

A positive displacement pump is a work machine for incompressible media (fluids), the working chamber of which is periodically altered by the displacer (piston). The displacer's motion can be either oscillating (reciprocating pump) or rotating (rotary piston pump).

Reciprocating pumps mainly use automatically operating, pressure-controlled valves to control the process, i. e., to connect and disconnect the working chamber to the suction and the pressure line. Rotary piston pumps use ports to do this.

In each case, the discharge of the medium directly follows the characteristic of the displacer's motion (volume displacement).

Theoretically, the maximum pressure achievable with positive displacement pumps is unlimited and determined only by internal leakage losses, the medium's compressibility, the component strength and the motive power.

During delivery, mechanical energy is transferred to the medium as potential energy, which serves to compensate for level or pressure differences.

A difference is made between reciprocating pumps with rigid pistons (disc and plunger pistons and plungers, Fig. 10.26) and with elastic pistons (diaphragm, hose, Fig. 10.27).

Radial and axial piston pumps in which the piston is typically designed as a plunger are also used in high-pressure hydraulics. Depending on the design (radial or axial), the stroke motion in these pumps is generated by a rotating eccentric cam or a swash plate and a fixed cylinder unit, i. e., similar to reciprocating pumps with crankshaft drive.

In part, the lift stroke for a fixed eccentric or swash plate is also produced with a rotating cylinder unit (drum/star). In systems with a rotating cylinder unit, control blocks with ports are used instead of the working valves otherwise customary in reciprocating pumps (Figs. 10.28, 10.29).

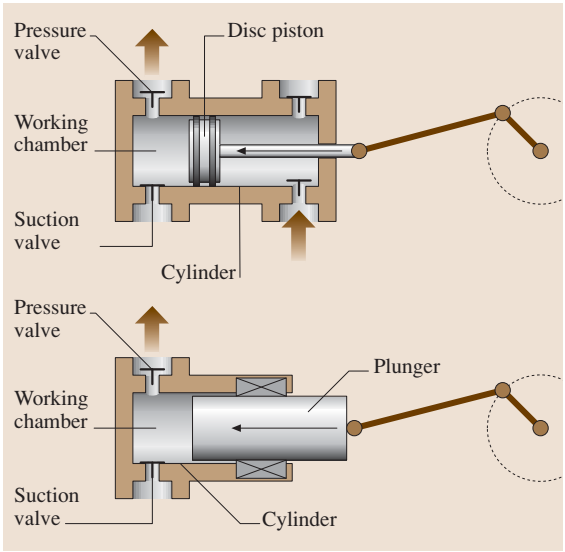

Fig. 10.26 Rigid piston design

Rotary piston pumps are classified according to the primary motion of the displacer as single rotation piston machines, planetary rotation piston machines and circulation piston machines (Figs. 10.30–10.33).

Other designs for delivering media with solid fractions or for liquefied gases or even with direct drive without crankshaft drive, e.g., steam and pneumatic pumps or hand pumps, are characterized in every configuration by special requirements and have different, usually oscillating types of motion, which for the most part are directly generated without a crankshaft drive or the like (Fig. 10.34).

Furthermore, other designs exist that cannot be directly classified in the categories cited because of their types of motion. One example is the peristaltic pump used in medicine and laboratories (Fig. 10.35).

The vane pump, primarily used for garden irrigation and in small boats, is simple in design and durable in operation (Fig. 10.36).

10.2.2 Basic Design Parameters

Figure 10.37 presents the principle of reciprocating pump operation.

The crankshaft drive, consisting of the crankshaft, connecting rod and crosshead, converts rotary drive mo-

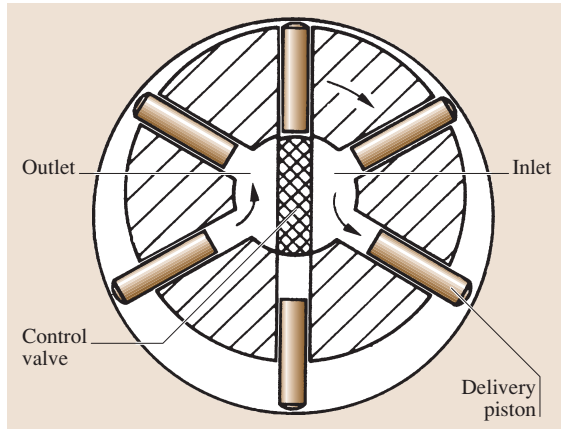

Fig. 10.29 Radial piston pump

Single rotation piston machines	Planetary rotational piston machine	Circulation piston machine
Moving parts induce uniform rotation around their centers of mass.	The center of gravity of the uniformly rotating displace describes a circular path.	Along with uniformly rotating parts there are also irregularly moving parts that execute circular or circle-like or even oscillating motions.
Moving parts are directly balanced: bearings and shafts are not subjected to stress from centrifugal forces → High speeds are possible.	The rotary imbalance can only be directly balanced. Increased stresses on bearings caused by centrifugal forces. Speeds are limited.	Increased friction in the machine → overall efficiency decreases. Wear increases.
Examples: Gear pump, screw design, roots blower, gear tooth design, liquid ring design.	Examples: Trochoidal-type design, eccentric screw pump, eccentric design, rolling piston design.	Examples: Multi-cell or impeller cell design, rotary valve design, external-vane design.
Operating principle  (Gear pump)	Operating principle  (Eccenter-type design)	Operating principle  (Vane-type design)

Fig. 10.30 Rotary piston machines

tion into an oscillating motion, which the piston rod transmits to the piston. In the cylinder, the piston executes a motion between the two dead center positions, the crank dead center (CDC) and the head dead center (HDC), whereby the volume trapped between piston and cylinder cover diminishes and expands periodically.

In principle, the function and process are identical for rotary positive displacement pumps. The resultant working cycle can be broken down as follows:

1. Induction. The volume of the working chamber expands during the piston's motion from CDC to HDC. This produces a vacuum in the working chamber causing the suction valve (SV) to open. This vacuum causes the fluid delivered from the suction line to flow into the cylinder. At nearly constant pressure, induction theoretically occurs during the complete piston stroke (corresponding to line 1–2 in the p–V diagram).
2. Pressure rise. The piston motion reverses in the crank dead center. The resultant reduction in volume causes the pressure in the working chamber to rise and the suction valve to consequently close. Since liquids are theoretically incompressible, the pressure rises at a constant volume to the pressure at the pressure valve (PV) (corresponding to line 2–3 in the p–V diagram).
3. Expulsion. The reduction in volume during the piston's motion from CDC to HDC causes the pressure in the working chamber to increase. When a pressure is attained, which dominates on the pressure side of the pump, the pressure valve opens. The fluid is expelled approaching the pressure, which dominates at the outlet (corresponding to line 3–4 in the p–V diagram).
4. Pressure drop. When the head dead center is reached, the piston motion reverses again so that the pressure drops at constant volume causing the pressure valve to close and the suction valve to open (corresponding to line 4–1 in the p–V diagram).

Whereas the crankshaft has a constant angular velocity (speed), the piston speed in the cylinder is not constant. It is zero at the dead centers. During its motion from one dead center to the other, there is acceleration and deceleration, each corresponding to the crankshaft's law of motion (Sect. 10.1.3). The piston speed is a function of the angle of rotation α and, as a function of the crankshaft drive's connecting rod ratio (10.23), has an approximately sinusoidal characteristic line.

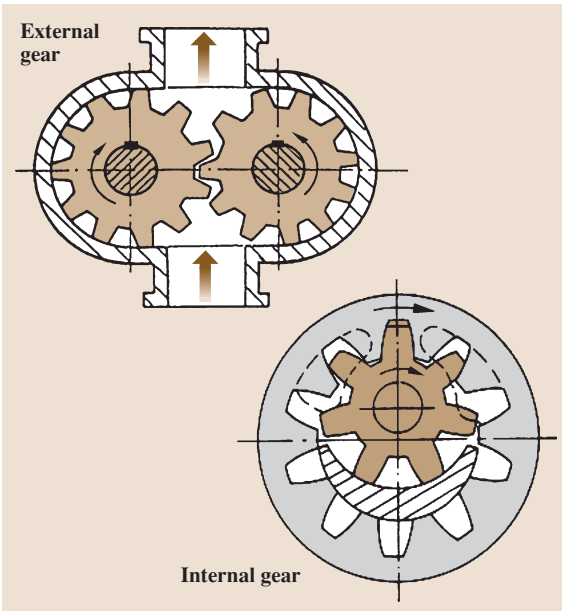

Fig. 10.31 Single rotation piston design

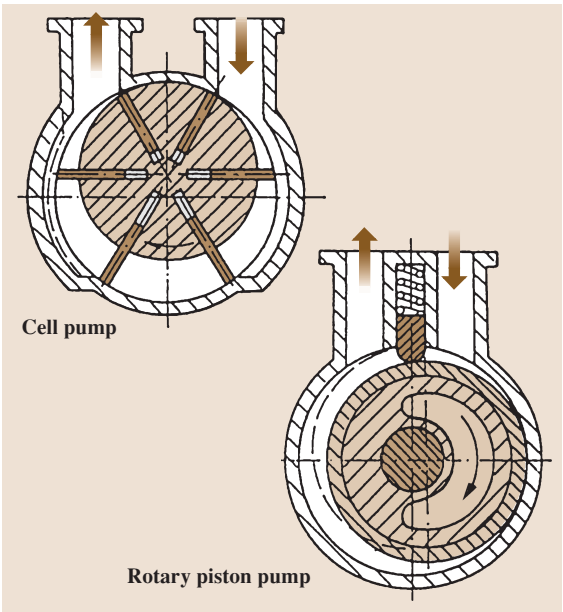

Fig. 10.33 Circulation piston design

Operating Behavior

The p–V diagram in Fig. 10.37 represents an ideal development of pressure, presuming a massless fluid flows without loss. Since losses and inertial forces always have an effect under real conditions, the real p–V diagram of a piston pump in Fig. 10.38 is produced. The ideal pressure development from Fig. 10.37 has been incorporated for comparison.

- Since the frictional losses in the suction line and the suction valve have to be compensated for, suction occurs at a pressure lower than the suction tank pressure. Moreover, another drop in pressure is needed to open the suction valve since the valve opening resistance (valve acceleration, surface ratios at the valve seat, valve elastic force) has to be overcome. The mass inertia of the decelerated liquid column or the suction pressure can also cause a slight rise in pressure toward the end of the intake stroke.
- Since the mass inertia does not cause the suction valve to close abruptly when the CDC is reached and a real fluid is not fully compressible, the pressure does not rise at a constant volume. Moreover, fluids frequently contain small quantities of gas that cannot be compressed. As a result, the real pressure rise from 2′ to 3′ is not isochoric.
- Expulsion occurs at a higher pressure than on the pressure side of the pump since the corresponding losses again have an effect here. Analogous to the

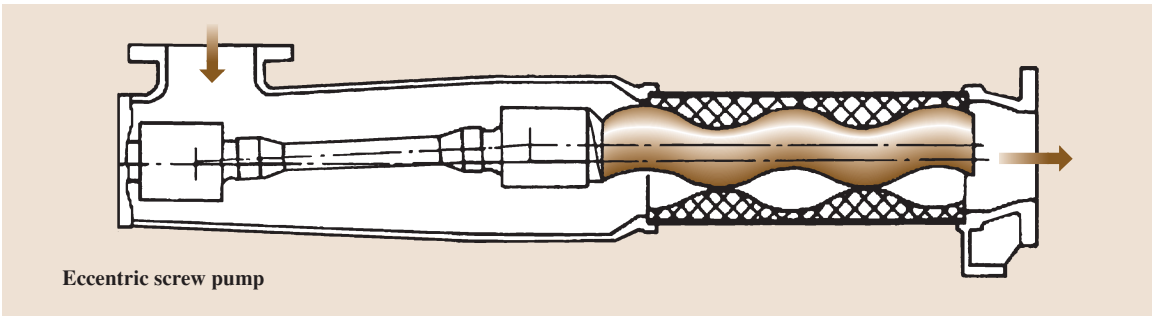

Fig. 10.32 Planetary rotation piston design

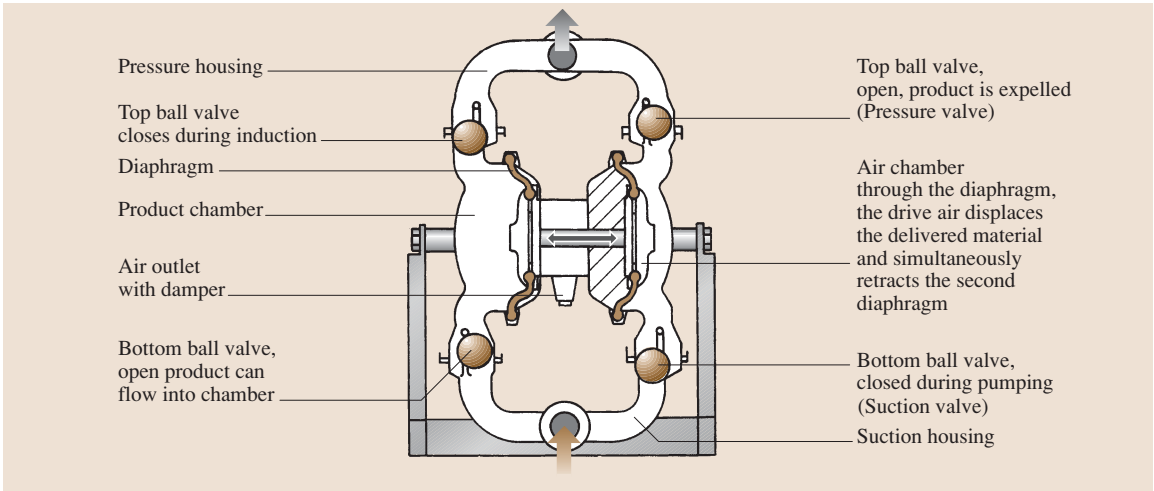

Fig. 10.34 Compressed-air diaphragm pump (after [10.8])

suction valve, an additional increase in pressure is needed to open the pressure valve.

- In turn, the pressure cannot drop at a constant volume since there are inertial forces and potential back-flows from the pressure line when the pressure valve closes and the gas fractions re-expand. As a result, the ideally isochoric pressure drop from $4'$ to $1'$ is not isochoric.

In contrast to centrifugal pumps, piston pumps have a characteristic curve with a delivery rate that is nearly independent of delivery pressure. As a result of the displacement, the delivery rate is calculated as the product of the piston surface s, stroke and rotational speed n

$$\dot{v} = Q = A_K s n \,. \tag{10.48}$$

Consequently, throttling, i. e., changing the system head curve, cannot regulate the delivery rate. On the other hand, an inordinate rise in pressure has to be prevented from destroying the pump and system components.

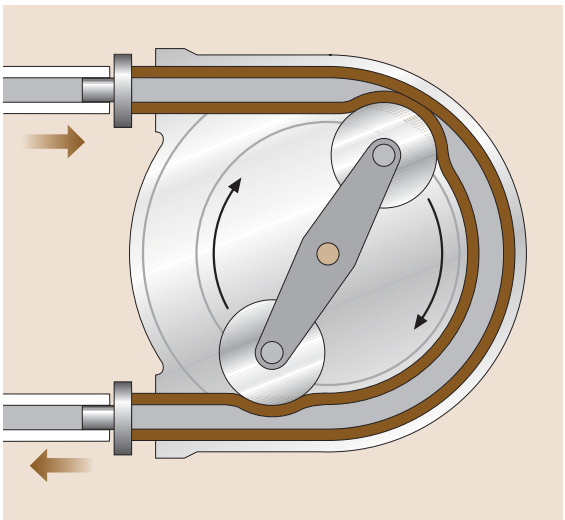

Fig. 10.35 Peristaltic pump (after [10.9])

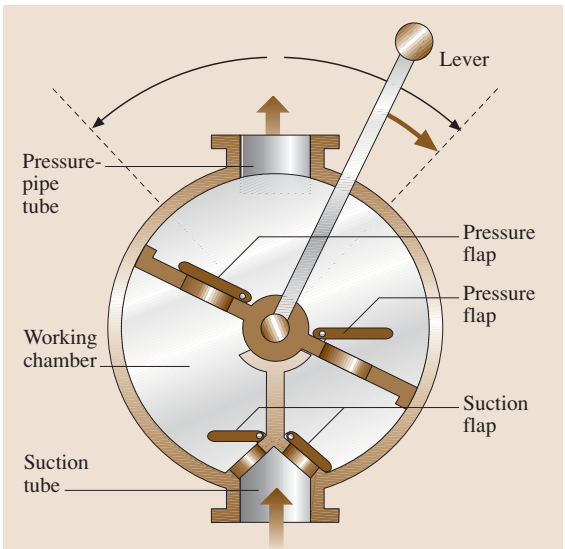

Fig. 10.36 Sliding vane pump

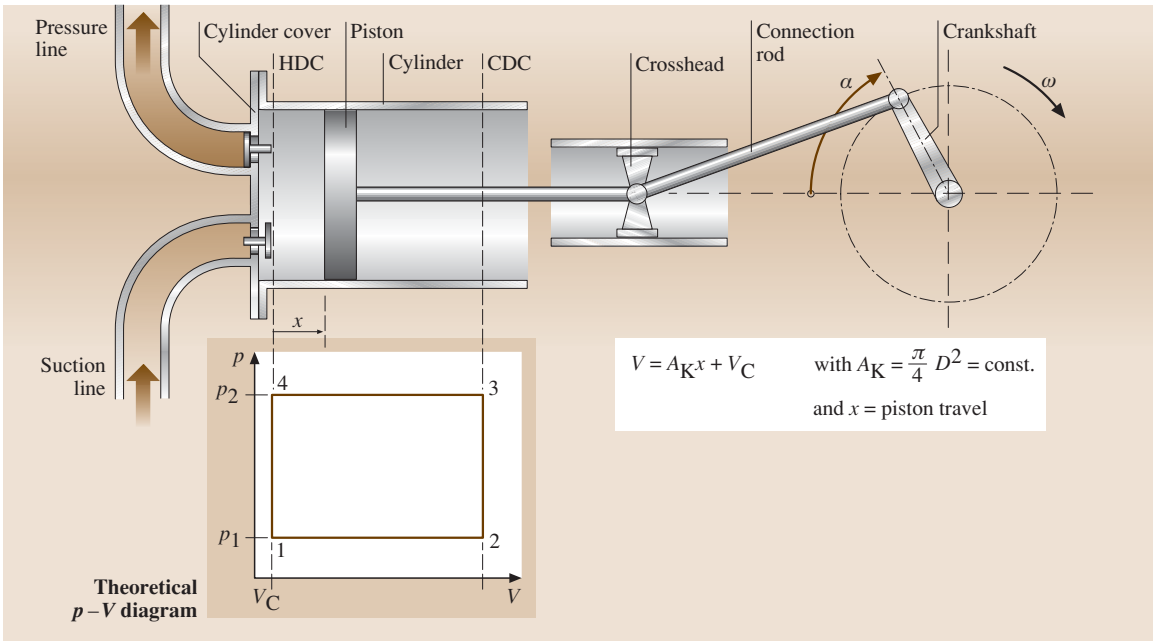

Fig. 10.37 Principle of reciprocating pump operation

Hence, any time a piston pump is used, a *safety valve* must be incorporated on the system's pressure side.

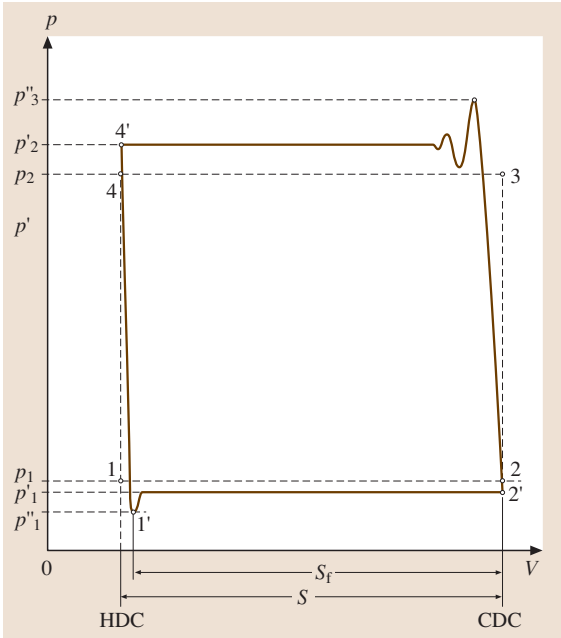

Fig. 10.38 Ideal and real piston pump p–V diagram

Energy and Efficiency

Specific Effective Energy of the Complete System w_{st}. Figure 10.39 shows a simple pump system.

The pump feeds mechanical work to the fluid in order to increase the pressure of the potential energy, i. e., to facilitate delivery and/or a rise in pressure.

If this work is applied to the fluid's mass (disregarding changes in density), then the specific effective energy of the system is obtained

$$w_{st} = w_{geo} + \frac{(p_a - p_e)}{\rho} , \qquad (10.49)$$

$$w_{geo} = H_{geo} g , \qquad (10.50)$$

where w_{geo} is the specific geodetic delivery work, p_e is the pressure on the fluid in the suction tank, p_a is the pressure on the fluid in the pressure tank, ρ is the density of the pumped medium, g is the gravitational acceleration, and H_{geo} is the level difference.

Expressed in pressures and levels, the following ensues

$$p_{st} = H_{geo}\rho g + p_a - p_e , \qquad (10.51)$$

$$H_{st} = H_{geo} + \frac{(p_a - p_e)}{\rho g} . \qquad (10.52)$$

The system's specific effective energy is independent of the type of pump, the size of the delivery flow, and the layout of the pipe system.

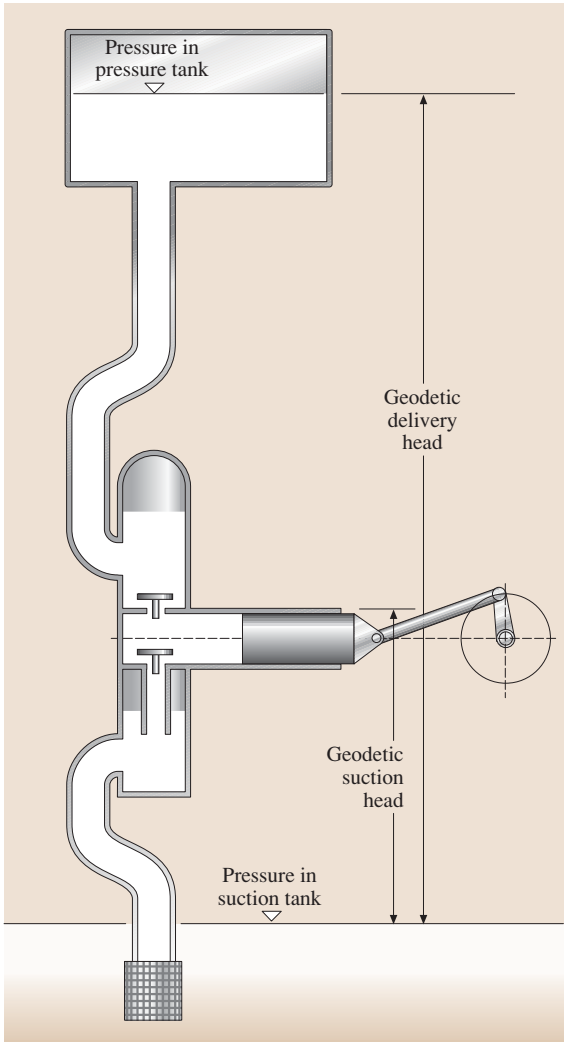

Fig. 10.39 Piston pump system

Specific Effective Energy of the Pump w. The specific delivery work required to deliver the mass flow of the fluid in the selected system is referred to as the specific effective energy of the pump. The proportions of energy loss and velocity energy are taken into account here

$$w = w_{st} + w_{dyn} + w_V \,, \tag{10.53}$$

$$w_{dyn} = 0{,}5\left(v_2^2 - v_1^2\right) \,, \tag{10.54}$$

where v_2 and v_1 are the velocities in the suction and pressure tubes, respectively, and w_v is the specific energy loss in the suction and pressure lines.

The pump's specific effective energy depends on:

1. The type of pump
2. The size of the delivery flow and
3. The layout of the pipe system

Delivery Rate η_{Vol}. As a result of volume losses, a pump's effective delivery rate is lower than the theoretical rate. These losses are caused by:

1. Leaks or valve-closing delays (volumetric efficiency λ_L)
2. The presence of gases or incomplete filling (λ_F)

The product of λ_L and λ_F constitutes the delivery rate η_{Vol}. The following empirical values apply to the delivery rate η_{Vol}:

1. 0.88–0.92 for small pumps
2. 0.92–0.96 for medium-sized pumps
3. 0.96–0.98 for large pumps

Indicated Efficiency η_i. Indicated efficiency expresses the ratio of a system's effective power to a pump's indicated power (determined from the indicator diagram). Thus, hydraulic losses are also taken into account.

$$\eta_i = \frac{P_Q}{P_i} \,, \tag{10.55}$$

$$P_Q = \rho Q w_{st} \,, \tag{10.56}$$

where Q is the feed rate and P_i is the indicated power (from the indicator diagram).

Mechanical Efficiency η_m. Mechanical efficiency expresses all the losses caused by *mechanical friction* inside the pump. In the process, the ratio of indicated power to coupling power (input power) is expressed by

$$\eta_m = \frac{P_i}{P_{zu}} \,. \tag{10.57}$$

Experience has shown that pumps with crankshaft drive have a mechanical efficiency in the range

$$\eta_m = 0.85 - 0.95 \,. \tag{10.58}$$

Total Efficiency of the Pump η. Total efficiency η is expressed by the ratio of the effective power to the input power

$$\eta = \frac{P_Q}{P_{zu}} \,. \tag{10.59}$$

Experience has shown that a pump with crankshaft drive has a total efficiency in the range of $\eta =$ 0.70–0.80.

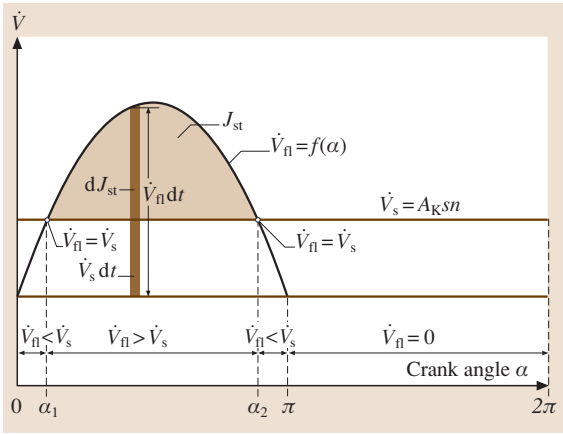

Fig. 10.40 Time progression of the volumetric delivery of a single-action one cylinder pump

Mass Actions

On the one hand, the reciprocating pump's discontinuous working process results in a constantly fluctuating speed of the pumped medium in the connected lines. On the other hand, the portions of the pumped medium subjected to accelerations undergo a mass action. The time-varying delivery rate follows the laws of piston motion up to a fixed limit (the vapor pressure) so that the time progression of the volumetric delivery corresponds exactly to the piston velocity. The valves' action is used to allocate the positive and negative fractions to the intake and the delivery stroke (Fig. 10.40).

The crankshaft's rotation is split into the intake and the delivery stroke. Thus the total delivery rate must be pumped during a half rotation of the crankshaft. The maximum value of the speed is considerably larger than the average value. There are only two times during both the intake and the delivery stroke at which the instantaneous delivery rate corresponds exactly to the average volumetric flow. This is not the case at any other time.

The maximum acceleration is at a crank angle of 0°, i. e., the theoretical start of the intake stroke. However, a maximum acceleration of the amount of fluid also corresponds to a maximum mass action, which results in a maximum reduction in the pressure in the working chamber (Fig. 10.41).

To prevent cavitation, the so-called vapor pressure p_0 of the fluid must not be reached during pump operation. Consequently, the piston acceleration and the mass of the fluid present in the intake tract yield the

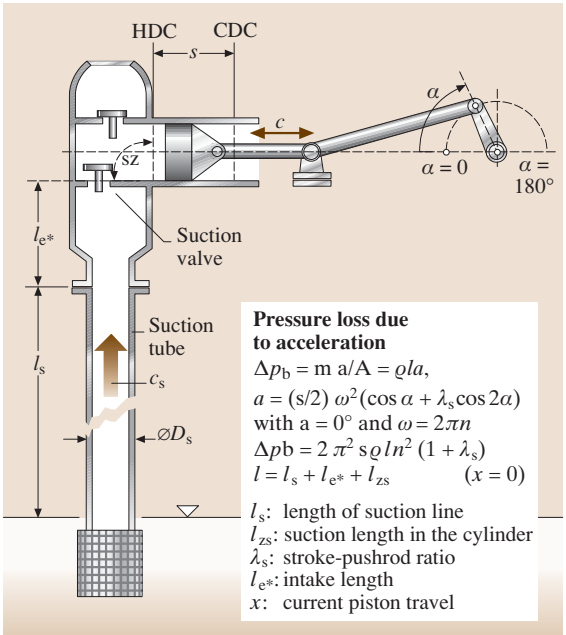

Fig. 10.41 Suction side of a reciprocating pump system

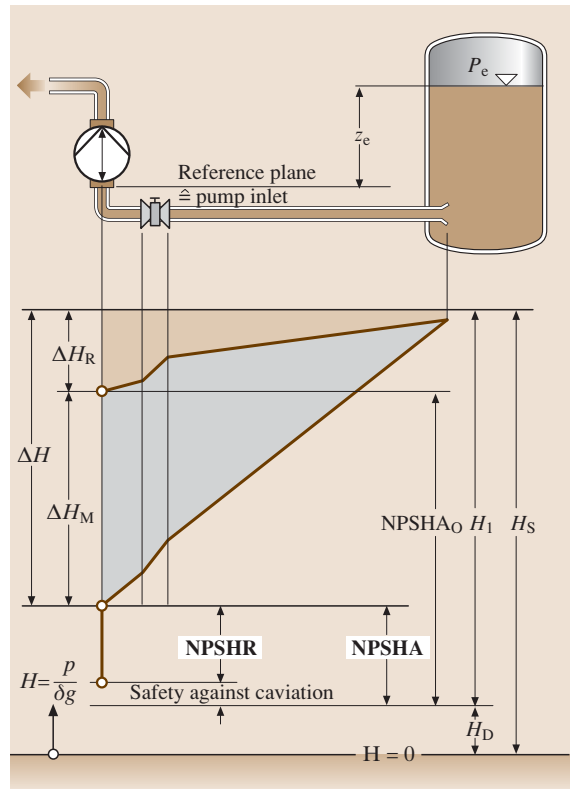

Fig. 10.42 NPSH value of the intake tract of a pump system (after [10.10])

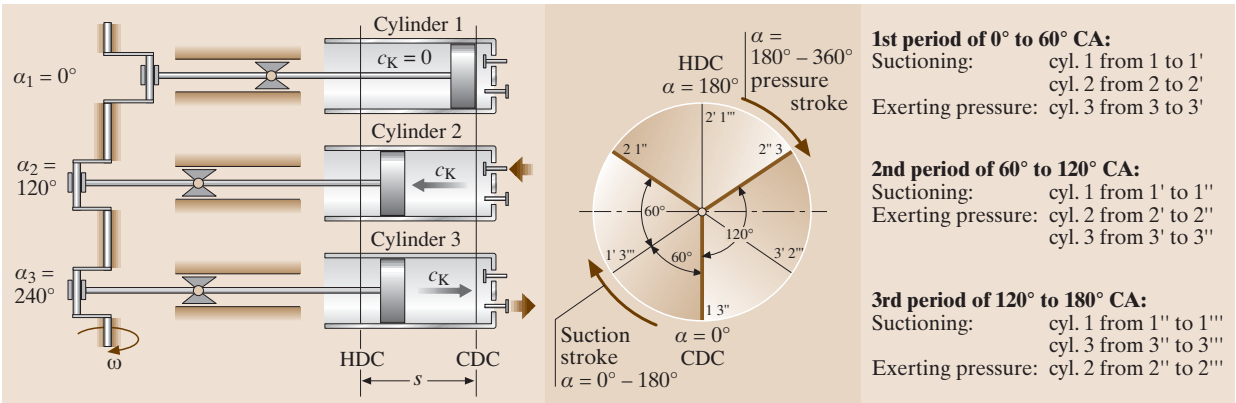

Fig. 10.43 Function of a three-cylinder pump

maximum permissible suction head. Conversely, when the suction head is known, it yields the maximum permissible speed for the pump.

The net positive suction head (NPSH; Fig. 10.42) is used to designate a pump's volume flow rate. The difference between the actual and the required NPSH is a measure of protection against cavitation.

When several working cylinders are employed, conditions change with the effect that several cylinders are able to draw from one suction line at the same time (Fig. 10.43). Here, the drop in pressure as a result of the mass action must be determined individually for the single parts of the intake tract. Employing several cylinders improves the overall balance since the entire amount of fluid is not subjected to maximum acceleration and, when there are upwards of three working chambers, the flow velocity in the suction line is never zero.

To reduce the pulsation of the delivery rate both on the suction and the pressure side, employing several cylinders is expedient.

If using several cylinders proves insufficient, then installing elastic components, the so-called expansion chamber, is advisable. Here, interconnecting an elastic accumulator (gas cushion) achieves a homogenization of the delivery rate.

The cyclic irregularity of the the pressure on the piston is consulted as a decision criterion for integrating an expansion chamber

$$\delta_p = \frac{(p_{K-max} - p_{K-min})}{p_{K-m}}, \qquad (10.60)$$

where

$$p_{K-m} = \frac{p_{K-max} + p_{K-min}}{2}. \qquad (10.61)$$

This applies to both the suction and the pressure side.

The cyclic irregularities considered limit values for the use of expansion chambers are $\delta_{p-s} \leq 0.1-0.05$ (suction side), and $\delta_{p-d} \leq 0.05-0.02$ (pressure side).

The expansion chambers can be constructed both as a simple air tank open toward the fluid (Fig. 10.44) or as a diaphragm or bladder accumulator (Fig. 10.45).

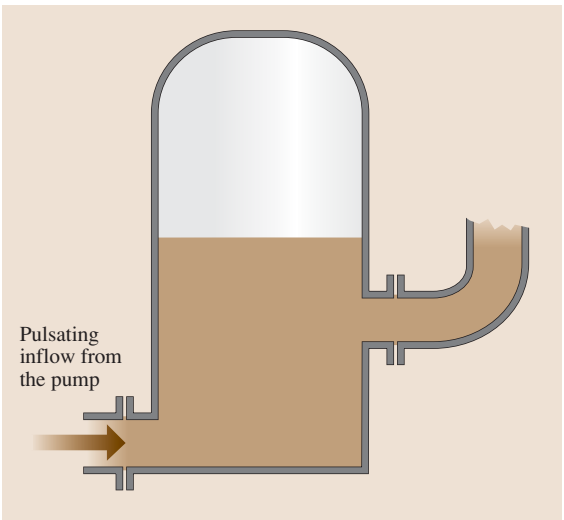

Fig. 10.44 Pressurized air chamber

10.2.3 Components and Construction of Positive Displacement Pumps

Working Valves

Automatically operating, pressure controlled valves are used in reciprocating pumps to separate the suction and expulsion processes. These valves can be constructed as

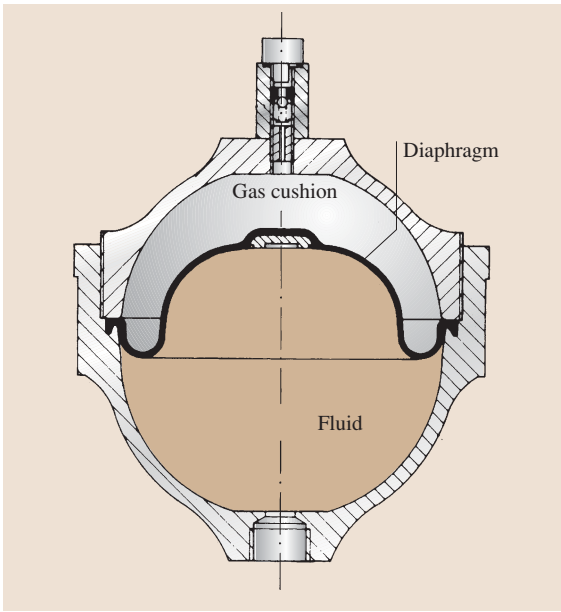

Fig. 10.45 Diaphragm accumulator (after [10.11])

flat seat, conical seat or ball valves. Both, elastic force and gravitational force can trigger their closing forces (Fig. 10.46).

Multiple annular valves (Fig. 10.47) are also used to reduce the force of acceleration at the valve and above all to lower their speed when they close. These make large openings possible when strokes are small.

To open such a valve, a pressure differential must always be present, which essentially depends on the elastic force, the friction and the valve face (Fig. 10.48).

Reciprocating Pumps

Compression Pumps. Compression pumps are pumps that, as boiler feed pumps for example, work approaching pressures up to 7000 bar and achieve delivery flows of 0.01–160 m^3/h. As a result, pump components are under most extreme stresses, most notably in the cylinder (called the pump head here) the valves and the plunger seal (stuffing box). In view of the high pulsating stress of the components, the design not only has to apply appropriate methods of calculation and employ the requisite material but also produce particular surface finishes to ensure sufficient operational reliability.

For economic reasons, such pumps, which are usually only manufactured in small quantities, are often engineered based on *standardized* engines with crossheads. Thus, they are then designed for specific forces along the rod (piston forces). When standard engines are used for different pumps, a specific maximum piston diameter is produced for every pressure to be reached. The number of cylinders and the speed determine the delivery flow pumped. By combining pump heads in these engines, appropriate pumps can be assembled (modular system) for the widest variety of applications with relatively little effort.

The design engineering and material selection for individual components such as the plunger, pump cylinder, valves, etc. are extremely important for pumps with higher pressures. Composite materials or prestressed components are used at extreme pressures (Fig. 10.49).

An important aspect of design is making the disassembly of wearing parts (valves, stuffing box packing) as easy as possible. Above all, it is essential to avoid having to disassemble the suction and pressure lines when removing the valve since these are very rigid at extreme pressures.

The stuffing box packings in compression pumps are under extreme stress and therefore may not be used as a plunger guide. To this end, a corresponding guide bushing (not functioning as a seal) is used.

Metering Pumps. The chemical industry as well as the food processing industry needs metering pumps on a large scale to ensure fluid is metered precisely and consistently. Delivery pressures of up to 4000 bar and precisely repeatable metered quantities of 0.001 l/h or 0.2 mg/stroke up to 200 000 l/h have to be achieved. The required metered quantities are regulated by adjusting the speed or more frequently the plunger stroke. While continuously variable transmissions or frequency converters are widely used to adjust the speed, different variants are used to adjust the piston stroke, which, depending on their design, operate with the *fixed mean position of the piston* or with the *fixed dead center of the piston* from stroke zero onward.

Both plunger- and diaphragm-type metering pumps are constructed.

The stroke can be adjusted in different ways, e.g.:

- Crankshaft drive with adjustable crank radius (Fig. 10.50).
- Double eccentric with adjustable eccentricity (Fig. 10.51).
- Radially adjustable rotary eccentric (Fig. 10.52).
- Spring cam drive units (Fig. 10.53) are often used for simple, primarily smaller diaphragm metering pumps. An adjustable limiting bolt mechanically adjusts the stroke. The stroke can be adjusted by using the limiting bolt to increase or decrease the

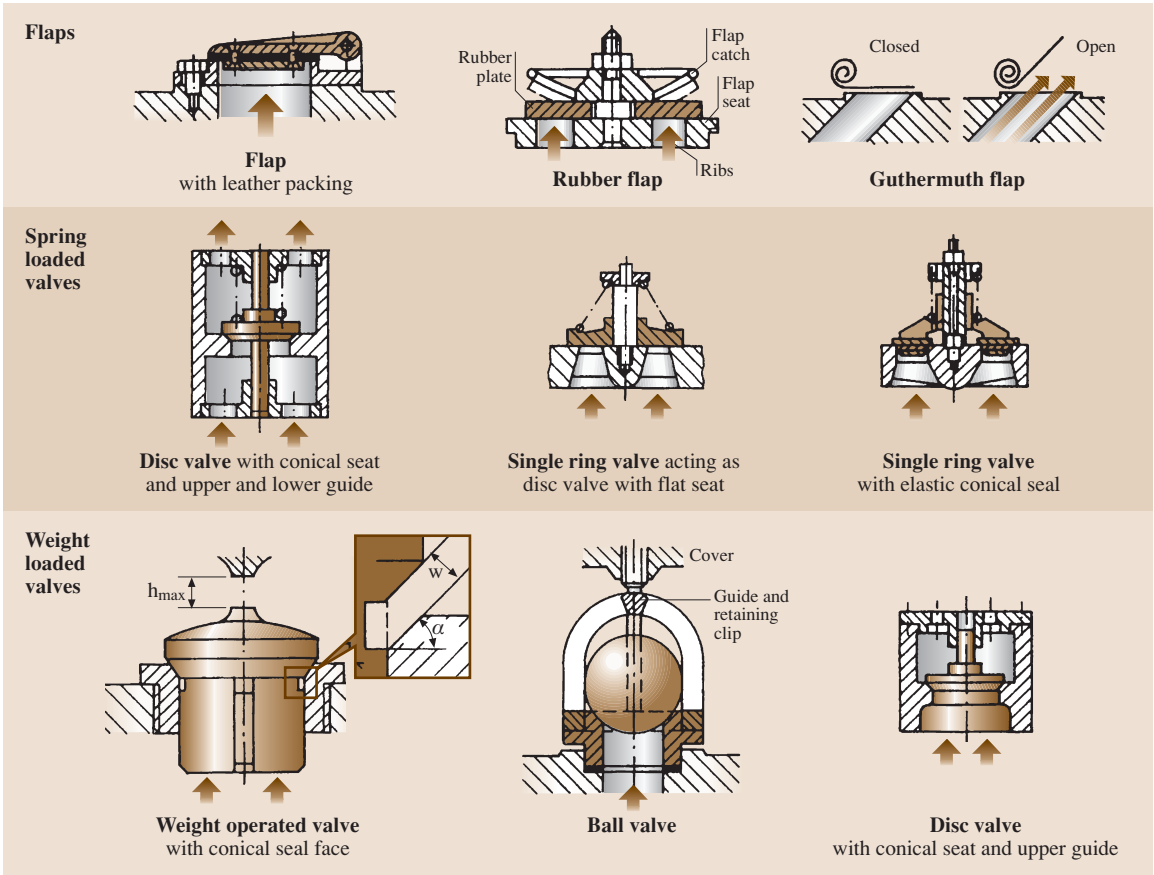

Fig. 10.46 Valve types (after [10.12])

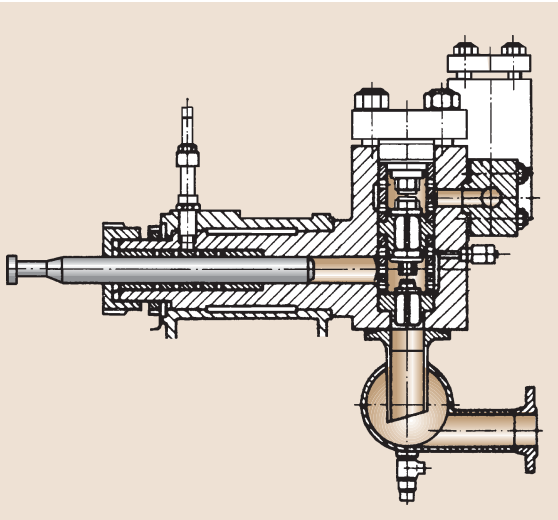

Fig. 10.49 Maximum pressure piston pump for pressures up to 7000 bar (after [10.13])

distance between the follower and the cam's basic circular path. A rotary eccentric cam is the cam shape used. A so-called phase angle occurs in which only part of the stroke is utilized. However, strong forces of acceleration act in this drive unit at the start of the effective stroke so that the range of adjustment at higher pressures is limited to values between a complete stroke and a maximum of 50% of the stroke.

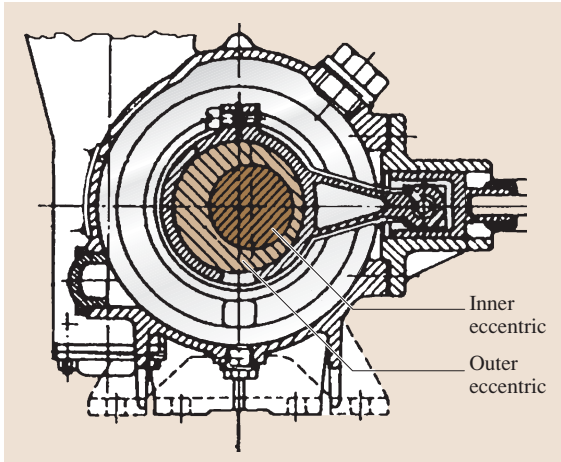

Fig. 10.51 Double eccentric (after [10.14])

Diaphragm metering pumps are used for applications in which the delivery chamber must be absolutely impermeable to the environment. The diaphragm can be operated mechanically as well as hydraulically (Figs. 10.54 and 10.55).

The delivery pressure in mechanical drives subjects the membrane edge to great stress. A hydraulic drive does not subject the diaphragm to great stress and considerably higher delivery pressures are possible.

With regard to adjusting the stroke, the same applies to hydraulically powered diaphragms as to mechanically powered diaphragms. The hydraulic system is

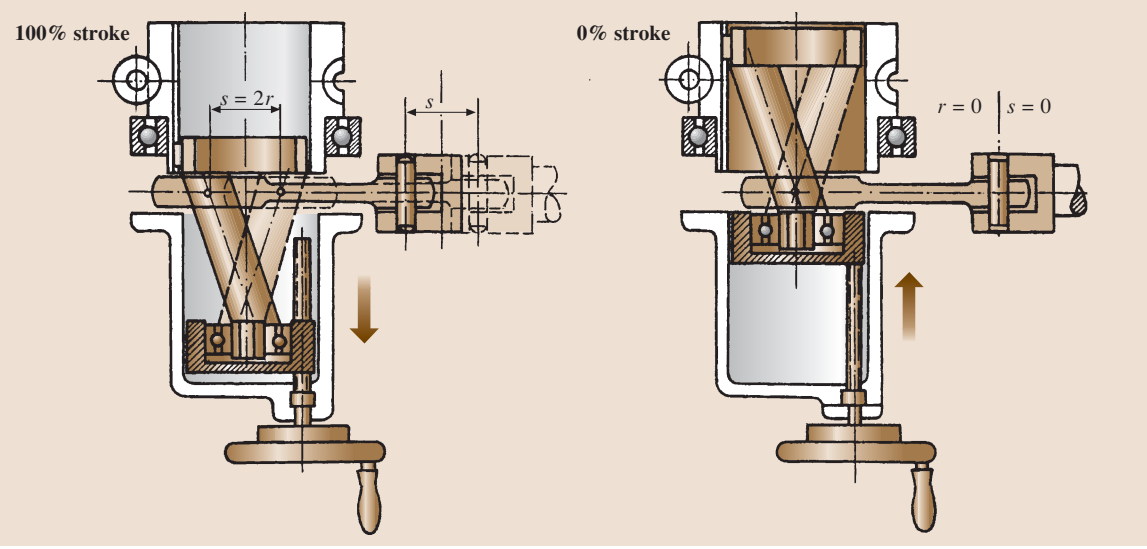

Fig. 10.50 Adjustable crank radius (after [10.11])

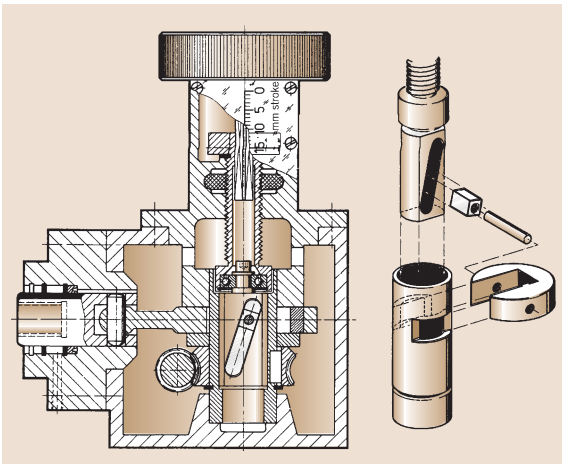

Fig. 10.52 Adjustable rotary eccentric (after [10.14])

simply connected between the plunger and the diaphragm and serves to transfer the quantity pumped in a ratio to the volume of 1 : 1. The force and travel ratios follow the continuity equation. The amount of leakage potentially occurring in the hydraulic system is replenished from the storage tank during each stroke so that the diaphragm's stroke motion is retained with its end positions. Frequently, there is a diaphragm position control. Employing a device to redefine the diaphragm's end position during each stroke prevents overloading of the diaphragm.

A multiple membrane with an inserted control medium is used for cases in which contamination of the pumped fluid by the hydraulic fluid must be prevented or emergency operation guaranteed.

Rotary Piston Pumps

Along with the type of motion, the absence of working valves is a significant feature of piston pumps with rotary displacers. Ports control the suction and pressure

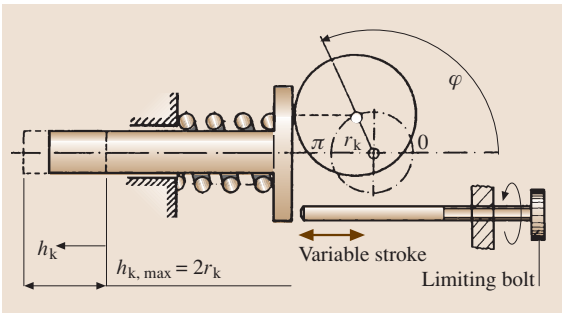

Fig. 10.53 Flexible cam drive unit

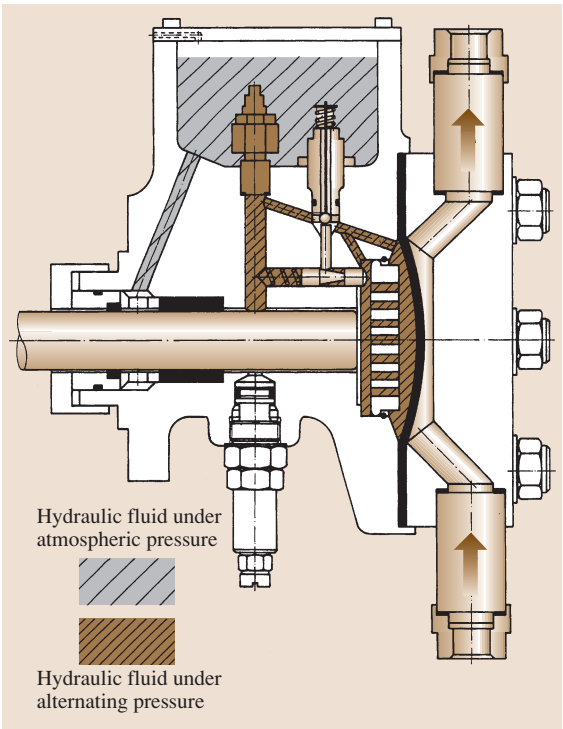

Fig. 10.54 Diaphragm metering pump with diaphragm position control (after [10.11])

process. As a result, when a pressure difference exists in the adjacent medium, these machines can also function as power machines. In order to prevent this, non-return valves (that do not have the function of working valves) are used.

Single Rotation Piston Machines.

Gear Pumps. A gear pump consists of two or more gearwheels arranged in a housing and intermeshed. The driveshaft is attached outside the housing, the remaining gearwheels being driven by the gearing. The suction and pressure sides are separated by the meshing and the sealing gap between the tooth tips, gear-side surfaces and housing.

The rotating gearwheels cause the pumped medium to be delivered from the suction side to the pressure side. In the zone of gear meshing, the teeth displace the medium from the tooth gaps (displacement effect). Simultaneously, the intermeshed tooth flanks seal the suction chamber off from the pressure chamber (Fig. 10.56 (Sp)). Moreover, the tooth tips seal the individual volumes off from the housing (Fig. 10.56). In addition, the axial gap must be confined to narrow lim-

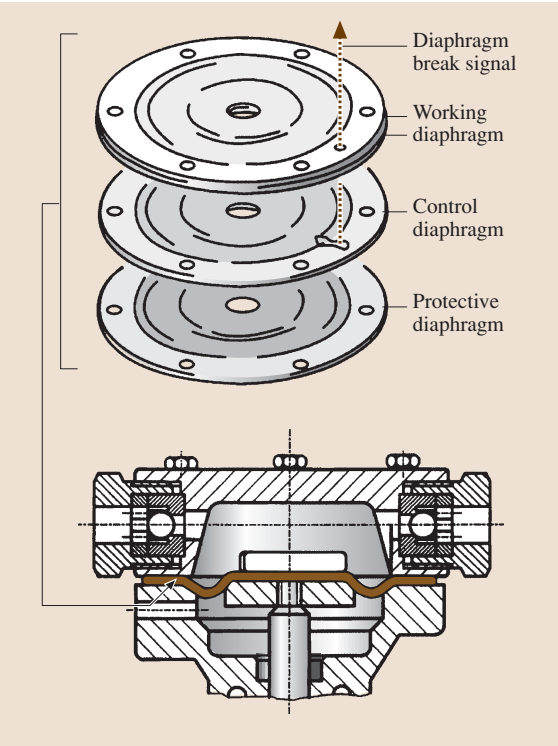

Fig. 10.55 Multi-diaphragm pump (after [10.11])

its by maintaining slight axial clearances. An optimal seal enables the gear pump to attain high delivery rates (volumetric efficiencies).

As a rule, the same involute profile used for transmission gears is used for the tooth flank profile of gear pumps. Thus, the gearwheels can be manufactured cost effectively by using the same tools on identical machines. Other, more-expensive profiles are reverted to only for special applications such as pulsation-free sine pumps. Helical gears are also rarely used. While intended to achieve smoother running, they generate an axial thrust to the gearwheels and bearings as well as unequal axial gap widths.

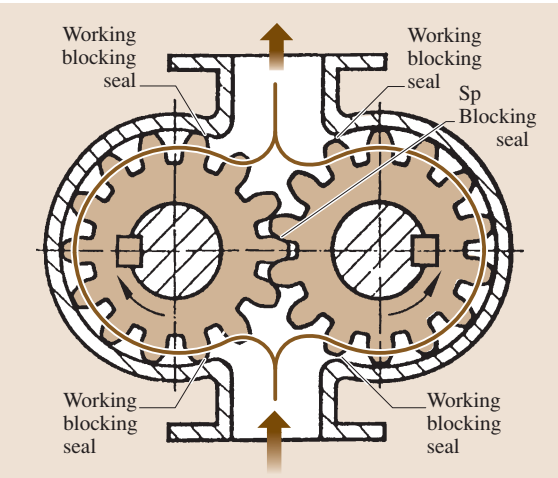

Fig. 10.56 Principle of the gear pump

When rolling, a self-contained volume is produced in the tooth gap into which the opposing tooth immerses. This causes a change of volume. Since a change of volume in enclosed spaces cannot be tolerated when fluid is being pumped, appropriate measures must ensure fluid is supplied to and removed from the tooth gap (Fig. 10.57).

To this end, either so-called compression slots are made in the side panels of the pump or on the teeth flanks or boreholes are made in the bottom land of a gear, which the grooves in a fixed axis connect to the suction or pressure chamber. Alternatively, the tooth flank clearances are made sufficiently large.

When they are being engineered, the clearances between the components must be dimensioned to correspond to the viscosity of the pumped medium and the delivery pressure. This can lead to problems, most notably when there is axial play.

Axial hydraulic clearance compensation is applied to improve impermeability at high pressures and to simultaneously reduce friction during starting. Thus, delivery pressure is utilized to reduce running clearance.

Internal gear pumps can additionally be given radial hydraulic clearance compensation (Fig. 10.58).

Low-pressure pumps ($\Delta p < 16$ bar) are usually designed with eight to 14 teeth while medium- to high-pressure pumps ($\Delta p > 160$ bar) have 16–25 teeth.

Single Rotation Piston Pumps. Rotational motion piston pumps are often incorrectly called eccentric rotational motion piston pumps. Since they are frequently positively driven by external gears, the sliding of their plungers past one another without contact is common to all rotational motion piston pumps. As a result, these pumps are well suited for delivering non-lubricating and abrasive liquids. This aspect fundamentally distinguishes this type of pump from gear pumps. The types are classified according to the number of impellers and the type of hub design (Fig. 10.59).

In some cases, the design selected for the displacer ranges from a multi-impeller to a gear type. However, the rotational motion piston pump is not a gear pump

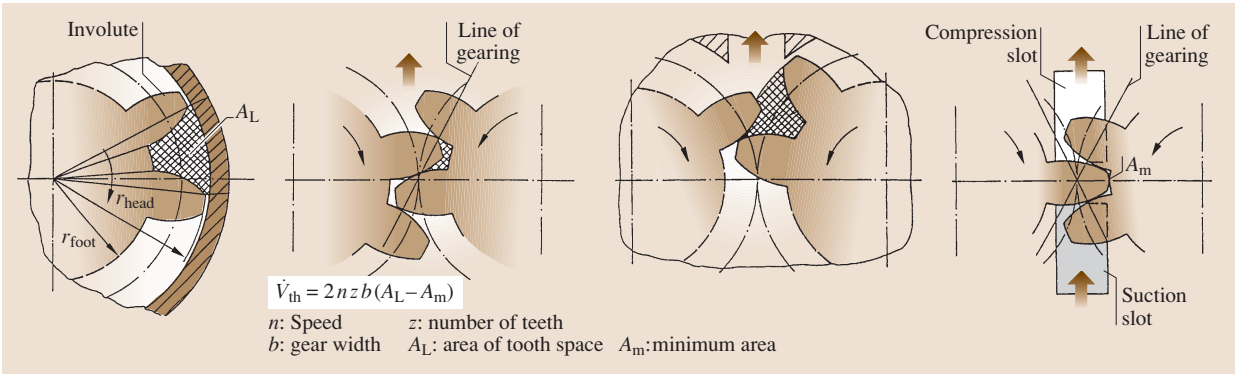

Fig. 10.57 Displacement in a gear pump

since exterior synchronizer gears enable the displacer to run without contact.

The fixed hub produces a seal covering the space between the displacers. The plunger shape creates a flat seal in the space between the housing and the displacer so that the fixed hub is able to achieve better inner impermeability.

These pumps are used, for instance, to deliver finishes, paints, oils, gasoline, food and alcohol and for foaming liquid–gas mixtures.

The pressure range of these pumps reaches 20 bar at delivery rates up to 500 m^3/h. They can pump media with very high viscosities.

Other displacer forms, some without dead space, are also used for special applications such as those in the food processing industry (Fig. 10.60).

Rotary Screw Pumps. Among other things, rotary screw pumps are called *degenerate* gear pumps with helical gears and few teeth. The inter-rotating profiles effect an axial delivery. Rotary screw pumps are constructed with two, three or five spindles. The design with two or three spindles is most widespread. The secondary spindles are arranged around the main spindle (Fig. 10.61).

These pumps are engineered both with single and dual flow to compensate for the axial thrust. The main spindle is usually double-threaded; the secondary spindles double or triple threaded. Depending on the pumped medium, pitch and profile, they are constructed with or without synchronizer gears.

Basically three profiles are used:

- Involute profile, without synchronizer gears (e.g., Leistritz)
- Epicycloidal profile (e.g., IMO AB, Stockholm, Sweden: manufacturer of rotary positive 3 screw pumps)
- Trapezoidal or rectangular profile, only with synchronizer gears (e.g., Bornemann)

Rotary screw pumps are constructed for:

- Delivery rates of 10–150 m^3/h
- Pressures of 15–150 bar
- Speeds of 500–1500 min^{-1}
- Viscosities of 25×10^{-6}–5×10^{-3} m^2/s

Planetary Rotation Piston Machine.

Eccentric Screw Pumps. The principle of the eccentric screw pump (Fig. 10.62) goes back to the Frenchman Moineau. A rotor with a single-threaded diamond knurl rotates in a housing (stator) with a double-threaded diamond knurl. An alternative name for the eccentric screw

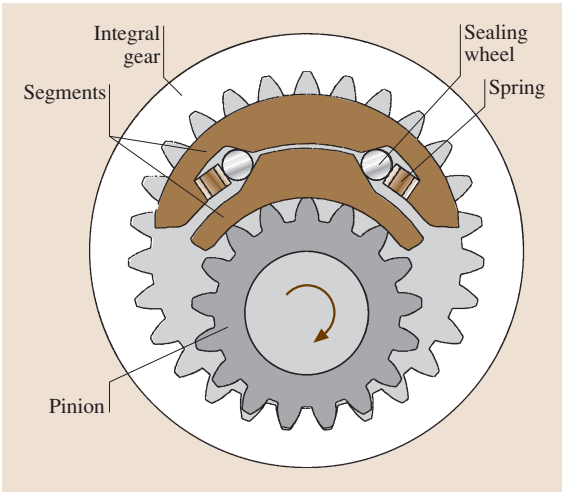

Fig. 10.58 Internal gear pump with clearance compensation (after [10.15])

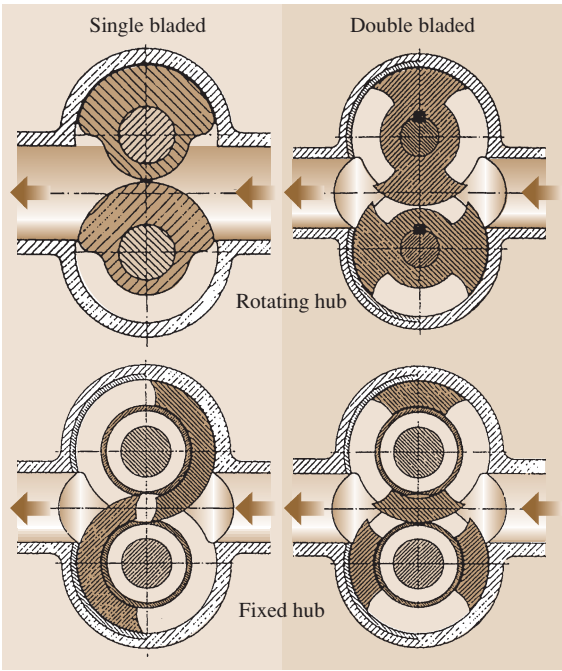

Fig. 10.59 Variants of rotational motion piston pumps (after [10.16])

pump is the single-spindle pump. Depending on its design, this pump is an eccentric rotational motion piston pump.

At every point, the rotor has a circular section with its center lying on the rotor axis on a helix. The housing has an oval section and twice the pitch of the rotor.

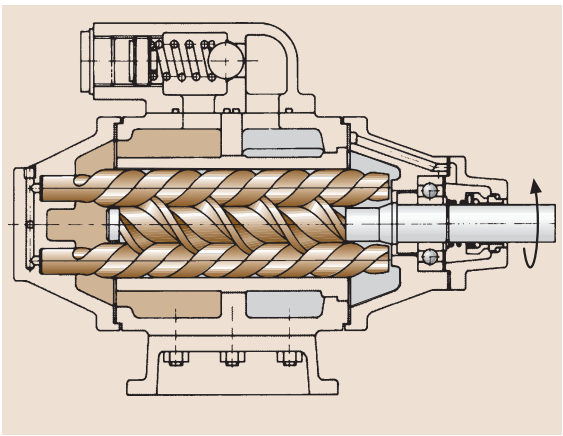

Fig. 10.61 Rotary screw pumps with three spindles (after [10.17])

Eccentric screw pumps attain delivery rates of 0.6–1000 m^3/h at pressures of up to 40 bar. Apart from being able to deliver abrasive and highly viscose media, the eccentric screw pump provides the advantage of a pulsation-free delivery rate (Fig. 10.63). Since dry running the pump has to be avoided in any operational situation, the suction and compression flanges in this type of pump are frequently arranged on the top side of the housing.

Typically, the rotors are made of CrNi steel or cast iron and the housing of red brass or cast iron. The stator is made of elastic material such as rubber, polytetrafluoroethylene (PTFE) or neoprene.

The medium may contain a solid content of up to 45%. However, this leads to a sharp power increase and

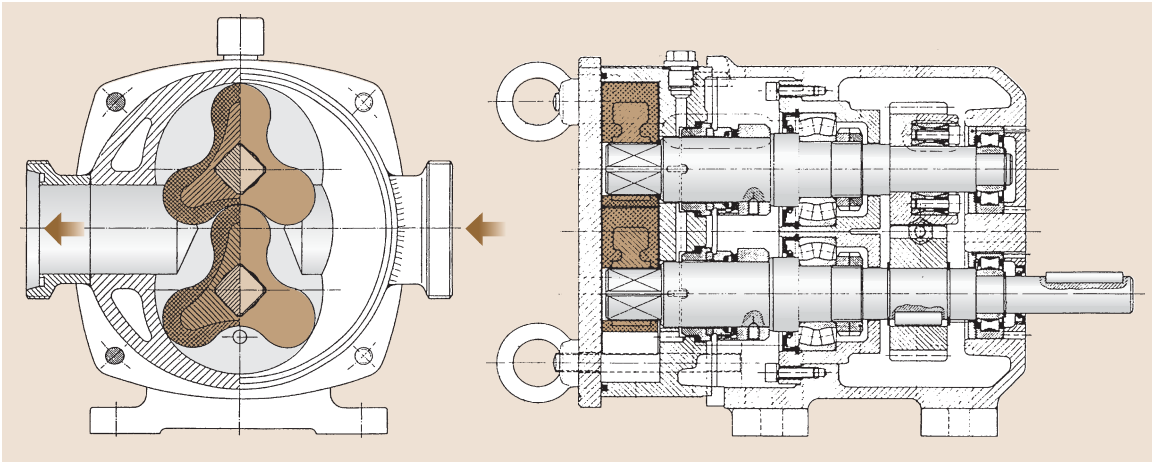

Fig. 10.60 Rotational motion piston pump for food, cross and longitudinal sections (after [10.16])

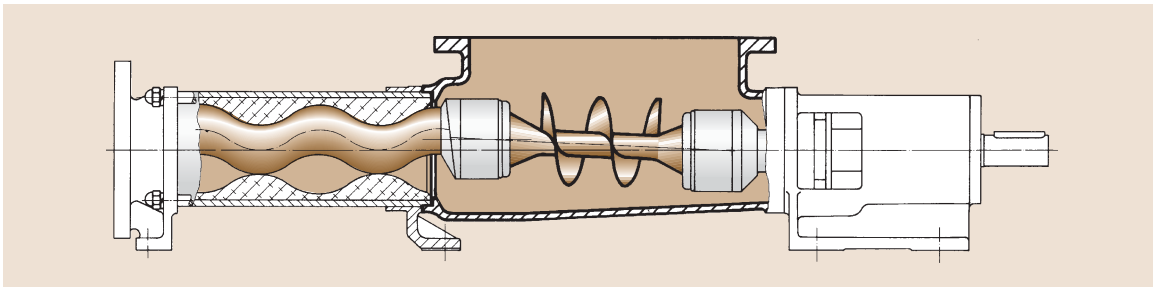

Fig. 10.62 Eccentric screw pump (after [10.18])

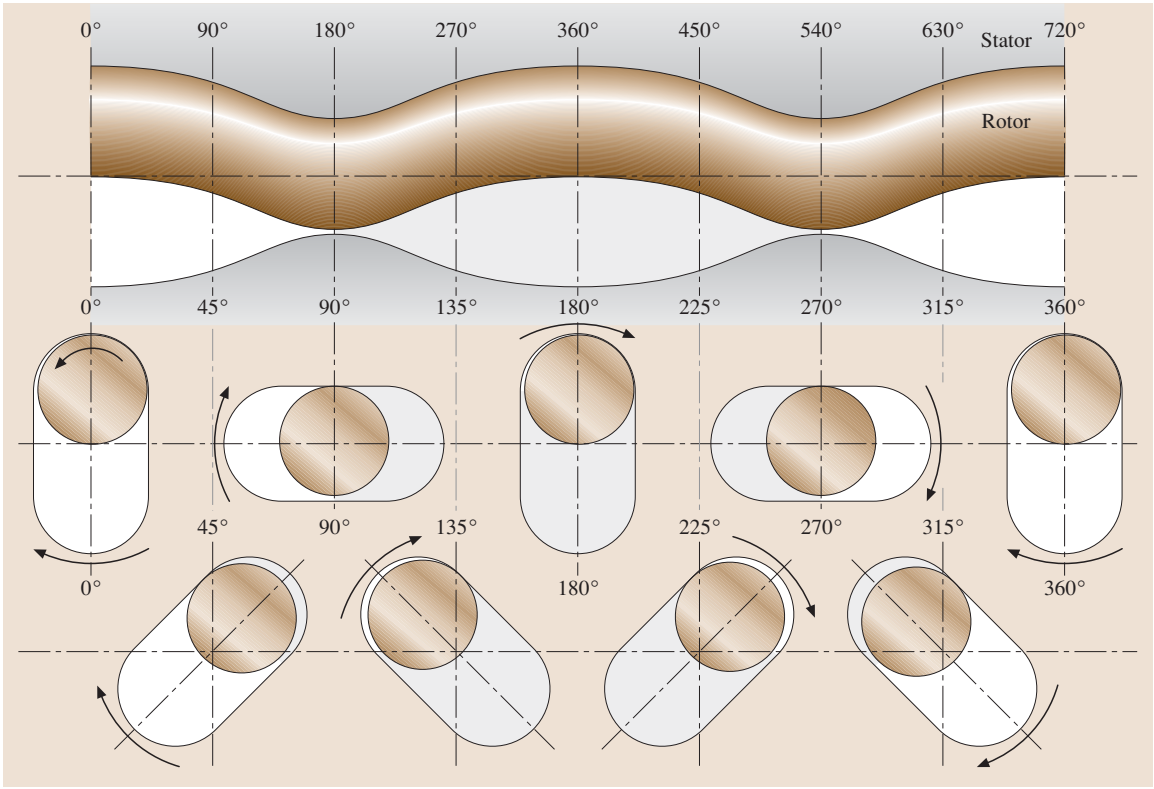

Fig. 10.63 Displacement effect of the eccentric screw pump (after [10.18])

causes low speeds. The elastic stator makes it possible to attain high impermeability and a suction head of up to 8.5 m.

The rotor executes a circular motion with its center axle so that it must be driven by cardan joints. In some cases, only one cardan joint is used in smaller units. As a result, the stator must absorb part of the motion. In addition, a joint can be used, which compensates for a parallel axle offset. Impellers or screws that improve the feeding of the pumped substance are often mounted on the cardan shafts.

Eccentric screw pumps are used to pump mortar, among other things.

Circulation Piston Machine.

Cell Pumps. Cell pumps (Fig. 10.64) are frequently used for low delivery rates of up to 25 m^3/h. As a rule, four to six slide valves are employed. Up to 12 slide valves are used at higher pressures of up to 100 bar. In some cases,

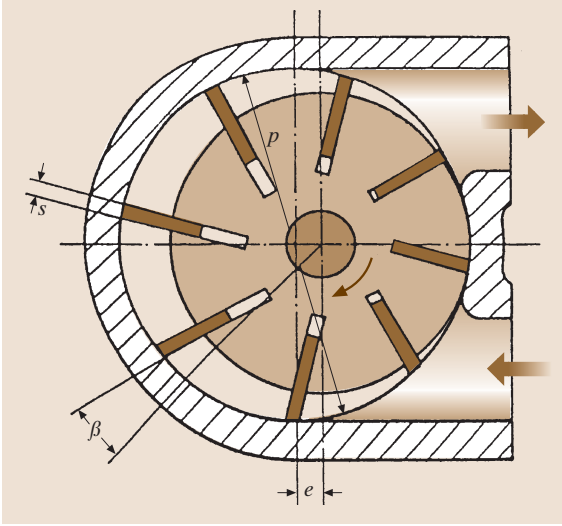

Fig. 10.64 Cell pump

even two slide valves per channel are used to increase impermeability.

Normally, the centrifugal force alone lifts the slide valves negatively. As a result, these pumps are relatively leaky at low speeds. The principle is broadly applied to fuel feed pumps for instance. The roller cell pump is another common type. Rollers are used instead of slide valves. Their shape gives them advantages over slide valves in terms of wear.

This type of pump is used for example as an electric fuel pump to pump gasoline in cars (Fig. 10.65).

So-called impeller pumps are also used when delivery flows are smaller, e.g., for garden pumps or coolant pumps for boat engines (Fig. 10.66).

The working chamber changes volume by bending the rotor's elastic, usually rubber impellers against the sickle-shaped part of the housing deviating from a circular shape.

The rotor is installed axially without any gap in order to guarantee high impermeability. Thus, these

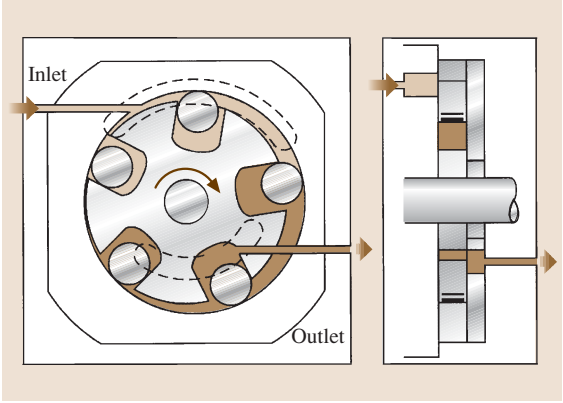

Fig. 10.65 Roller cell fuel pump (after [10.19])

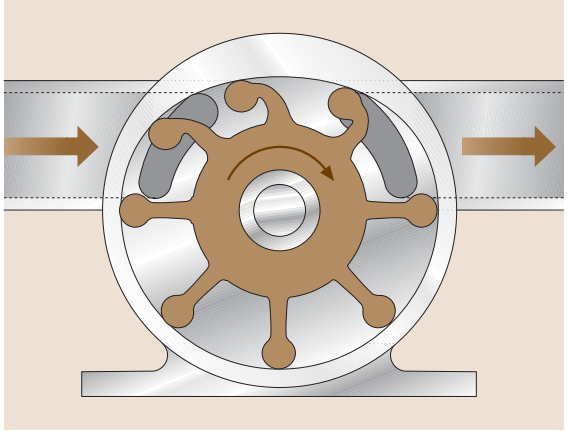

Fig. 10.66 Impeller pumps (after [10.20])

pumps are self-priming. The impellers' ability to upright themselves determines the maximum speed. The delivery pressure depends on the flexural strength of the impellers. These pumps are insensitive to contamination of the pumped medium but can only reach low pressures of approximately 4 bar. They are used as boat motor seawater pumps and as garden pumps.

10.3 Compressors

Compressors can be divided into two general categories: positive displacement type and non-positive displacement types. Positive displacement compressors deliver essentially the same volume of air regardless of the pressure ratio while non-positive displacement compressors will have reduced flow at higher delivery pressures. Axial flow and centrifugal compressors are non-positive displacement types and reciprocating, rotary-screw, and diaphragm compressors are of the positive displacement type. This section discusses the characteristics of positive displacement reciprocating compressors.

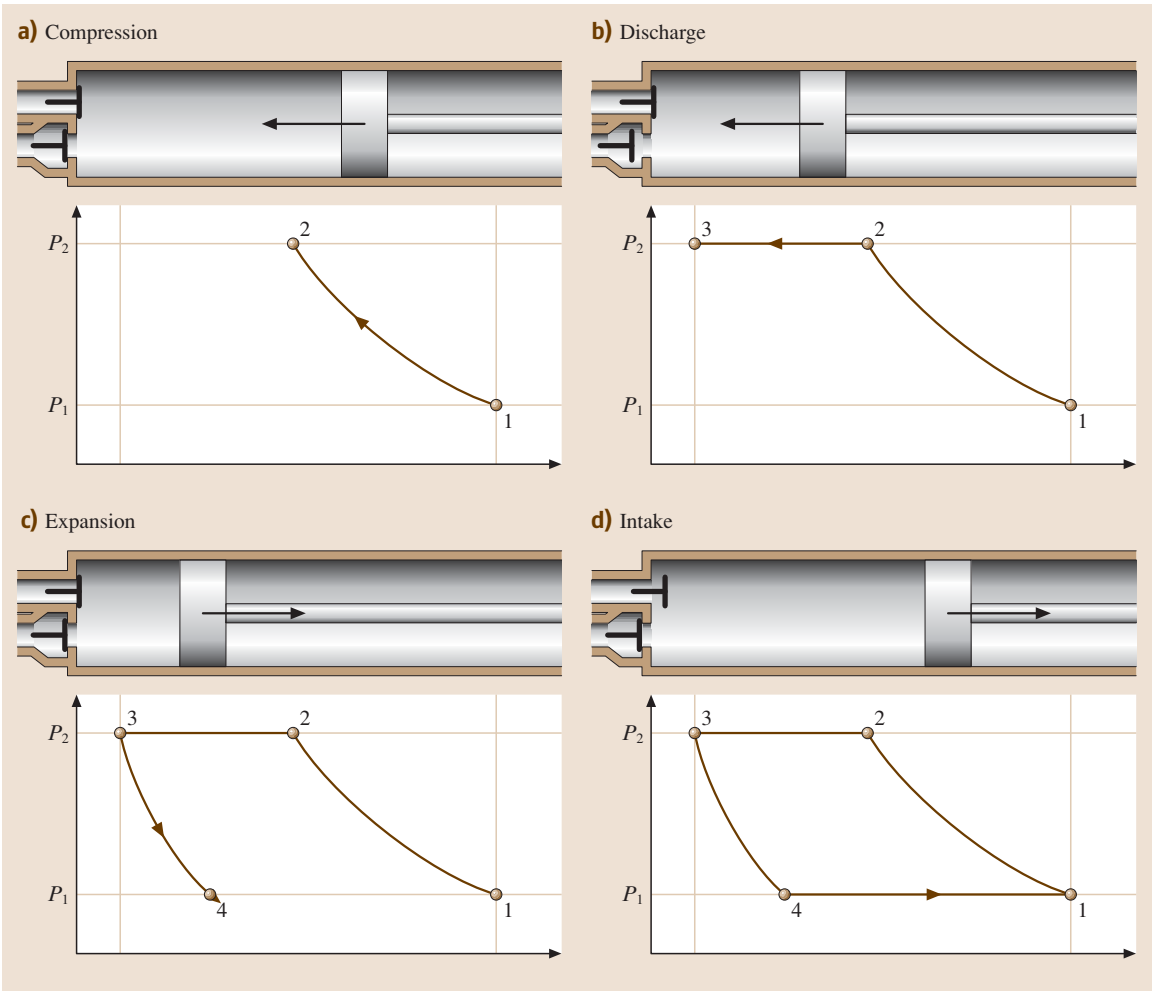

Fig. 10.67a–d Reciprocating compression processes: **(a)** compression **(b)** discharge **(c)** expansion **(d)** intake

Reciprocating compressors are frequently used when high pressures are needed, although they generally use multiple stages of compression to limit the power required for the process. The basic compression process can be visualized as occurring in a piston–cylinder configuration that is similar to that of an internal combustion engine. In practice, reciprocating compressors frequently use both sides of the piston in *double-acting* systems. Inlet and discharge valves are spring-loaded so that they will automatically open when there is an appropriate pressure in the cylinder. The inlet valve will open when the cylinder pressure drops below the inlet pressure, and the discharge valve will open when the cylinder pressure exceeds the receiver pressure.

10.3.1 Cycle Description

Figure 10.67 shows the sequence of processes followed by reciprocating compressors. The upper part of each diagram shows the piston position in the cylinder and whether the valves are open or closed. The lower part of each diagram shows the corresponding pressure–volume diagram for the process. In Fig. 10.67a the piston moves to decrease the volume with the valves closed. The pressure rises from state 1 to state 2 following a process line that depends on the amount of heat loss during the compression process. When the cylinder pressure exceeds the receiver pressure, the discharge valve will be forced open and the gas is discharged at constant pressure, as shown in Fig. 10.67b. When the

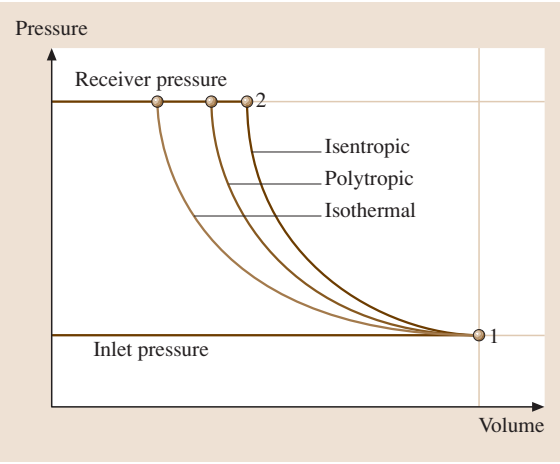

Fig. 10.68 Compression process lines

piston reaches the point of minimum volume, the cylinder volume is equal to the clearance volume. This is the starting point for the expansion process from state 3 to state 4, shown in Fig. 10.67c, where the pressure falls from the receiver pressure to the intake pressure. Finally, when the cylinder pressure has dropped to the inlet pressure, the intake valve opens and fresh air is drawn into the cylinder as shown in Fig. 10.67d.

The compression process for a reciprocating compressor will generally follow a polytropic process line that is between a reversible adiabatic process (isentropic) and a constant temperature (isothermal) process as shown in Fig. 10.68. The isothermal process accomplishes the compression with the least work input. Ideal gases follow the relationship

$$pV = \mathrm{R}T \,. \tag{10.62}$$

When an ideal gas is compressed it usually follows a polytropic process line that is modeled as

$$pV^n = \text{const} \,. \tag{10.63}$$

The usual values for n are between 1, which corresponds to an isothermal process and k, which is the ratio of specific heats and is equal to 1.4 for air at 25 °C.

For the polytropic process, the pressure at the end of the compression process will depend on the compression ratio $r_\mathrm{v} = \frac{V_1}{V_2}$ according to the following equation

$$p_2 = p_1 \left(\frac{V_1}{V_2}\right)^n = p_1 r_\mathrm{v}^n \,. \tag{10.64}$$

The final temperature can be calculated as

$$T_2 = T_1 r_\mathrm{v}^{n-1} = T_1 \left(\frac{p_2}{p_1}\right)^{\frac{n-1}{n}} = T_1 r_\mathrm{p}^{\frac{n-1}{n}} \,. \tag{10.65}$$

The power required for the compression process is

$$Pwr = p_1 \dot{v}_1 \left(\frac{n-1}{n}\right)\left(r_\mathrm{p}^{\frac{n-1}{n}} - 1\right) \,, \tag{10.66}$$

where $\dot{v}_1$ is the volumetric flow rate entering the compressor, r_p is the pressure ratio p_2/p_1, n is the polytropic exponent, and p_1 and p_2 are the pressures at states 1 and 2, respectively.

At high pressures, many gases will deviate considerably from ideal gas behavior. Usually, these deviations are incorporated into the calculation through the use of a compressibility factor Z. The equation between temperature, pressure and volume becomes

$$pV = ZRT \,. \tag{10.67}$$

The value of Z depends on the state, and charts are widely available for most common gases.

While reciprocating compressors are usually designed to encourage heat rejection, it is more common to have an intercooler between separate stages of compression. The intercoolers and multiple compressor stages are usually integrated into a common assembly that may take advantage of double-acting pistons.

10.3.2 Multi-Staging

Compression at constant temperature requires less work input than when the temperature is allowed to rise. In practice, isothermal compression is difficult to achieve. However, incorporating intercooling between multiple stages of compression can approximate isothermal compression.

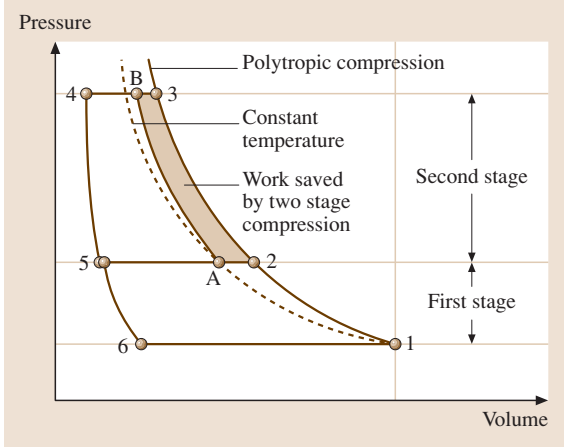

Fig. 10.69 Two stage compression

In the limiting case of an infinite number of compression stages that include intercooling back to the inlet temperature, the total work required will be equal to that for isothermal compression. Even the division of a compression process into two stages can save considerable work input.

A two-stage compression process is depicted in Fig. 10.69. The compression process begins at state 1, which corresponds to the piston at BDC and inlet pressure. The gas is compressed in the first stage to the inter-cooler discharge pressure at state 2. The gas is then discharged at p_2 into an intercooler before entering the second compressor stage at state A. In this idealized case, the intercooler is assumed to operate at constant pressure but the volume of gas is decreased due to the drop in temperature to the initial temperature of the gas. Then, the gas is compressed to state B before being discharged at p_B. If the pressure increase had been attempted with a single stage of compression, then the process line would pass through states 1, 2, and 3. Since the area enclosed on the p–V diagram is the work needed to accomplish the process, the shaded area is the difference in work between the single stage and two-stage compression processes. Clearly, the two stage compression is more efficient.

The optimum pressure for intercooling is generally assumed to correspond to an equal pressure ratio for each stage. This assumes the intercooling is able to reduce the gas temperature to the inlet temperature at each stage. If r_s is the pressure ratio for each stage, r_t is the overall pressure ratio, and s is the number of stages, then

$$r_s = \sqrt[s]{r_t} \,. \tag{10.68}$$

10.3.3 Design Factors

At the end of the compressor's discharge stroke, shown in Fig. 10.67b, gas fills the clearance volume at the discharge pressure. This gas expands as the piston moves away from the cylinder head until its pressure drops below the inlet pressure when the intake valve opens. The induction of fresh charge does not begin until this point is reached so the full volume displaced by the piston is not utilized. When the clearance volume is large, then the capacity of the compressor is less.

The volumetric efficiency of a compressor can be approximated as

$$\eta_v = 1 - \frac{V_{\text{clearance}}}{V_{\text{Displ}}}\left(r_{\text{p}}^{\frac{1}{k}} - 1\right) - \text{Leakage} \,, \tag{10.69}$$

where the leakage can generally be assumed to be between 0.03 and 0.05. Lower-molecular-weight gases usually have higher leakage.

It can be seen from the equation for η_{v} that an increase in clearance volume directly causes a decrease in volumetric efficiency. Its significance is much greater for high values of the pressure ratio r_{p}.

Although compressor designers try to minimize it, the clearance volume cannot be entirely eliminated. Reducing it to less than 4% of the displacement volume is difficult. The amount of clearance volume will affect the capacity of the compressor and its efficiency. Overall compression efficiency is improved when valve flow area is large. However, the desire to minimize the clearance volume conflicts with the desire to maintain large valves. Thus, there is often a tradeoff between volumetric efficiency and compression efficiency, which determines the actual value of the clearance volume.

10.4 Internal Combustion Engines

In an internal combustion engine, the working fluid consists of a fuel–air mixture and the combustion products of this mixture. Although many cycles have been proposed, the traditional two-stroke and four-stroke cycles still dominate current use.

Depending on their design and application, internal combustion engines provide excellent portability, power density, and fuel economy. Vehicles that utilize internal combustion engines provide unsurpassed range, drivability, and driver comfort while maintaining low levels of hazardous pollutants.

10.4.1 Basic Engine Types

Engines can be categorized in many different ways. The number of cylinders, the type of valve actuation, and whether the engine is turbocharged or naturally aspirated are all possible choices. Some engines are spark-ignited and utilize a homogeneous fuel–air mixture and some are compression-ignited, also called diesel engines, and utilize a heterogeneous fuel–air mixture. Another characteristic is whether the engine uses the two-stroke or four-stroke engine cycle.

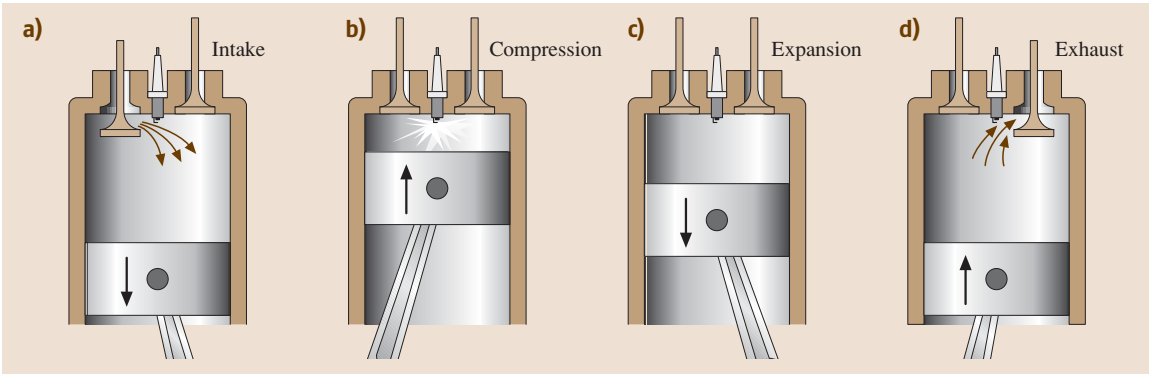

Fig. 10.70a–d Four stroke cycle events

All reciprocating internal combustion engines need to go through the four processes of intake, compression, expansion, and exhaust. The basic difference between two-stroke and four-stroke cycle engines is that the two-stroke engine accomplishes the four processes in a single revolution, or two strokes of the piston (one up and one down). The four-stroke engine needs two revolutions to complete the cycle.

The processes are shown in Fig. 10.70 for a four stroke cycle. In Fig. 10.70a, the intake valve is open and fresh charge is drawn in as the piston moves downward toward the bottom dead center (BDC) position. After BDC, the intake valve closes and the piston compresses the air on its upward compression stroke. Near the end of the compression stroke, close to top dead center (TDC), the spark plug fires and ignites the fuel–air mixture. In a diesel engine, only air is drawn in through the intake valve and fuel is injected into the air near the end of the compression stroke. This fuel self-ignites after a short delay. For both spark-ignited and diesel engines, the combustion products do work on the piston as it moves out for the expansion stroke as shown in Fig. 10.70c. In Fig. 10.70d, the exhaust valve opens near BDC and the combustion products are expelled from the cylinder by the upward motion of the piston. At the end of the exhaust stroke, the intake valve opens and the cycle is repeated with another intake stroke.

The two-stroke cycle is depicted in Fig. 10.71. When the piston is near the BDC position, air enters the cylinder from a port in the cylinder wall. There is a deflector on the top of the piston to inhibit the direct passage of the fresh charge across the cylinder and out the exhaust port on the other side. As the piston moves upward, it covers the intake and exhaust ports and compresses the fuel–air mixture. Near TDC, the spark fires to start the combustion process. In a two-stroke diesel engine the fuel is injected into the compressed air at this point. For both types of engines, the combustion products expand and do work on the piston surface until the point where the piston uncovers the upper edge of the exhaust port. At this point, the gases in the cylinder rapidly blow down until the pressure in the cylinder

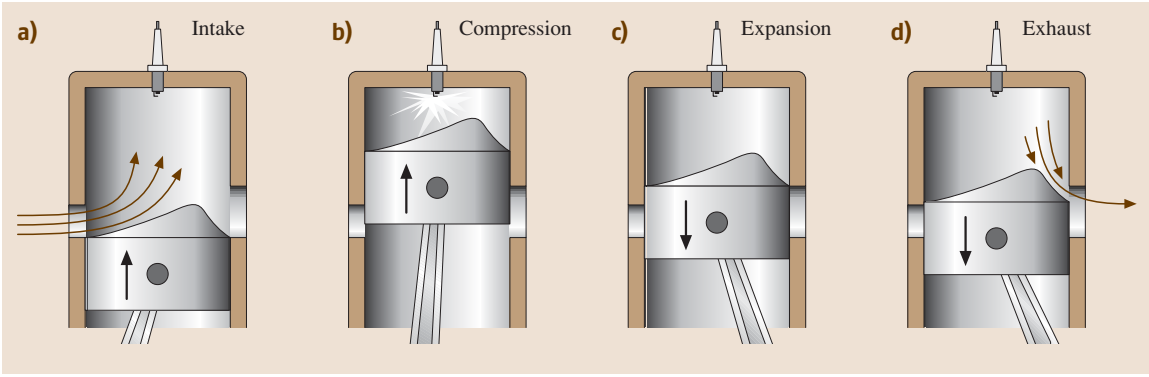

Fig. 10.71a–d Two stroke cycle events

is close to the exhaust pressure. As the piston continues its downward motion, it uncovers the intake port so fresh charge can enter the cylinder and repeat the cycle.

Because the two-stroke engine needs to complete all four processes in a single revolution, it must start the exhaust process well before the piston has reached bottom dead center. A four-stroke engine can wait until about 140° after TDC before starting to open the exhaust valve since the primary criterion is that the period of rapid pressure equalization that occurs when the valve is first opened, called the blowdown, is essentially complete by BDC. A two-stroke engine must start opening the exhaust port at about 90° after TDC to provide sufficient time for the blowdown before the intake port opens and the intake process starts. Opening the exhaust valve early so that the cylinder pressure is throttled down to ambient allows no recovery of the energy in those hot gases and is the major reason why two-stroke engines are less efficient than four-stroke engines.

In four-stroke engines, almost the entire cylinder contents of burned product gases, called residual gases, is expelled when the piston reaches TDC at the end of the exhaust stroke. Then, as the piston moves away from TDC, it produces a low pressure in the cylinder which draws in a fresh air charge through the intake valve. Four stroke engines are said to be self-scavenging. That is, the piston motion is directly responsible for moving the exhaust gases out of the engine and drawing in fresh air. Two stroke engines are not self-scavenging. Some mechanism other than piston motion is needed to exchange the gases in the cylinder. By opening the exhaust valve early, while the cylinder pressure is still high, most of the residual gases can be expelled. The fresh charge must be forced into the cylinder from a pressurized source, which might be a crankcase that is pressurized by the downward motion of the piston as in single cylinder two-stroke engines used for hand-held power equipment. It might also be from an engine-driven blower as is common in diesel two-stroke engines.

10.4.2 Performance Parameters

Engine speed and torque are the two most fundamental quantities of engine performance. Both are usually measured quantities with speed given in revolutions per minute (rpm) and torque in Newton-meters (N m). Power is defined as torque times rotational speed. When the torque is measured at the engine flywheel, it is called the *brake torque* and the power calculated from it is the brake power, as

$$P_b = T_b \omega = T_b 2\pi N \,, \tag{10.70}$$

where P_b is the brake power, T_b is the brake torque, ω is the rotational speed, usually in radians/unit time, and N is the rotational speed in rev/unit time.

The source of power in the engine is the work done on the piston by the expanding combustion gases. The power associated with this piston work is called the *indicated power*. The difference between the indicated power and the brake power is the power required to overcome friction and to drive the accessories including the water and oil pumps

$$P_i = P_b + P_f \,, \tag{10.71}$$

where P_i is the indicated power, P_b is the brake power, and P_f is the friction power.

Direct calculation of the indicated power requires measurement of the cylinder pressure. The brake power can be calculated from the measured engine torque and speed. The friction power must be calculated from the difference of the indicated and brake power.

Generally, small engines run at high rotating speeds and large engines run at low rotating speeds. To allow comparisons between engines of different sizes, it is common to calculate the *mean piston speed*, which is the average velocity of the piston as the engine makes one revolution

$$\text{MPS} = \frac{2S}{\text{time for one revolution}} = 2SN \,, \tag{10.72}$$

where S is the stroke, and N is the engine rotating speed.

The *mean effective pressure* (MEP) is a way to normalize the work done by the engine against the size of the engine. It is intended as a measure of engine loading. The MEP is defined as the ratio of the work done by the engine in one cycle to the displacement volume. A four-stroke engine undergoes one cycle in two revolutions (or 4π radians) so the work done is equal to the torque times the angular displacement. When the brake torque is used, the quantity is known as the *break mean effective pressure* (BMEP)

$$\text{BMEP} = \frac{4\pi T_b}{V_d} \,. \tag{10.73}$$

Since work is measured in N m and volume in m^3, the ratio has units of pressure N/m^2. The MEP is sometimes described as the pressure which, if applied as a constant pressure during the expansion stroke, would give the same work as actually produced by the engine.

The *mechanical efficiency* is a measure of how much of the power produced by the combustion process is delivered to the output shaft. It is defined as the ratio of the brake power to the indicated power

$$\eta_m = \frac{P_b}{P_i} = 1 - \frac{P_f}{P_i}, \tag{10.74}$$

where η_m is the mechanical efficiency, P_b is the brake power, P_i is the indicated power, and P_f is the friction power.

The *thermal efficiency* is defined as the ratio of the power produced by the engine to the rate at which fuel energy is supplied to the engine, as indicated by the lower heating value (LHV). When the brake power is used, the quantity is known as the brake thermal efficiency

$$\text{Brake thermal efficiency} = \eta_{bt} = \frac{P_b}{\dot{m}_{fuel}\,(\text{LHV})}. \tag{10.75}$$

The mechanical and thermal efficiencies are sometimes confused. For a modern engine running at full load, the mechanical efficiency may be 90% or higher. However, the thermal efficiency will generally be 30–45%.

The *specific fuel consumption* (SFC) is the ratio of the fuel flow rate to the power of the engine. When brake power is used, the quantity is known as the brake specific fuel consumption

$$\text{BSFC} = \frac{\dot{m}_{fuel}}{P_b}. \tag{10.76}$$

The BSFC is similar to an efficiency in that it measures how little fuel may be required to do a certain quantity of work. The lower the BSFC, the more efficient the engine.

The *volumetric efficiency* is a measure of how well air moves through the engine. For a four-stroke engine

$$\eta_v = \frac{\dot{m}_{actual}}{\dot{m}_{ideal}} = \frac{\dot{m}_{actual}}{\rho_{ref} V_d \left(\frac{\text{rpm}}{2}\right)}, \tag{10.77}$$

where η_v is the volumetric efficiency, $\dot{m}_{actual}$ is the actual mass flow rate of air (or air–fuel mixture) entering the engine, $\dot{m}_{ideal}$ is the ideal mass flow rate of air (or air–fuel mixture), ρ_{ref} is a reference density, V_d is the displacement volume, and $\frac{\text{rpm}}{2}$ is the number of engine cycles per minute.

For spark-ignited engines, the values of $\dot{m}_{actual}$ and $\dot{m}_{ideal}$ refer to the fuel–air mixture entering the engine. For diesel engines they refer only to the air entering the engine.

The volumetric efficiency tends to be ambiguous for several reasons:

1. There is uncertainty about where the reference density should be calculated. Some sources suggest using ambient conditions while others suggest using the average intake manifold pressure and temperature.
2. Although it is considered to be an efficiency, there is no reason why the volumetric efficiency cannot be greater than one. If the ambient density is used to compute the volumetric efficiency of a turbocharged engine, the volumetric efficiency may be as high as 2 or 3. Even a naturally aspirated engine with a tuned intake system can have a volumetric efficiency of 1.2 or 1.3.
3. In engines with a large valve overlap period, a significant amount of air can blow through the engine directly from the intake to the exhaust without participating in a combustion process. This air could contribute to a high volumetric efficiency but is not available for combustion.

10.4.3 Air Systems

The power produced by all internal combustion engines is limited by their ability to draw air from the atmosphere. Fuel systems can always be designed to provide the amount of fuel appropriate to this air flow. To increase the power produced by an engine of a certain displacement volume, the air flow needs to be increased. This can be done with passive techniques that are incorporated into the engine's design or through the addition of external devices, such as a supercharger.

Natural Aspiration

In a naturally aspirated engine, the air flows into the cylinder through the intake manifold and intake ports without the use of an external compressor of blower. At high engine speed this air moves at high velocity. When the piston approaches the end of the intake stroke, the momentum of the air keeps the air moving toward the cylinder and can continue to force air into the cylinder after the piston has started upward on the compression stroke. By properly timing the closing of the intake valve, the amount of air trapped in the cylinder can be increased beyond that which would be predicted based on ambient air density. This phenomenon, called the *ram effect*, increases with air velocity and therefore with engine speed.

A second effect that can be utilized to increase engine air flow is to take advantage of the pressure waves that are induced in the intake and exhaust system due to valve opening and closing events and piston motion. For example, the high-pressure wave created when the exhaust valve opens and rapidly blows down the cylinder contents travels to the end of the exhaust pipe and is reflected as a low-pressure wave or rarefaction wave. If this wave is timed to enter the cylinder near the end of the exhaust stroke it can assist in evacuating the residual gases and draw in fresh charge as the intake valve opens. Similarly, rarefaction waves in the intake system are reflected from the open end of the intake as pressure waves that will force more air into the cylinder. This process, known as tuning, is highly dependent on the relationship between valve timing, pipe lengths, and the speed of sound in the intake and exhaust gases. As a result, the benefits of tuning tend to be concentrated at specific engine speeds and the effects at other speeds may actually be negative. Other passive effects involving resonator cavities connected to the intake and exhaust pipes can also be used to raise the air flow to the engine. The engine air flow can also be increased with the addition of a compressor in a technique known as supercharging to be discussed later.

Effect of Speed on Volumetric Efficiency

Engine volumetric efficiency is affected by engine speed. At higher speeds, the pressure drop resulting from frictional effects associated with higher flow velocity tends to cause less air–fuel mixture to enter the cylinder. Up to a certain speed, this effect can be offset by the ram effect and tuned intake and exhaust pipes. These flow enhancing effects can keep the volumetric efficiency relatively high over most of the engine's operating range but at a certain speed, which depends mostly on valve area and mean piston speed, the volumetric efficiency drops off sharply.

Poppet Valves

Flow through a poppet valve is usually modeled as the product of isentropic flow through a restricted area passage and a flow coefficient that varies with valve lift and geometry. This equation is valid through all flow ranges, except when the flow is choked

$$\dot{m} = C_D \rho_0 c_0 A_x \times \sqrt{\left(\frac{2}{k-1}\right)\left[\left(\frac{P_x}{P_0}\right)^{\frac{2}{k}} - \left(\frac{P_x}{P_0}\right)^{\frac{k-1}{k}}\right]}, \tag{10.78}$$

where $\dot{m}$ is the actual mass flow rate through the valve, C_D is the discharge coefficient for the valve, ρ_0 is the density at the upstream stagnation state, c_0 is the speed of sound at the upstream stagnation state, A_x is the minimum flow area between the valve and seat, k is the ratio of specific heats $\frac{C_p}{C_v}$, P_x is the downstream static pressure, and P_0 is the upstream stagnation pressure,

C_D is greatest at low valve lifts. Under these conditions the air flow fills the entire flow channel without the separations that reduce the effective flow area. As the valve opens further, the flow separates from the valve edge and the seat, which reduces the actual flow area and decreases C_D. The value of C_D tends to be independent of the flow Reynolds number, except at low lift where C_D decreases as the Reynolds Number increases reflecting a greater significance of boundary layers on the flow.

Valve Timing

The timing for the opening and closing of the intake and exhaust valves can have a major impact on the engine performance. In four-stroke engines, the exhaust valve opens about 120–140° after TDC. Earlier timing will reduce expansion work and later may delay the exhaust blowdown so that high cylinder pressures early in the exhaust stroke increase the pumping work. Intake valve closing typically occurs at 20–60° after BDC and has a strong effect on the engine's volumetric efficiency. Earlier closing may reduce the air flow into the cylinder due to the ram effect described earlier, especially at high engine speeds. Later closing delays the start of the compression process and may allow some of the fresh charge to backflow into the intake manifold. The timings for closing the exhaust valve and opening the intake valve are not as critical for engine performance.

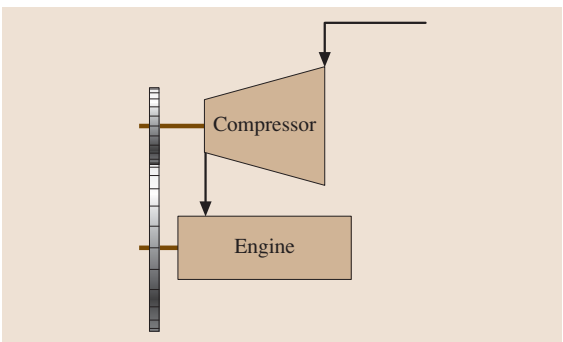

Fig. 10.72 Engine-driven supercharger

Supercharging

Supercharging is a general term for a variety of techniques used to boost the pressure of the air entering the cylinder to increase the engine's power. In some cases this involves devices to compress the air that might be driven directly by the engine or by the engine's exhaust gas. These devices are known as superchargers. When the device is driven by exhaust gas, it is called a turbo-supercharger or just turbocharger.

Figure 10.72 shows a schematic of an engine-driven supercharger that is driven by a set of gears, although belts are also frequently used. Engine-driven superchargers have the advantage that they provide air flow even at low speeds so they can be used to provide the scavenging needed for two-stroke engines during start-up. They also do not have the acceleration lag often noted with exhaust-driven turbochargers.

Turbocharging

A specific type of supercharging that utilizes power recovered from expanding the exhaust gas to atmospheric pressure is called *turbocharging*. Figure 10.73 shows a schematic of a typical system. Air, after being filtered, is compressed and then supplied to the engine. Single-stage radial-design compressors are most common and are generally capable of 3 : 1 pressure ratios. The compressor is directly coupled to an expansion turbine that provides the work to drive the compressor. While the turbine imposes a back pressure on the engine, this is more than offset by the higher potential power available from the increased pressure in the intake system.

In diesel engines, the air supplied by the turbocharger is more dense and allows more fuel to be injected while still maintaining the air–fuel ratio limits imposed by exhaust emissions concerns. In fact, due to the greater availability of air, turbocharged engines can usually be operated at higher air–fuel ratios than naturally aspirated engines which improves both particulate and NO_x emissions. Although engine power can be increased by a factor of 2–3 over a similarly sized naturally aspirated engine, fuel economy improves only slightly. This improvement is generally associated with the fact that friction losses do not increase proportionately with the increase in overall power so the mechanical efficiency of the engine improves. Turbocharging offers additional benefits of improved scavenging and piston cooling by allowing a portion of the compressed charge to short circuit through the cylinder during the valve overlap period.

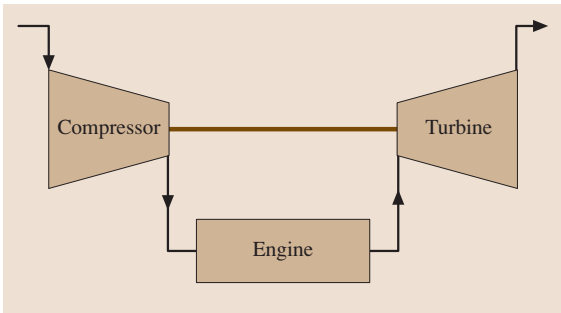

Fig. 10.73 Typical turbocharger configuration

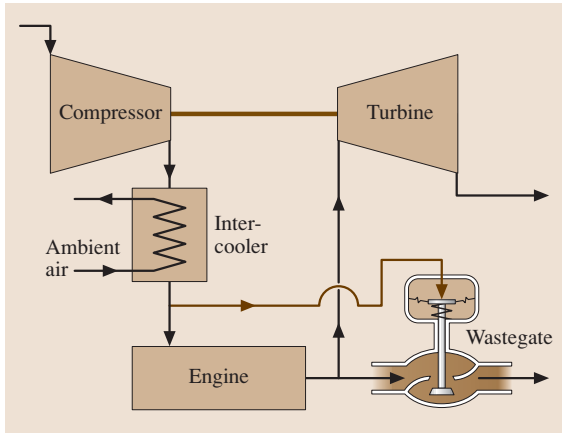

Fig. 10.74 Turbocharged engine with intercooler and waste gate

Part of the density increase potential of the turbocharger is lessened by the fact that the air leaving the compressor is at high temperature. It is common to insert a heat exchanger, called an intercooler or aftercooler, into the airstream after the compressor. Figure 10.74 shows this configuration. The compressed air may be cooled by engine coolant, or more commonly in heavy-duty applications, by ambient air.

Also shown in Fig. 10.74 is a waste gate. This device allows a portion of the engine's exhaust gas to bypass the turbine. A diaphragm actuator senses compressor boost pressure and releases a portion of the exhaust gas so that the boost pressure does not become excessive. Turbocharger design and matching to a specific engine is usually a compromise between providing sufficient air at the low-speed peak-torque condition while not delivering excessive pressure at the high-speed high-load conditions that will cause high peak cylinder pressures.

For engines that are consistently operated at high loads, there is more energy available in the exhaust gas than is needed to operate the compressor. One option

to utilize this excess energy is to add a second turbine, sometimes known as the power turbine, that will recover energy from the exhaust gas leaving the first turbine, which drives the compressor. As shown in Fig. 10.75, the power turbine is connected to the engine's drive train through a mechanical connection so the power can be delivered to the engine's output shaft. This technique is often referred to as *turbocompounding*. The fuel economy benefits of turbocompounding can be significant, especially when the engine is designed for minimum heat rejection, which tends to increase exhaust energy. However, at current fuel prices, the savings in operational cost has not been enough to justify widespread acceptance of this technology.

Other technologies have been developed to provide optimum turbocharger performance over a larger fraction of the engine's operating range. Fig. 10.76 shows a twin-turbocharger technology developed by Opel that utilizes two turbochargers. As shown in the figure, exhaust gas from the engine is directed through two separate passage-ways to two turbochargers. The passage to the larger turbocharger is equipped with a flapper valve to limit the flow. At light load conditions, the flapper is mostly closed, which forces most of the exhaust flow through the small turbocharger so it has sufficient flow to operate at its most efficient condition. The large turbocharger is essentially free-spinning at this point and not providing much compression. As the engine speed and load increase, the exhaust flapper is opened allowing the larger turbocharger to become active so it can supply air for the high power condition. A check valve is provided in the intake pipe so that the high air flow does not all have to pass through the small turbocharger compressor. This arrangement provides efficient operation over a wide range of engine operating conditions.

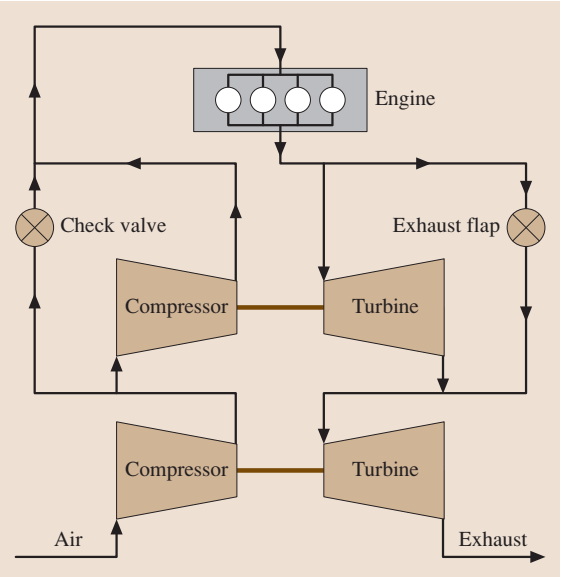

Fig. 10.76 Twin turbocharger configuration

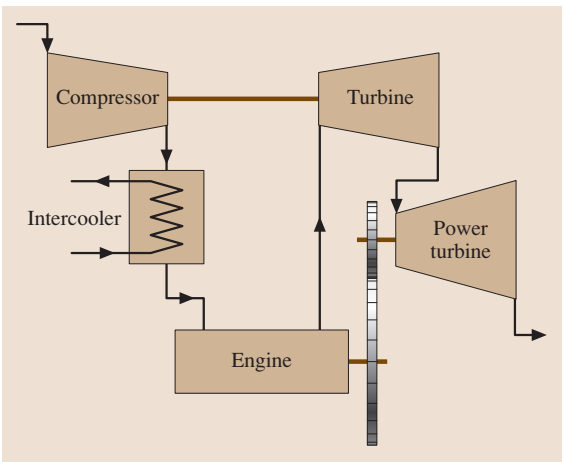

Fig. 10.75 A turbocompounded engine

Efficiency Definitions

The efficiency of a turbocharger is determined by the efficiency of its various elements. The efficiency of the compressor is calculated from the ratio of the work that would be required for a reversible adiabatic (isen-

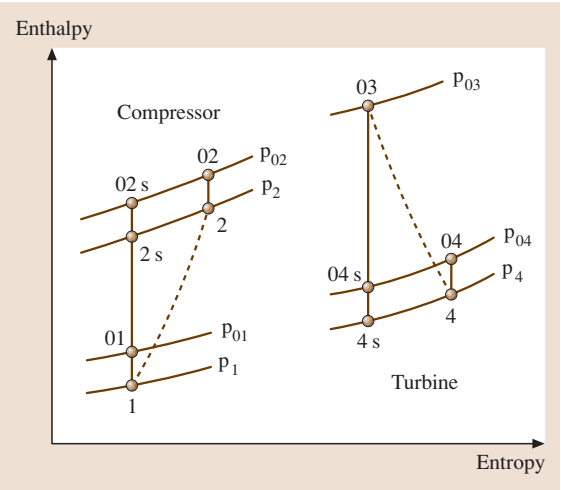

Fig. 10.77 State definitions for compressor and turbine efficiencies

tropic) process divided by the actual work for the process. The compressor efficiency can be calculated using stagnation states at the inlet and outlet, or since the kinetic energy leaving the compressor is not recovered, the efficiency can be calculated from the inlet stagnation state to the outlet static state. The latter choice is more conservative and allows the effectiveness of the compressor outlet diffuser to be included in the efficiency. The equation for compressor efficiency is provided below based on the state definitions given in Fig. 10.77

$$\eta_C = \frac{h_{2s} - h_{01}}{h_{02} - h_{01}} . \tag{10.79}$$

In a similar manner, the efficiency of the turbine from the inlet stagnation state to the outlet static state can be written as

$$\eta_T = \frac{h_{03} - h_{04}}{h_{03} - h_{4s}} . \tag{10.80}$$

Although the simple design of the turbocharger offers little opportunity for frictional losses, a mechanical efficiency can be defined that consists of the power delivered to the compressor divided by the power produced by the turbine

$$\eta_M = \frac{-\dot{W}_C}{\dot{W}_T} . \tag{10.81}$$

10.4.4 Fuel Systems

This section will cover gasoline and diesel fuel systems. The principles, main designs, key operating characteristics and controls of each system will be explained. Other important adjuncts such as low-pressure systems, filtration and sensors will also be covered.

Gasoline systems are divided into carburation and fuel injection; fuel injection is further broken down into throttle body, port injection and direct injection.

Diesel systems are divided into cam-driven and common-rail systems; cam driven systems are further divided into two main groups: pump-line-nozzle (inline, distributor, unit pump) and unit injector.

Gasoline Fuel Systems

Principle. Gasoline fuel systems can be divided into two main types: carburation and fuel injection. For all systems the goal is to achieve a stoichiometric air–fuel ratio, which is the ideal ratio whereby all of the fuel is completely mixed and burned. For normal gasoline this is usually around 14.7 : 1 air mass to fuel mass.

Carburation [10.21]. The simplest of all systems is the carburetor, which consists of the following subsystems:

- Inlet system to maintain a constant level of fuel in the reservoir
- Metering system to maintain the desired air–fuel ratio
- Accelerator-pump system to provide extra fuel during acceleration
- Power enrichment system to provide extra fuel during periods of high demand
- Choke system to provide a rich mixture for start and cold-engine operation

The carburetor uses the venturi principle: the inlet air flows through a necked-down area (venturi), where the flow increases in speed and decreases in pressure. A passage connects the fuel reservoir to the venturi; since the fuel in the reservoir is at atmospheric pressure, fuel flows from the reservoir to the lower-pressure area inside the venturi and then into the engine.

The pressure drop at the venturi increases with engine speed and with throttle position, thus causing fuel flow from the reservoir to the venturi to increase as engine speed and throttle position increase.

Fuel Injection [10.22]. Fuel injection can be divided into two basic types: manifold (throttle body and port) and gasoline direct injection (GDI). Manifold injection sys-

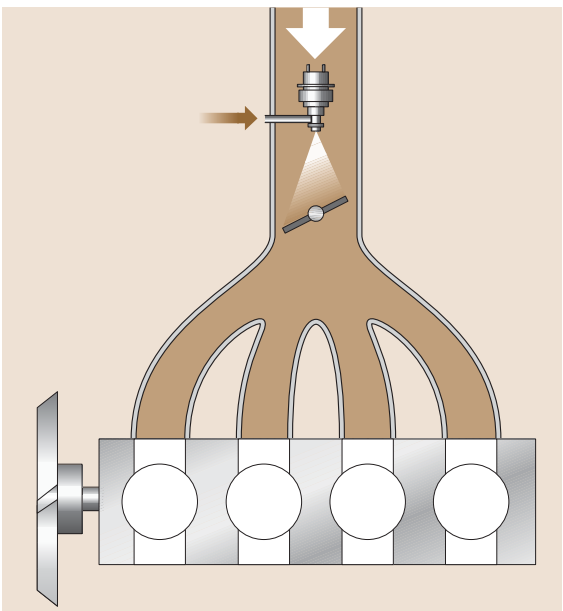

Fig. 10.78 Throttle body injection

tems allow only a homogeneous operating mode; GDI allows this and several other modes as well.

Throttle Body Injection. Throttle body fuel injection is also known as single point because there is a central point of injection: a single electromagnetically operated injector is located directly above the throttle valve Fig. 10.78.

Port Injection. Port injection is also known as multipoint because fuel is injected into every intake port, i. e., onto the cylinder's intake valve Fig. 10.79.

There are four types of port injection:

- Simultaneous fuel injection: all injectors open and close together. Half of the fuel quantity is injected in one engine revolution; the remaining half is injected in the next revolution.
- Group fuel injection: the injectors are combined into two groups. All injectors in a group open and close together. One injector group injects the total fuel quantity needed for its cylinders in one engine revolution, then the second set injects its total fuel quantity in the next revolution.
- Sequential fuel injection (SEFI): fuel is injected individually for each cylinder. Injectors are triggered is the same sequence as the firing order. Duration and start of injection (relative to each cylinder's top dead center) are the same for all cylinders.
- Cylinder-individual fuel injection (CIFI): the duration of injection (i. e., fuel quantity) can be varied for each individual cylinder.

Gasoline Direct Injection. Fuel is injected directly into each cylinder's combustion chamber Fig. 10.80.

An electric fuel pump delivers fuel to the high-pressure pump, which pressurizes the fuel to 50–120 bar (depending upon the engine operating condition) and sent on to the accumulator rail. Since all injectors are connected in parallel to the rail, they are all constantly pressurized and inject only when an electric signal is sent to each injector.

GDI allows not only homogeneous operation but also stratified charge, homogeneous stratified charge, homogeneous anti-knock and stratified-charge/catalyst heating.

Fuel Injection Control System. The injected fuel quantity is determined by the control system which consists of sensors that measure various input parameters, a processor to determine the optimum fuel quantity based upon the sensor input, and actuators which carry out the commands of the processor.

Examples of sensors: inlet air temperature, airflow, accelerator pedal position, throttle-valve angle, rail-pressure, Lambda, coolant temperature, etc. Examples of actuators: injectors, idle-air control valve, throttle valve, fuel-pressure regulator, etc.

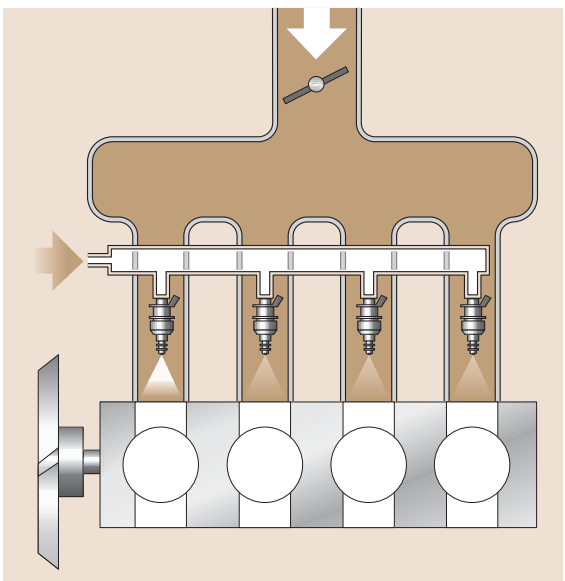

Fig. 10.79 Port injection

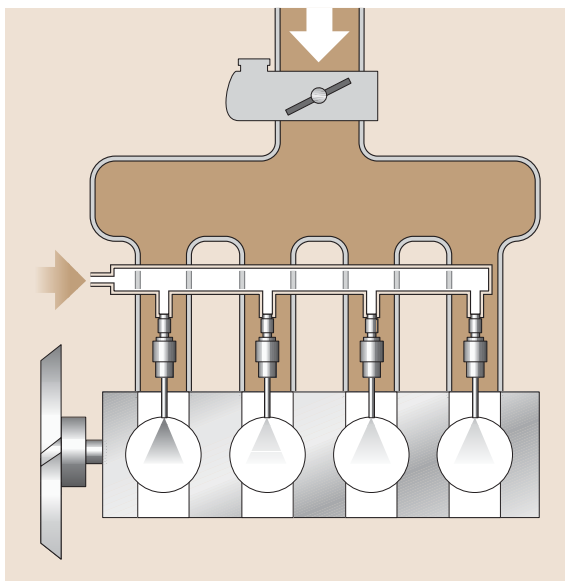

Fig. 10.80 Gasoline direct injection

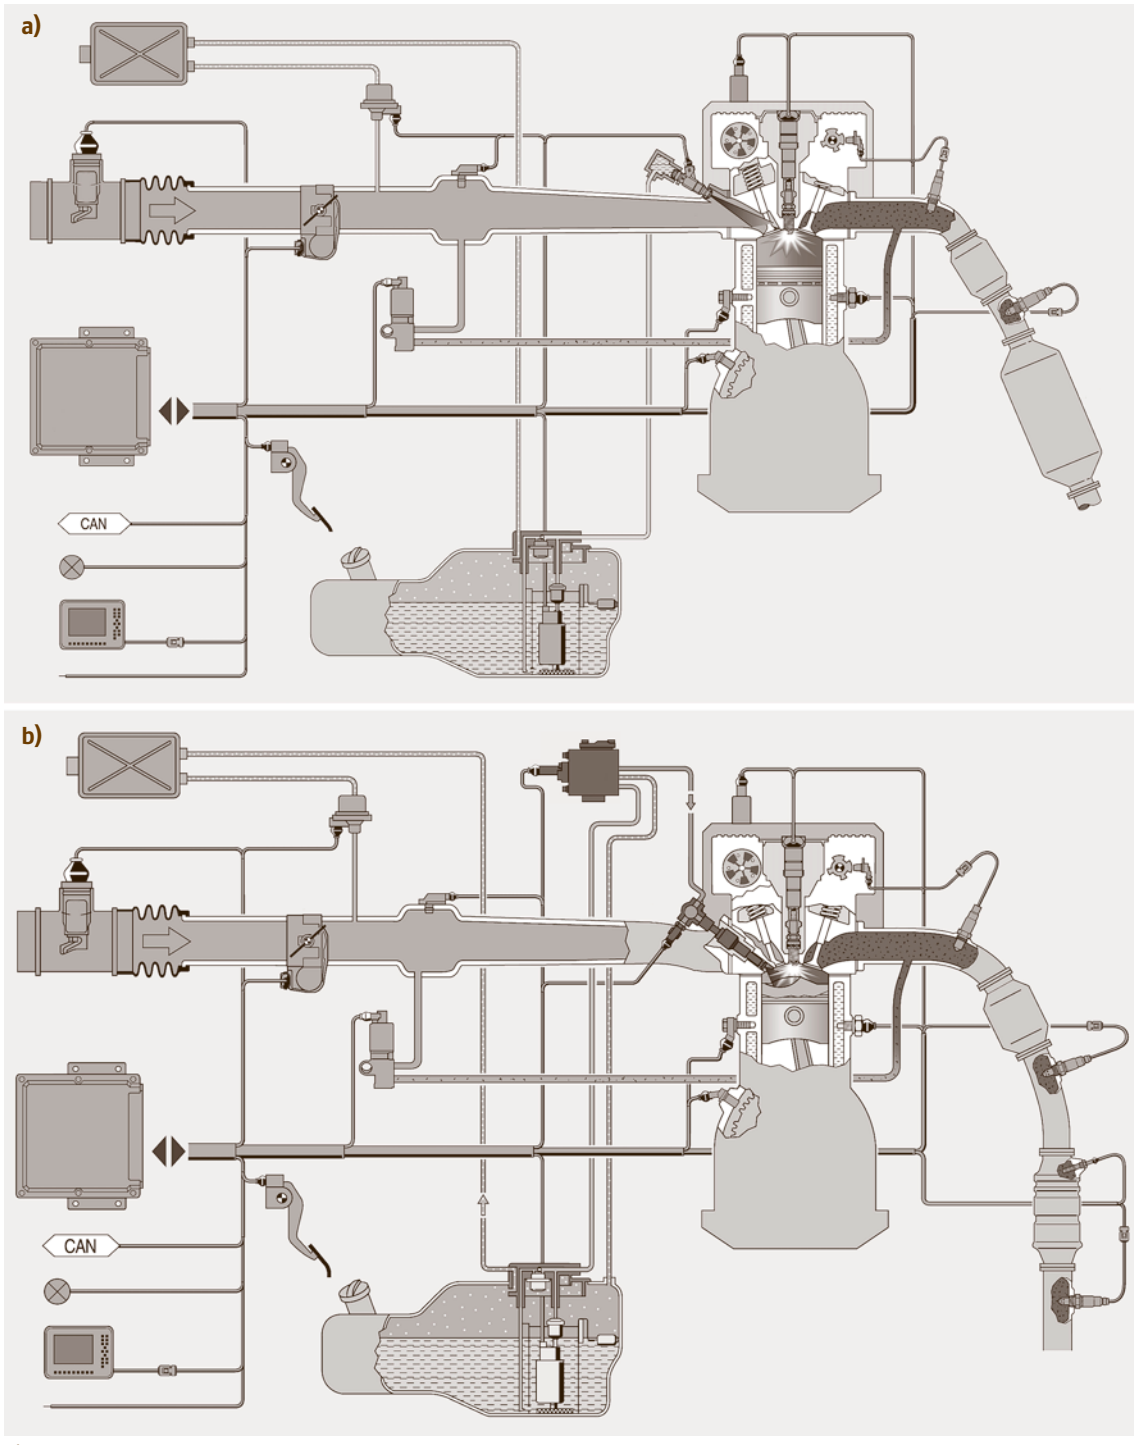

Fig. 10.81a,b Fuel injection control systems

The control system has to maintain the proper air–fuel ratio under the following engine operating modes:

- Start and warm-up
- Idle and part load
- Full load
- Acceleration and deceleration
- Overrun

The fuel injection control system may be combined with the ignition control system to allow for coordinated total engine management. The first image of Fig. 10.81 shows such a system for port injection and the second image of Fig. 10.81 shows a system for direct injection.

Fuel Supply System. For both carburetors and fuel injection, the fuel must be pumped from the storage tank by a mechanical or electrical pump, and must pass through a filter to remove impurities. The fuel pressure is regulated to a constant value.

Diesel Fuel Injection Systems

Principle. There are essentially two types of diesel fuel injection: indirect and direct. Since the indirect diesel injection (IDI) is for pre-chamber or whirl-chamber engines, both of which are seldom being applied today, we will concentrate on direct injection (DI).

In the DI process the fuel is injected directly into the highly compressed hot air in the combustion chamber above the piston (Fig. 10.82). A multi-hole nozzle is used to distribute the fuel uniformly in the combustion chamber to ensure rapid mixing. Very high injection pressures (up to 2000 bar) are required to properly and completely atomize the fuel.

For any combination of engine operating parameters, the fuel injection system must deliver the correct amount of fuel, at the correct time, at the correct injection pressure, with the correct timing pattern, and at the correct point in each cylinder's combustion chamber. Limits such as emissions, combustion pressure, exhaust temperature, engine speed and torque and vehicle-specific loads may need to be taken into account when determining the proper fuel injection.

Injection Characteristics. The key parameters and their corresponding units for every fuel injection system are:

- Injected fuel quantity (mm^3/stroke or mg/stroke)
- Injection pressure (bar or psi)

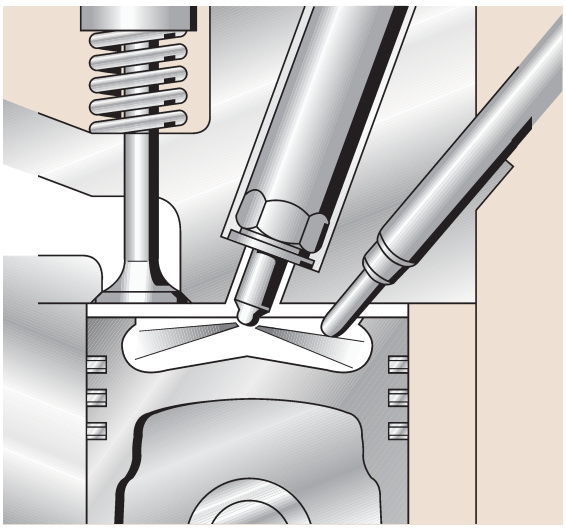

Fig. 10.82 Direct injection process

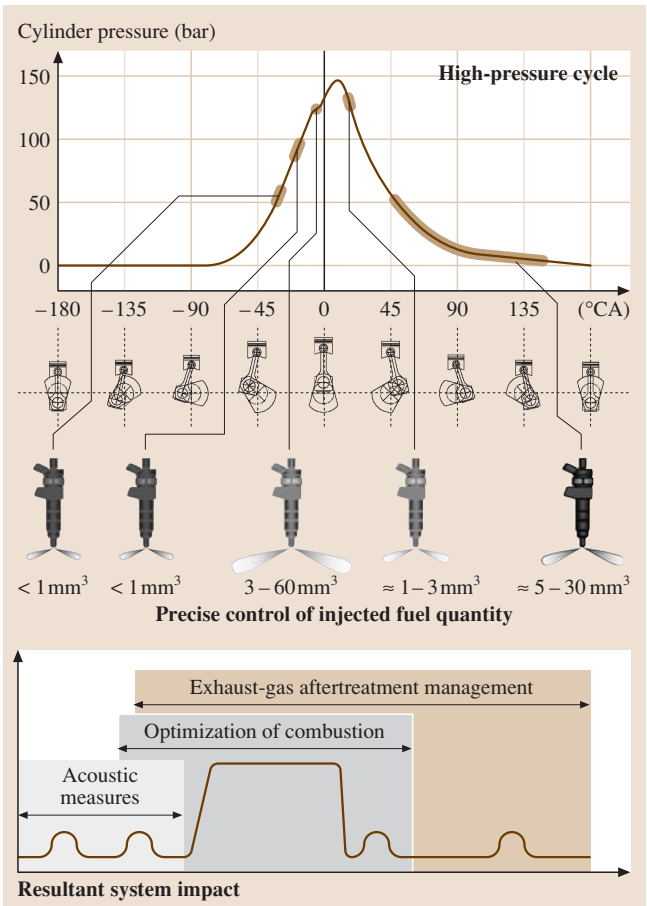

Fig. 10.83 Injection pattern

- Injection duration (degrees crank angle)
- Injection timing (degrees before or after the engine piston's TDC)
- Injection spray plume:
  - Number of plumes
  - The plume angle (degrees)
  - Location of the plume in the combustion chamber (height above piston bowl, position in cylinder)
  - The shape of the plume itself

Depending upon the type of fuel injection system, one or more additional injection characteristics may be available:

- Injection rate shape (mm^3 as a function of crank or cam angle)
- Injection pattern (number and form of injections during each combustion cycle, Fig. 10.83; up to five injections per combustion cycle may be required)
- Pre-injection 1: to reduce noise, improve warm-up (by avoiding misfire and white smoke)
- Pre-injection 2: to further reduce noise, improve warm-up (by avoiding misfire and white smoke)
- Main injection
- Post-injection 1 (close after the main injection): to reduce soot emissions
- Post-injection 2 (retarded): to act as a reducing agent for an after-treatment device

Fuel Injection System Designs [10.23]. To cover the wide variety of diesel engines in the marketplace (from motorcycles with 10 kW/cylinder up to railway locomotives with up to 1000 kW/cylinder), there is a corresponding variety of fuel injection designs. Figure 10.84 shows the various designs and Fig. 10.85 shows their corresponding injection pressure ranges. These can be divided into two main groups: cam driven and common rail.

Cam-Driven Systems. The cam-driven pumps can be further divided into two main groups: pump-line-nozzle and unit injector.

Pumping Arrangement of Cam-Driven Systems. The different designs within the pump-line-nozzle group:

- Inline fuel-injection pumps: one pumping unit per engine cylinder, mounted in a common housing
- Rotary fuel-injection pumps (axial-piston and radial-piston): one pumping unit for all engine cylinders; the fuel is distributed to each cylinder by a rotating shaft
- Individual-cylinder pumps: one pumping unit per engine cylinder, mounted separately and usually actuated by separate cam lobes on a common camshaft (Fig. 10.86)

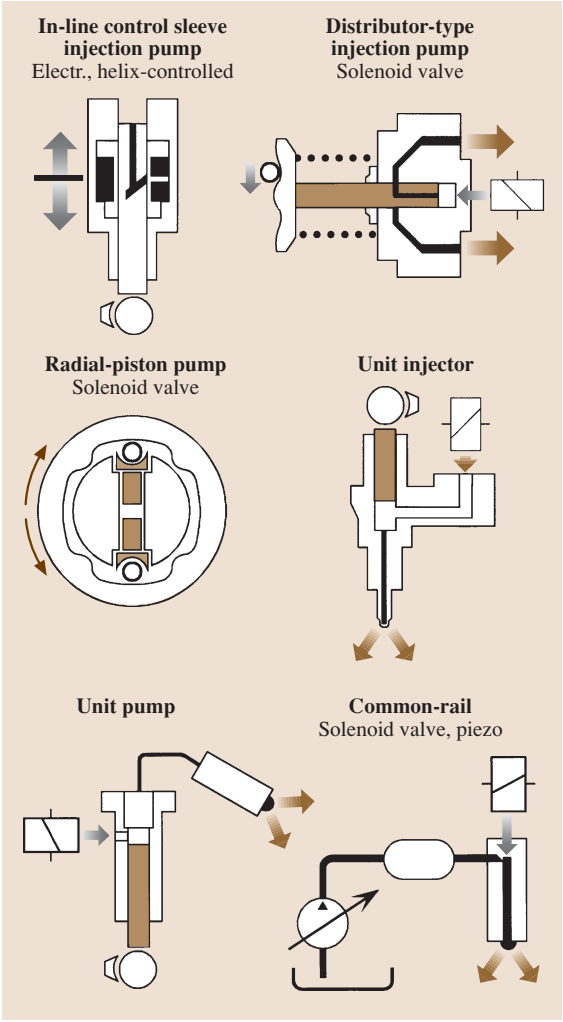

Fig. 10.84 Fuel injection systems

Each of the above has a high-pressure line to connect each pumping mechanism to its corresponding nozzle.

The unit injector combines the pumping unit and nozzle in one assembly for each engine cylinder; each unit injector is actuated by a separate cam lobe on a common camshaft (Fig. 10.87).

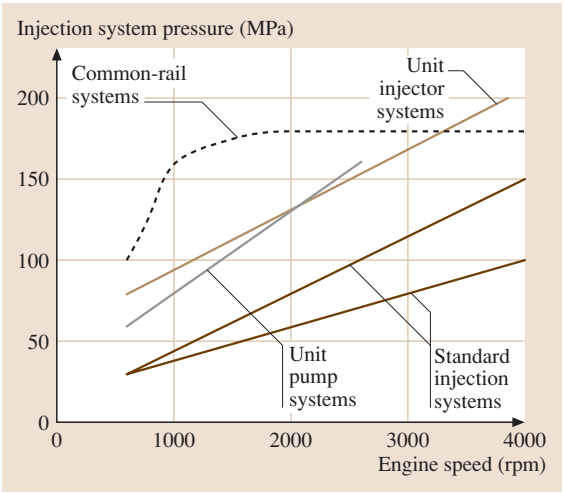

Fig. 10.85 Pressure ranges of fuel injection systems

Pumping Principle of Cam-Driven Systems. The pumping principle is essentially the same for all cam-driven systems: the cam lobe, which is driven by the engine's crankshaft and is thus phased to the crankshaft, pushes a plunger which pressurizes the fuel. This pressurized fuel travels to the nozzle and as soon as the pressure exceeds the nozzle's opening pressure, the nozzle needle lifts and fuel is injected into the engine.

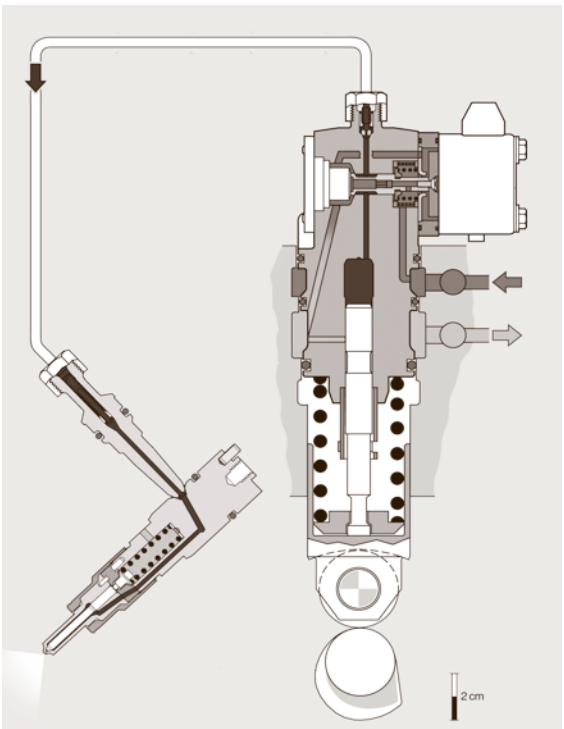

Fig. 10.86 Individual-cylinder pump

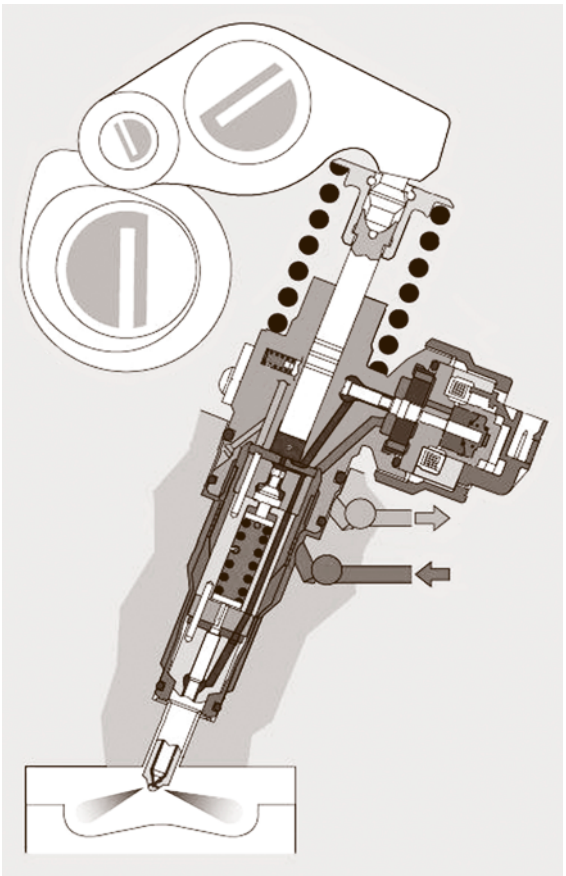

Fig. 10.87 Unit injector

Control System of Cam-Driven Systems. The fuel quantity is controlled by varying the length of delivery, which is accomplished by varying either the beginning of delivery (and keeping the end constant), the end of delivery (keeping the beginning of delivery constant), or by varying both. Governing can be mechanical, pneumatic, electromechanical, or electronic, whereby the majority of new applications are electronic.

In addition to fuel control the timing may also be controllable, either by changing the phasing of the pumping cam to the crankshaft or by changing the point at which pressure starts to build up on the pumping cam.

Injection-rate and pilot injection may also be controlled in some instances.

Common-Rail Systems. This system offers the greatest flexibility in the choice of fuel-injection parameters.

Pumping Arrangement. The common-rail (CR) system utilizes a single pump to pressurize the fuel which is delivered to an accumulator rail. One injector per engine cylinder is connected to this rail by means of a high-pressure line (Fig. 10.88).

Pumping Principle. Fuel is delivered by the low-pressure system to the high-pressure pump, where it is pressurized by the pumping plungers (arranged either radially or inline) and sent from there to the accumulator rail. Since all injectors are connected in parallel to the rail, they are all constantly pressurized and inject only when an electric signal is sent to each injector.

Control System. The start of injection (timing) and duration of injection (fueling) is controlled by a solenoid valve (electromagnetic or piezo) on each injector. When the actuating signal is sent to the injector, a coil or piezo stack inside the injector is energized, upsetting the pressure balance (on both sides of the nozzle needle) that was holding the nozzle closed. The needle then lifts and the injector delivers fuel to the engine. When the signal ceases, the pressure above the needle increases, forcing the needle closed and thus ending injection.

In addition, a sensor in the high-pressure circuit monitors the system pressure and sends this information to the electronic control unit (ECU) so that the pressure can be regulated to a value that is optimal for the engine's operating condition.

Low-Pressure System. Regardless of the fuel injection design, all fuel injection systems require a primary fuel pump to deliver the fuel from the fuel tank through the fuel filter to the injection pump.

Primary Fuel Pump. The primary fuel pump can be either mechanical or electric; the electric pump can be inside the fuel tank, mounted on the engine, or mounted on the vehicle.

Fuel Filter. The fuel filter must strain out impurities in the fuel, as contamination will cause wear, orifice plugging, component sticking, and seizures. The filter medium must be fine enough to trap small particles and the filter size must be large enough to assure adequate service life. Often a preliminary filter is used in addition to the main filter to extend the filter change interval.

In addition, filters should have the ability to separate water out of the fuel, as water will cause wear, corrosion, and seizures.

Many filters today have water separation, a water-in-fuel indicator, and a heater combined in one unit.

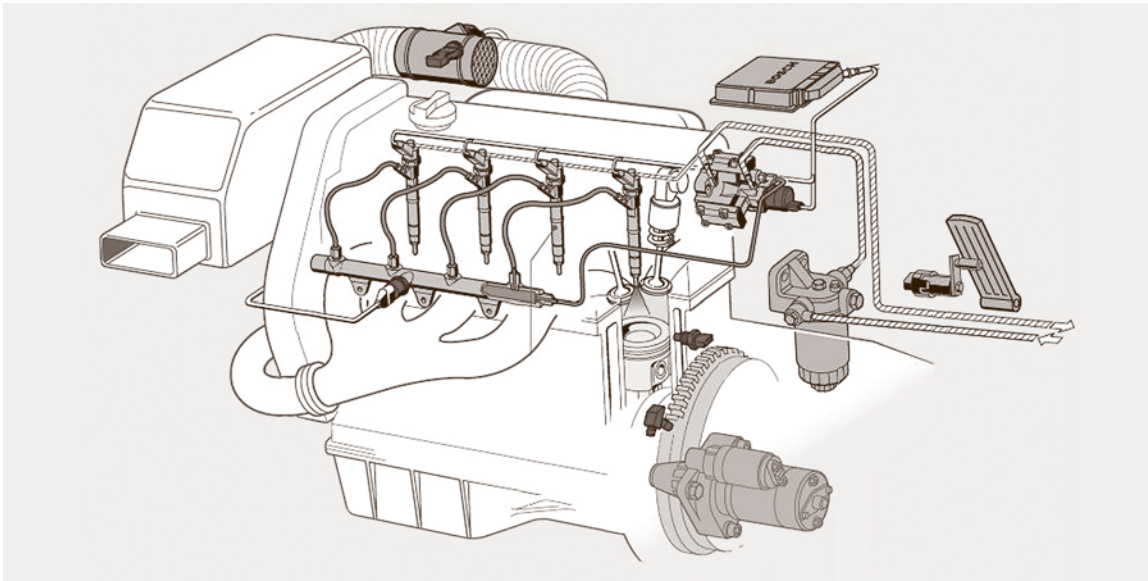

Fig. 10.88 Common-rail system

10.4.5 Ignition Systems

This section will cover the principles of ignition and the two main design types. It will explain how the high voltage needed for ignition is generated and the importance of ignition timing. Lastly it will cover spark plug design and function.

There are two basic types of ignition system: conventional coil and electronic. The conventional coil design can have one of three types of trigger; the electronic design can either have a distributor or be distributor-less. All designs use essentially the same method for generating high voltage, and all systems use the same design type of spark plug.

Principle

A gasoline internal combustion engine needs a spark to ignite the compressed air–fuel mixture in the combustion chamber. The spark is a discharge between the two electrodes that protrude into the combustion chamber. The ignition system generates the high voltage (up to 30 000 V) [10.24] needed to create the spark discharge and also initiates the spark to occur at the proper piston position (ignition timing).

Ignition System Design

Conventional Coil Ignition. This system consists of an ignition coil, ignition distributor, and spark plugs; see Fig. 10.89. As the coil is similar for all types of systems it is explained under point 3 (*high-voltage generation*).

The distributor rotates in sequence with the engine's crankshaft and at half of the crankshaft's speed for four-stroke engines or at crankshaft speed for two-stroke engines. One of three types of triggers is used in the distributor to control the current through the ignition coil:

- Mechanical breaker points: a mechanical switch that is closed and opened once per firing event by a cam located on the distributor shaft. The number of cam lobes equals the numbers of cylinders.
- Breaker-triggered transistorized ignition: this design is similar to mechanical breaker points except the primary ignition circuit is controlled by a transistor instead of by the breaker points. Only the control current is switched by the breaker points; this extends the breaker-point life and allows higher primary currents to be controlled.
- Transistorized ignition with Hall-effect trigger or induction-type pulse generator: the breaker points are totally eliminated and replaced by either a Hall-effect sensor or an induction-type pulse generator located in the distributor. The sensor or generator create one signal per cylinder; this signal is used to charge and discharge the coil.

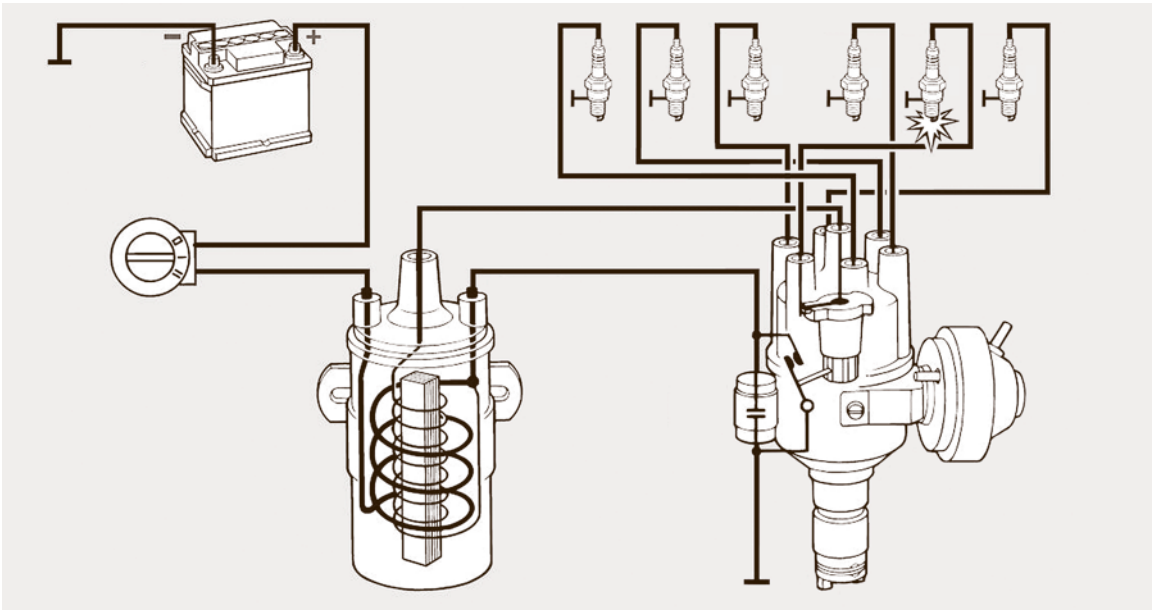

Fig. 10.89 Conventional coil ignition

A mechanical advance and vacuum unit define the proper ignition point as a function of engine speed and load.

Electronic Ignition. This system requires no centrifugal or vacuum-based timing control. Sensors monitor engine speed and load; these signals are sent to the ignition control unit, which determines the optimal ignition timing.

Engine speed is sensed by an inductive pulse sensor; engine load is sensed by a pressure (vacuum) sensor connected to the intake manifold. The ignition control unit uses these signals in a timing program map to determine optimal ignition timing for each speed/load point. Additional sensors may be used to monitor engine temperature, intake air temperature, throttle-plate position, and other operating parameters which are then taken into consideration when determining ignition timing.

This system may utilize a distributor to contain the engine speed/position sensor and to distribute the high voltage (Fig. 10.90a, or may instead be distributor-less (Fig. 10.90b. The latter system has a separate ignition coil for each cylinder or pair of cylinders. These coils may be mounted on the engine or directly attached to the spark plugs.

The ignition control system may be combined with the fuel injection control system to allow for coordinated total engine management (see Sect. 10.4.4).

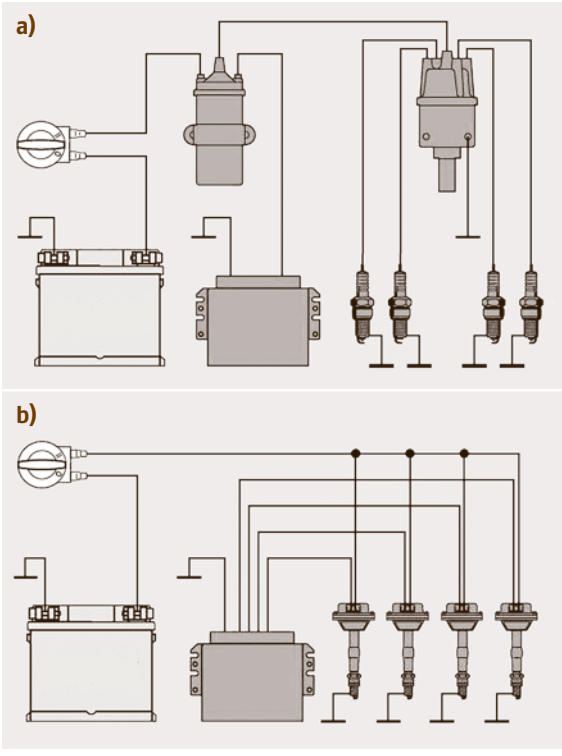

Fig. 10.90a,b Electronic ignition

High-Voltage Generation

The high voltage needed to bridge the spark-plug gap is typically generated by a coil. The coil consists of two copper windings (primary and secondary), an iron core, and a plastic casing. Energy is transferred from the primary winding to the secondary winding by means of magnetic induction. The current and voltage amplification from primary to secondary is the ratio of the number of coil windings.

Charging and discharging the coil to generate the high voltage needed for the spark plugs is essentially the same for all types of ignitions. The trigger closes and opens once for each cylinder's combustion event. When the trigger closes, current flows through the coil's primary winding and to ground. This produces a flux field in which ignition energy is stored. The time available for charging is determined by how long the trigger is closed (referred to as the dwell angle). The current is interrupted when the trigger opens.

The flux field in the primary winding produces high-tension voltage in the secondary winding. For a distributor-type system, this voltage is conducted to a center contact in the distributor cap. A rotor within the distributor rotates with engine rotation and distributes

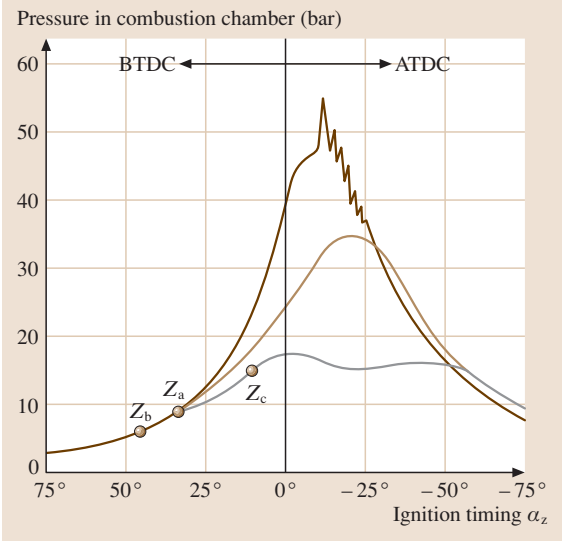

Fig. 10.91 Effect of ignition timing on combustion pressure

the high voltage to the spark plugs via the distributor cap and ignition wires. For a distributor-less system, the voltage is fed directly to the spark plug.

Ignition Timing

As engine speed increases, ignition timing must be advanced relative to piston top dead center to allow the air–fuel mixture more time to burn. As load increases, ignition timing must be retarded to prevent detonation (knock). The effect of ignition timing on combustion pressure is illustrated in Fig. 10.91.

Spark Plug Design

All ignition system designs include a spark plug, which consists of a:

- Terminal post which leads the current from the ignition wires to the center electrode
- Insulator which is made from a ceramic material and insulates the center electrode and terminal post from the shell
- Shell which houses the insulator and allows mounting to the cylinder head
- Gasket and seat which seals the combustion pressure
- Electrodes that form a gap that the high voltage must bridge to pass to ground, thus causing a spark

Electrodes may be made from a compound of corrosion-resistant nickel and copper, a composite with silver as a base, or platinum. The electrode gap determines the length of spark; the voltage required to jump the gap increases as gap width increases.

Figure 10.92 shows a spark plug cross section of two different electrode designs (front electrode and side electrode).

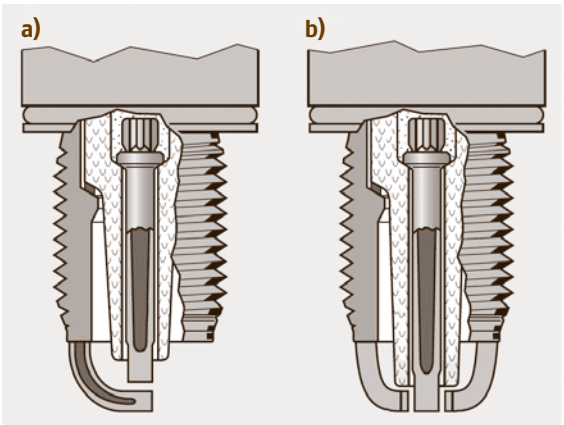

Fig. 10.92a,b Electrode designs

The heat range defines the operating temperature of the spark plug's insulator nose and should be chosen to maintain 500–900 °C. If the temperature is below 500 °C combustion residue will form on the insulator nose. If the temperature is above 900 °C the hot combustion residue gases promote electrode oxidation. Above 1100 °C auto-ignition may result. Figure 10.93 shows the proper operating range.

10.4.6 Mixture Formation and Combustion Processes

All fuel–air mixtures have limits for the mixture ratios that can be used in engines. When there is too little fuel, the mixture is said to be *lean* and flame propagation is slow and misfire is likely. When the fuel concentration is too high, the mixture is said to be *rich*, and the combustion produces products of incomplete combustion such as carbon monoxide.

Spark Ignition Engines

In spark-ignited engines, a homogeneous charge of fuel and air is introduced into the cylinder and a flame is initiated with a spark near the end of the compression

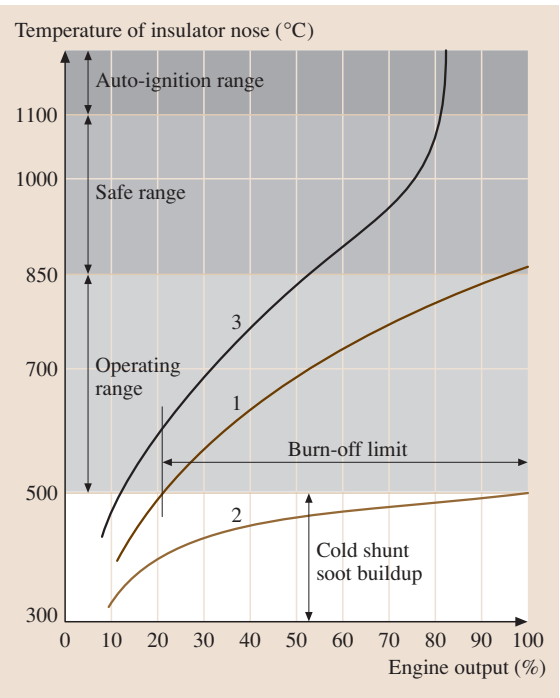

Fig. 10.93 Operating temperature of the spark plug's insulator nose

process. The flame propagates outward from the spark source. Turbulence is required for the flame to achieve the speed necessary to complete the combustion process before the exhaust valve opens. In the early part of the combustion process, immediately after ignition, the flame growth is slow. The combustion zone, called the flame kernel, is small and very little energy has been released. The progress of combustion at this point is sensitive to the balance of energy released by combustion and the heat lost to the cooler surroundings. Leaner mixtures and lower temperatures and pressures can slow the energy release rate and increase the likelihood of misfire. Cycle-to-cycle variations in this critical phase of the combustion process can cause large differences in the development of the cylinder pressure.

In some cases the combustion process may not proceed in the normal manner of a deflagration wave propagating away from the spark. In one such case, the gases in front of the flame front, which are compressed as the cylinder pressure rises from combustion of the gases behind the flame front, may spontaneously ignite. This *auto-ignition*, also called *knock*, can be extremely violent and significantly raises engine noise levels. If a large percentage of fuel is involved in the event, it can cause mechanical damage to the engine. Some fuels are more prone to auto-ignition than others. The resistance of the fuel to auto-ignition is characterized by the fuel's octane number. Fuels with high octane numbers can be operated with less chance of knock.

Basic thermodynamics indicates that engines with high compression ratio should have better fuel economy and performance. However, the higher temperatures and pressures that result from the higher compression ratio increase the tendency for knock. High octane fuels are needed for engines with elevated compression ratios. Because knocking combustion is so rapid, it tends to approximate the thermodynamic ideal of constant volume combustion. In fact, many engines demonstrate their highest efficiency when operated with light knock. However, as more fuel is consumed by the auto-ignition, the pressure oscillations in the cylinder tend to disrupt the thermal boundary layers in the cylinder and increase the heat loss from the combustion gases.

Another type of abnormal combustion is known as pre-ignition or surface ignition. In this case, the fuel–air mixture may be ignited by a hot surface in the cylinder. This might be a valve surface, a carbon deposit, or even a piece of head gasket that protrudes into the cylinder. Because the combustion may be earlier than the spark, the flame-caused pressure rise may occur during the compression process causing the cylinder pressure to become very high. It has been proposed that knock and pre-ignition can be coupled. Knocking can increase heat transfer rates and raise surface temperatures so that pre-ignition is more likely. The resulting pre-ignition raises the gas temperatures in the cylinder and makes knock more likely.

When the fuel–air mixture is too lean, the flame kernel grows slowly and there is an increased probability of misfire in the engine. The mixture ratio where the misfire becomes unacceptable is the lean operating limit of the engine. There is a corresponding rich operating limit where there is insufficient oxygen to sustain combustion. The chemically correct mixture is known as the *stoichiometric* mixture. The air–fuel ratio for maximum engine power falls on the rich side of the stoichiometric mixture and the best fuel economy tends to be on the lean side.

In order for a spark-ignited engine to operate continuously, the air–fuel mixture must be between the two flammability limits. However, exhaust emission concerns dictate that the mixture be held close to stoi-

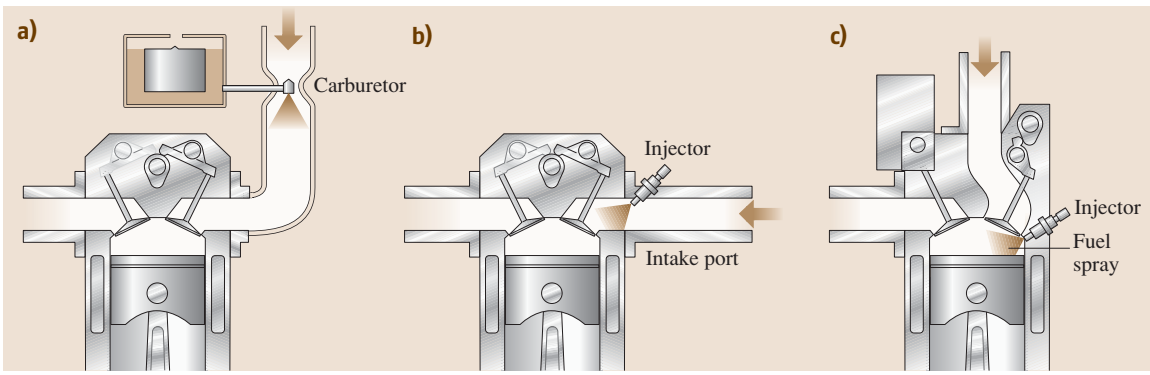

Fig. 10.94a–c Fuel–air mixture formation in spark ignited engines

chiometric. Except for cold starts and brief periods of high power demand, modern vehicles equipped with three-way catalysts and closed loop control of air–fuel ratio operate in a narrow band around stoichiometric.

Figure 10.94 shows three different approaches to fuel–air mixture formation in spark-ignited engines. The traditional approach of introducing the fuel with a carburetor into the intake air stream is only used for small engines and is obsolete for larger engines that are subject to emissions controls. Most engines today use port fuel injection, as shown in Fig. 10.94b. This approach provides very uniform air–fuel mixture between cylinders and excellent atomization of the fuel at all speeds. Figure 10.94c shows direct injection of the fuel into the cylinder. Although not yet widely used, this approach allows some degree of charge stratification in the cylinder and fuel economy that approaches the diesel engine.

Compression Ignition Engines

Compression ignition engines, also known as *diesel* engines, bring only air into the cylinder through the intake valve. The engines rely on compression of the air to produce sufficient temperature that the fuel auto-ignites soon after it is injected near the end of the compression process. In contrast to the homogeneous charge spark-ignited engine, the air–fuel mixture in the diesel engine is always heterogeneous. Since there is a distribution of fuel–air ratios ranging from very lean to very rich, there is always some location in the cylinder where conditions are optimum for auto-ignition and the cycle-to-cycle variability for diesel engines is very small.

Diesel engines run without throttles so they have the advantage of low pumping losses. Load is controlled by varying the amount of fuel that is injected into the cylinder. At light load and idle, the air–fuel ratio may be 70:1 or higher. At full load, the air–fuel ratio may be as low as 20:1. The stoichiometric ratio of 14.5–14.8 is generally not achieved because of high smoke levels.

Diesel engines can be categorized into direct injection (DI) and indirect injection (IDI), although indirect injection designs are now mostly obsolete. The IDI engines utilized a small chamber apart from the main chamber, called a prechamber or turbulence chamber, that was connected to the main chamber by a narrow passageway. Fuel was injected either into the separate chamber, or into the passageway, and the rapid air motion between the two chambers caused by the piston motion, provided excellent fuel–air mixing. This rapid mixing allowed high-speed operation of the engines but heat transfer and throttling losses exacted a severe fuel-economy penalty on IDI engines. Advances in fuel injection technology have allowed DI engines to operate at equivalent speeds with much better fuel economy. A DI engine with the fuel sprayed directly into a chamber in the cylinder formed by a toroidal recess in the piston is the most common configuration in modern diesel engines.

Alternative Combustion Systems

A major drawback of both spark ignited and compression ignited engines is their high NO_x emissions. Both engines require after-treatment to reduce NO_x to acceptable levels. Combustion systems that are homogeneous charge, like spark-ignited engines, but utilize auto-ignition, like a compression-ignited engine, have been developed. These engines utilize an air–fuel mixture that would ordinarily be quite lean, but by controlling the temperature, it can be made to auto-ignite in a gradual and controlled manner towards the end of the compression stroke. Temperature and air–fuel ratio can be optimized to reduce NO_x emissions to very low levels.

10.4.7 Fuels

This section will cover the basics of gasoline, diesel, and alternate fuels. It will start with the original of petrochemical fuels and the refining process. The basic composition and key characteristics of gasoline and diesel fuels will then be explained. Lastly an overview of fuel substitutes and alternate fuels will be given, whereby this cannot cover in detail the plethora of newly emerging fuels.

Petroleum Refining and Basic Organic Chemistry [10.25]

Most conventional fuels are made from petroleum crude oils, consisting primarily of paraffinic, naphthenic, and aromatic hydrocarbons. Raw crude oils have a wide range of densities ranging from as thin as water to as thick as tar. Crude oil is converted into usable products by means of refining; the most important products are gasoline, jet fuel, and diesel fuel. Other valuable products are heating oils, liquefied petroleum gas, lubricating oils and asphalt.

To convert crude oil the feedstock is typically distilled. Since the different components of crude oil (e.g., gasoline, diesel) have different boiling points, the lighter components (those with relatively low boiling points, e.g., propane and butane) rise to the top of the distillation column where they are drawn off. The next-heavier components (e.g., gasoline) are drawn off lower

on the column, then the subsequently heavier components (kerosene and then diesel) are drawn off towards the bottom.

The fuels must then be upgraded, usually by hydroprocessing (which uses hydrogen with a catalyst) to remove undesired components.

Fuels with higher boiling points are then cracked (broken down) into lower boiling points using very high temperatures and catalysts.

Gasoline

Basic Composition. Gasoline fuels for spark-ignition engines are hydrocarbon compounds, which sometimes contain oxygenous components to enhance performance.

Key Characteristics.

- Grade: usually stated as regular or premium; an indication of anti-knock property.
- Octane number: resistance to knock (pre-ignition).
- Density: weight per unit volume; energy content increases as density increases.
- Volatility: how easily the fuel vaporizes. The fuel must vaporize quickly for good cold starting but not so quickly as to cause vapor-lock. Volatility is characterized by the fuel's vapor pressure and/or evaporation points dependant upon temperature.
- Sulfur content: must be kept low to allow proper operation of the catalytic converter or other after-treatment device.
- Additives: may be used to enhance one or more of the properties stated above, or to protect against aging, contamination or corrosion.

Diesel

Basic Composition. Diesel fuels for compression-ignition engines are usually distilled from crude oil. They consist of a large number of different hydrocarbon compounds including *n*-paraffins, olefins, naphthenes and aromatic compounds. Diesel fuel ignites at $\approx 350\,^{\circ}\mathrm{C}$, much lower than gasoline, which ignites at $\approx 500\,^{\circ}\mathrm{C}$.

Key Characteristics.

- Grade: the standard to which the fuel must conform.
- Density: weight per unit volume; energy content increases as density increases.
- Viscosity: resistance to flow; low viscosity leads to leakage losses, while high viscosity may impair injection pump function.
- Cetane number: ease with which fuel ignites; combustibility increases as cetane number increases.
- Cold filter plugging point: the temperature at which the fuel clogs the filter.
- Flash point: the storage temperature at which flammable vapors are produced.
- Water content: amount of water in fuel; water causes corrosion and poor lubrication, leading to wear and seizures.
- Contaminants: foreign particles in fuel; the particles cause erosive and abrasive wear.
- Lubricity: measure of the fuel's lubrication properties; low lubricity causes wear and seizures.
- Sulfur content: amount of sulfur in fuel; sulfur does not harm the fuel injection system but will harm most after-treatment devices. The removal of sulfur by hydrogenation also removes the ionic fuel components that aid lubrication, reducing the lubricity properties of the fuel. Additives are thus needed to restore lubricity to a sufficient level.
- Oxidation stability: resistance to forming acids.
- Additives: may be used to enhance one or more of the properties stated above.

Alternate Fuels [10.26]

In addition to the standard fuels there are several alternatives to gasoline and diesel. These are often pursued in order to reduce emissions or to reduce consumption of nonrenewable fuels as most alternate fuels are from a renewable source.

It should be noted that alternate fuels are not always compatible with the fuel system (some require extensive modifications), and that they may increase one emission component while reducing another.

Alternate fuels can be divided basically into two categories: gasoline substitutes/additives and diesel substitutes/additives.

Gasoline Substitutes/Additives.

- Coal hydrogenation: coal and coke
- Liquefied petroleum gas (LPG): hydrocarbon mixtures (mostly propane) that are liquid at ambient temperatures under relatively low pressures
- Liquefied natural gas (LNG): methane that is cooled to $< -160\,^{\circ}\mathrm{C}$ and condensed to a liquid by compression
- Compressed natural gas (CNG): natural gas (mostly methane) compressed to high pressure
- Hydrogen: produced by electrolysis of water or from natural gas/coal

- Alcohol: methanol (usually made from natural gas but can also be made from biomass resources such as wood) and ethanol (made from grain or biomass). Either can be used alone or mixed with gasoline

Diesel Substitutes.

- Alcohol: methanol and ethanol as described above; usually mixed with diesel.
- Fatty acid methyl ester (FAME): often known as biodiesel, made from many sources the most popular of which are Rapeseed, soybean, sunflower and used cooking oils. Usually mixed with diesel in 5–50% concentrations, these bring lower PM emissions and improve lubricity but are critical regarding density, NO_x, water absorption, and stability.
- Diesel–water emulsions: reduce soot and NO_x but also lower power output
- dimethylether (DME): a gas-phase fuel, requiring extensive modification of the fuel injection equipment
- Oil sand/tar sand gasification
- Synthetic fuels: methane gas-to-liquid (GTL, tradename *Synfuel*), biomass-to-liquid (BTL, tradename *Sunfuel*), and coal-to-liquid (CTL).

10.4.8 Emissions

Emissions from engines are generally thought of as the harmful chemicals that are present in small amounts in the exhaust gas. However, vaporized fuel that is released during refueling or from leaks onboard the vehicle can also be a source of air pollution. Carbon dioxide, a major component of engine exhaust and an inevitable consequence of hydrocarbon combustion, was traditionally considered to be benign and not included as a hazardous air pollutant. Now that the role of carbon dioxide from fossil resources in global climate change has been identified, much more attention is being paid to this gas.

Emission regulations can be placed into two categories: those that limit emissions from specific engines or vehicles and those that limit the levels of emissions in specific spatial locations, without regard to their origin. The first category of regulations will be our primary focus as these are the regulations that engine and vehicle manufacturers are required to meet in order to sell their products. The second category of regulations tend to be the responsibility of cities or states, and while they may impose restrictions on the types of vehicles that can be sold within their jurisdiction, the sources of pollution are not limited to engines and vehicles.

Ambient Air Quality

Ozone has been the subject of what appear to be contradictory statements in the popular media. Ozone is described as essential to protect against skin cancer and is being depleted by chlorofluorocarbons (CFCs). At the same time, city dwellers are subject to warnings about

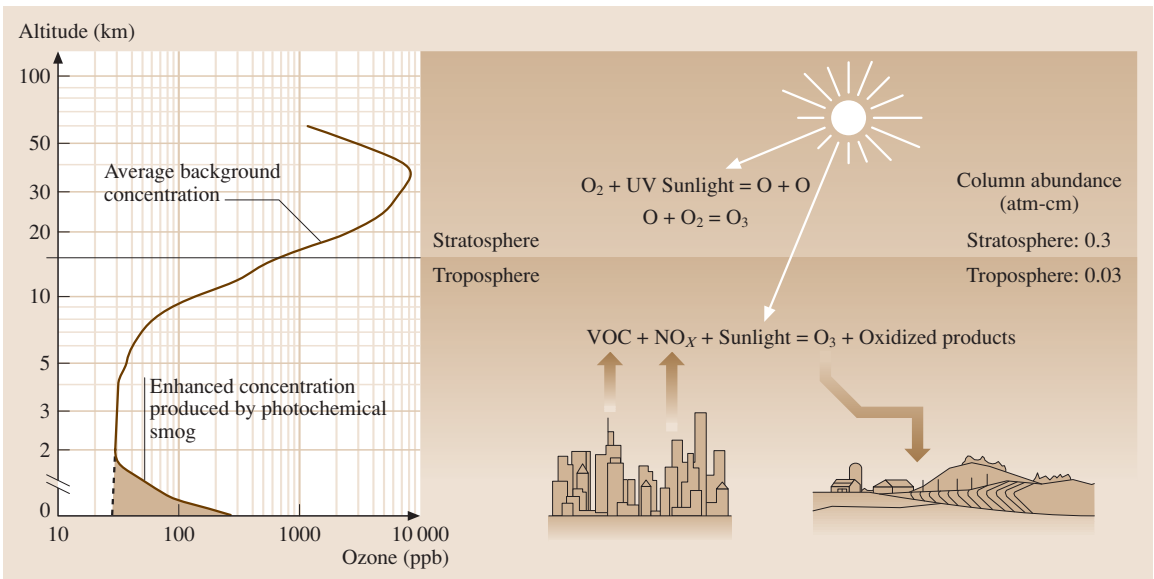

Fig. 10.95 Atmospheric ozone (after [10.27])

high ozone levels. The resolution of this apparent contradiction lies with understanding the role of altitude as explained in Fig. 10.95. In the stratosphere, above 15 000 feet, the concentration of ozone can be very high, approaching 10 000 ppb (parts per billion). This ozone is formed by reactions involving sunlight and oxygen. It filters the ultraviolet solar radiation that causes skin cancer. Some researchers have argued that this ozone is destroyed by reactions with chlorine atoms originating from CFCs.

At lower altitudes the natural concentration of ozone is up to 3 orders of magnitude lower than in the stratosphere. This is fortunate since high levels of ozone interfere with plant growth and are a strong irritant. High levels of ozone can be produced at lower elevations by reaction of volatile organic compounds (VOCs), carbon monoxide, oxides of nitrogen (NO_x), and sunlight. This complex set of chemical reactions produces a large number of different chemical compounds, many of which are harmful and irritating to people. Ozone, although only one chemical compound, is widely used as a measure of the overall concentration of the complex chemical mixture, sometimes known as *smog*. The EPA recently reduced the maximum allowable ozone concentration from 120 ppb averaged over a 1 h period to 80 ppb averaged over an 8 h period. Normal background levels of ozone are typically 20–40 ppb and can exceed 200 ppb during severe smog episodes [10.24].

Ozone is a secondary pollutant. It is not found in significant amounts in the exhaust of engines. However, compounds that are found in engine exhaust contribute to the formation of ozone, such as, VOCs, carbon monoxide, and NO_x. Another major source of VOCs is evaporative emissions. Evaporative emissions originate from losses of fuel during refueling as well as when the vehicle undergoes diurnal heating and cooling. These emissions are strongly tied to the Reid vapor pressure of the fuel, which is why it is now closely controlled in areas where air pollution is a problem. Evaporative emissions are only a problem with volatile fuels such as gasoline and its blends with alcohol. Diesel fuel's vapor pressure is so low that it does not contribute to evaporative emissions.

Regulated Pollutants

The Environmental Protection Agency (EPA) regulates the tailpipe emissions of both spark-ignition and compression-ignition engines in the United States. Regulated pollutants from spark-ignited engines include carbon monoxide, oxides of nitrogen, and unburned hydrocarbons. Compression ignited, or diesel, engines must meet requirements for particulates as well as these gaseous species.

Carbon monoxide is primarily determined by the engine's air–fuel ratio. When the engine is operated fuel-rich there is insufficient oxygen to convert all of the carbon to carbon dioxide, so a portion is converted to carbon monoxide. Carbon monoxide is actually an intermediate product in the oxidation of hydrocarbons and is always present in significant amounts during the combustion process. Measured levels in the exhaust are usually higher than would be expected because the oxidation of the carbon monoxide tends to be a slow process that is limited by the rate of the reaction of CO with the OH radical, as shown in the following equation

$$CO + OH \rightarrow CO_2 + H\,. \tag{10.82}$$

The concentration of the OH radical decreases rapidly as the in-cylinder temperature drops during expansion, leaving the CO frozen at an elevated level. An additional mechanism that affects homogeneous charge engines is the partial oxidation of trapped fuel that emerges from crevices or oil films during the expansion process when the temperature is too low to oxidize the fuel completely before the exhaust valve opens. In carbureted engines, rich-burning cylinders resulting from the nonuniform distribution of fuel between cylinders is an important source of carbon monoxide. Carbon monoxide emissions from diesel engines are generally well below regulation limits because diesels always operate with excess air.

Oxides of nitrogen (NO_x) consist primarily of nitric oxide (NO) and nitrogen dioxide (NO_2). Nitric oxide originates through three potential mechanisms that are usually categorized as fuel NO_x, prompt NO_x, and thermal NO_x. Fuel nitrogen can contribute to NO_x formation but is usually not important for engines because gasoline and diesel fuel contain small amounts of nitrogen. Prompt NO_x is formed by reactions between nitrogen and hydrocarbons during the combustion process. This mechanism also does not seem to be an important source of NO_x for engines. The primary source of engine NO_x emissions is thermal NO_x. This mechanism involves the following three reactions

$$O + N_2 \rightarrow NO + N\,, \tag{10.83}$$

$$N + O_2 \rightarrow NO + O\,, \tag{10.84}$$

$$N + OH \rightarrow NO + H\,. \tag{10.85}$$

Since these reactions require significant concentrations of the radicals O, N, and OH, they only occur at

high temperatures. The reactions also require significant time to equilibrate so most of the NO formation occurs in the post-flame gases. Virtually all NO_x control strategies, such as timing retard and exhaust gas recirculation (EGR) focus on reducing the temperature of the post flame gases.

Unburned hydrocarbon emissions from spark-ignited engines generally originate from fuel that is trapped in crevices, oil films, or deposits and is thus protected from combustion during the main combustion event. This sequestered fuel is released when the pressure drops during the expansion process but the temperature may be too low for complete combustion. Some of the fuel may burn to carbon monoxide but a significant portion will remain unburned or only partially burned and this will be released in the engine exhaust. Some of the products of partial combustion, such as olefins and aldehydes, are highly reactive and are strong contributors to photochemical smog reactions. Occasional misfiring cycles can also be a significant source of unburned hydrocarbon (UHC) from spark-ignited engines. UHC from diesel engines generally originate from fuel that has been overmixed with air so that the mixture is too lean to burn under the conditions in the cylinder. These conditions are most likely to be encountered at idle and light loads.

Regulated emissions from compression-ignited, or diesel, engines include the CO, NO_x, and UHC described for spark ignition (SI) engines, but also include particulates. Particulates from diesel engines are operationally defined as whatever collects on a filter when the exhaust is cooled to 52 °C after the filter has had a chance to equilibrate in a temperature and humidity controlled environment. The primary constituent is carbonaceous matter, usually referred to as soot, that originates from high temperature pyrolysis reactions in the fuel-rich regions of the cylinder. The carbonaceous particles provide sites for the condensation and adsorption of high molecular weight hydrocarbons as the combustion products cool and this portion of the particulate is often referred to as the soluble organic fraction (SOF) or the volatile organic fraction (VOF). These high molecular weight hydrocarbons may originate from the fuel but are more frequently associated with the lubricating oil. Particulate may also contain sulfates resulting from the reaction of fuel-based sulfur to sulfur trioxide and then to a variety of sulfate compounds which may be observed as small droplets of sulfuric acid. Finally, the particulate may include inorganic compounds resulting from engine wear and lubricant additives. Many of the compounds identified in the SOF are known carcinogens and the small size of the particulates (0.01–0.1 μm) increases the potential for their inhalation and retention in the lungs. For these reasons, the regulatory levels for particulate emissions have been progressively lowered so that after 2007 exhaust filtration technology has been required for most on-highway engines.

Measurement Instruments

A variety of instrumentation technologies have been developed to quantify the levels of pollutants in engine exhaust gases. Some techniques such as Fourier transform infrared spectral analysis have broad applicability and are widely used for engine development. For emissions certification, specialized instruments are still used that have been developed to measure specific species, and often over limited ranges. Oxides of nitrogen are measured with devices that take advantage of the chemiluminescent reaction that occurs when NO reacts with ozone to form NO_2 and oxygen. The photon of light that is emitted by this chemical reaction can be measured and directly related to the concentration of NO. Total NO_x can be measured by passing the exhaust gas through a catalyst that converts the NO_2 into NO before the gas is exposed to ozone.

Carbon monoxide and carbon dioxide are most commonly measured with nondispersive infrared (NDIR) absorption instruments that measure the amount of light of a specific wavelength that is absorbed by the exhaust gas. The wavelengths and path lengths for the light are chosen to provide the best sensitivity for the gas of interest. This technique requires that water vapor, a broad-band absorber of infrared radiation, be removed before the measurement can be performed. The water is usually removed by cooling the gas to condense the water or passing the gas stream through a chemical desiccant.

Unburned hydrocarbons are measured using a flame ionization detector. These devices contain a small hydrogen flame located between two electrically charged plates. A small amount of the exhaust stream is fed into the hydrogen flame and the hydrocarbon-based carbon atoms produce flame ionization that can be measured as an electric current between the charged plates. The particle filters and all connecting lines must be heated to prevent condensation of the hydrocarbon vapors before they enter the flame. The heated flame ionization detector (HFID) measures the number of carbon atoms associated with hydrocarbons in the exhaust and thus requires an assumption to be made regarding the chemical composition of the hydrocarbons. Measurements

performed on gasoline-fueled engines often assume the hydrocarbon has the same structure as hexane. Assuming the unburned hydrocarbons have the same chemical structure as the fuel is also a common assumption for both gasoline and diesel engines.

Particulates are measured by filtering a portion of the exhaust gas and then weighing the increase in mass of the filter. The temperature of the filter is carefully controlled because if it is too low an excessive amount of the unburned hydrocarbon vapors may condense on the filter. The techniques used to capture a representative sample of the exhaust gas and allow the determination of the amount of particulate during a transient test cycle are described in the following section.

Test Cycles

Emissions from passenger cars and other light-duty vehicles are measured while the vehicle is operated on a chassis dynamometer. The chassis dynamometer connects the drive wheels of the vehicle to a load absorber through a set of rollers. The device allows the vehicle to be operated in a controlled laboratory but with an accurate simulation of actual in-use driving conditions. Flywheels and dissipative absorbers are used to simulate vehicle inertia and air resistance so the vehicle can be operated over transient driving cycles. Test cycles that involve following a vehicle speed versus time curve that models different driving conditions are used for emissions certification. Trained drivers can follow these curves very exactly although most installations now use computerized throttle controllers.

The wide variety of transmission, drive line, and engine combinations used in heavy-duty applications precludes the emissions certification of vehicles. Heavy duty emissions testing focuses on testing the engine itself while it is outside the vehicle connected to a computer-controlled load absorber. The engine is operated over a 20 min cycle where both the engine speed and torque are specified on a second-by-second basis. The 20 min test cycle consists of four 5-min segments that model different types of city and highway driving.

Exhaust emissions for both chassis dynamometer and engine dynamometer test systems involve injecting some or all of the exhaust gas stream into a dilution tunnel to lower the temperature of the exhaust gas and to simulate the particulate agglomeration processes that occur when the exhaust enters the atmosphere. These systems are equipped with flow control systems so that a constant volumetric flow rate is maintained for the sum of the engine exhaust and the dilution air. A sample of the diluted exhaust gas is filtered and the weight of the particulate is measured. In the case of chassis dynamometers, the pollutant is expressed as g/mile and for the engine dynamometer it is expressed as g/horsepower-hour or g/kW h. The denominator of the engine dynamometer term is the total amount of work performed by the engine during the test cycle.

Gaseous emissions are also sampled from the dilution tunnel. They may be collected in special chemically inert bags to obtain an integrated total for the cycle, or measured second by second to investigate the effect of different parts of the test cycle on a pollutant of interest.

Both chassis and engine dynamometer testing are conducted under carefully controlled laboratory conditions. There have been some claims that this testing is not representative of emissions from in-use vehicles and attempts have been made to characterize in-use emissions using chassis dynamometers to test vehicles chosen at random from traffic flows. This experience has shown that significant numbers of vehicles have improperly operating emission control systems and actual emission levels are higher than would be expected from emission certification data. Measurements have been attempted using light absorption techniques from passing traffic but results have been mixed. Variability in measurement points, vehicle types, weather effects, etc. mean that extremely large numbers of measurements are required.

SI Engine Emissions Characteristics

The primary pollutants of regulatory concern for spark-ignited engines are carbon monoxide, oxides of nitrogen, and unburned hydrocarbons. The levels of these pollutants in the engine exhaust depend strongly on the engine's operating conditions such as spark timing, load, speed, and air–fuel ratio. While the engine speed and load are controlled by the operator (for a manual transmission), the timing and air–fuel ratio are set by the engine's electronic control module (ECM) to keep the levels of the exhaust pollutants within the range allowed by emissions regulations while ensuring adequate vehicle performance. Under cold starting and high-power-demand conditions the air–fuel ratio is calibrated to be fuel-rich. However, under all other operating conditions, the ECM maintains the air–fuel ratio close to the chemically correct, or stoichiometric, ratio.

The impact of timing, speed and most other operating parameters on carbon monoxide is secondary to the air–fuel ratio. There may be some effect on CO as these parameters are varied but this is most likely due to changes in air–fuel ratio or in causing the engine to operate at non-optimum conditions for oxidation of the CO.

As described above, oxides of nitrogen from spark-ignited engines are almost entirely thermally based and the two primary parameters that influence combustion temperature are spark timing and air–fuel ratio. Over the normal range of variation of spark timing used in modern engines, earlier timing (advanced) always increases emissions of oxides of nitrogen (NO_x) and later timing (retarded) always decreases NO_x. Since the spark timing that provides best fuel economy is usually well advanced from the timing needed to keep NO_x at a tolerable level, engine designers are confronted by a trade-off between the desire to provide good fuel economy while still keeping NO_x emissions at a level that can be controlled by the catalytic converter.

While spark-ignited engine UHC emissions are primarily dependent on design factors such as piston ring position, which controls the size of the crevice volume, they can be affected by speed, timing, load, and fuel–air ratio as these will affect the amount of fuel that is sequestered in crevices and the tendency to misfire. As mentioned earlier, evaporative emissions are another source of UHC from spark-ignited engines. While these can be controlled during engine operation by venting the fuel tank through a carbon canister to absorb fuel vapors, vehicle refueling still usually involves a release of vapors as capture systems are not required in most states. Evaporative emissions are best controlled by limiting the fuel's vapor pressure during warm weather.

In some parts of the United States, oxygenates are required to be added to gasoline to lower emissions. Ethanol is currently the most widely used fuel oxygenate. Methyl *t*-butyl ether (MTBE) is being rapidly phased out due to concerns about groundwater contamination resulting from fuel spills. Because of its lower oxygen requirement for combustion, ethanol decreases emissions of CO and UHC during cold starting and periods of high load. This is partially offset by higher evaporative emissions resulting from the higher vapor pressure when ethanol is blended with standard grades of unleaded gasoline.

Closed-Loop and Open-Loop Control. As described above, the pollutant species that need to be controlled from spark-ignited engines are carbon monoxide, unburned hydrocarbons, and oxides of nitrogen. It should be noted that the first two of these compounds need to have their oxidation process completed, while the third compound needs to be *un-oxidized* or reduced. This conflict in objectives is what makes the simultaneous elimination of the three compounds so difficult. Completion of the oxidation process can be accomplished by providing an excess of oxygen and then passing the exhaust gas through an oxidizing catalyst such as platinum. Reducing the oxides of nitrogen requires an oxygen-poor environment and an easily oxidized compound, called a reducing agent, to assist in breaking down the nitric oxide.

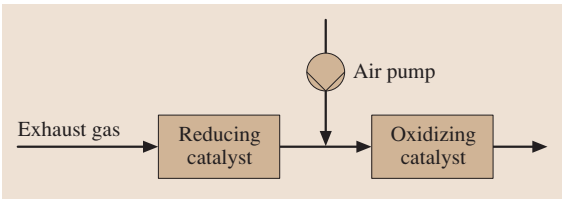

Fig. 10.96 Two-part catalytic converter

Early technology to achieve simultaneous control of the three pollutants required two operations, as shown in Fig. 10.96.

The engine was operated somewhat rich so that conditions were suitable for the exhaust entering the reducing catalyst, which eliminated most of the nitric oxide. Then an air pump supplied additional air to the exhaust stream to create the oxygen-rich conditions needed by the oxidation catalyst.

Modern catalysts, called three-way catalysts, can combine the oxidation and reduction functions into a single catalyst structure but require that the air–fuel ratio be controlled precisely in a narrow band around the stoichiometric value as shown in Fig. 10.97. Such exact

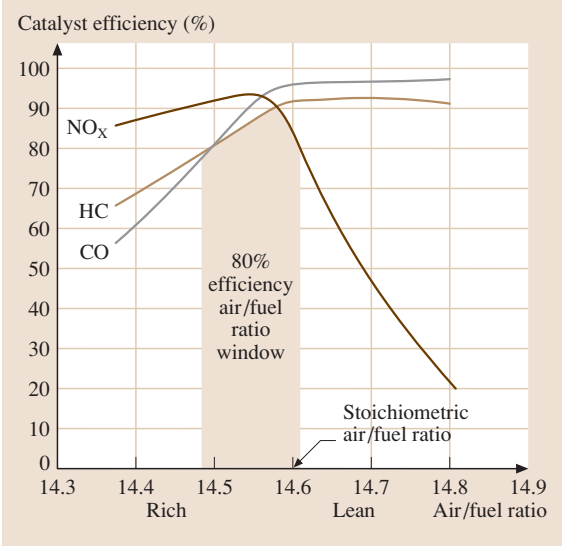

Fig. 10.97 Effect of air–fuel ratio on a three-way catalyst (after [10.28])

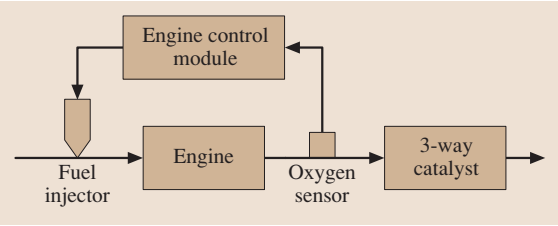

Fig. 10.98 Closed-loop engine control

control of air–fuel ratio could not be achieved without feedback from an exhaust oxygen sensor and closed-loop electronic control of fuel injection. Figure 10.98 shows the typical configuration of an oxygen sensor that measures the fuel–air ratio in the exhaust gas and then the engine's electronic control module adjusts the fuel injected to correspond to the air flow rate. This system maintains the air–fuel ratio entering the three-way catalyst in a narrow range around the stoichiometric ratio.

In reality, the nature of the oxygen sensor and the delay associated with the time required for changes in air–fuel ratio to reach the oxygen sensor results in an oscillation of the air–fuel ratio around the stoichiometric condition. This oscillation between rich and lean conditions enhances the catalyst's ability to provide the oxygen-poor conditions needed to reduce the oxides of nitrogen while using oxygen stored during the periods of lean operation to eliminate carbon monoxide and unburned hydrocarbons. Recent advances in oxygen sensor technology have incorporated heaters to decrease the time needed for the sensor to reach operating temperature and wideband sensing of air–fuel ratios to provide greater flexibility in control strategies over conventional rich-lean dual state sensors.

A complementary technique for NO_x reduction is exhaust gas recirculation (EGR). This technique directs a portion of the engine's exhaust gas back to the intake where it mixes with and dilutes the incoming charge. It reduces the flame temperature and the availability of oxygen without the fuel economy penalty that would accompany the equivalent NO_x reduction from spark timing retard. Exhaust gas recirculation is most effectively used under part-load conditions where it allows the throttle to be more open and thus can actually improve fuel economy by reducing throttling losses.

Compression Ignition (CI) Engine Emissions Characteristics

With the exception of carbon monoxide, exhaust emissions from compression ignited engines will be strongly affected by engine operating conditions. Carbon monoxide emissions are always low from diesel engines. They tend to be limited by factors such as late burning fuel that has insufficient time or temperature to combust completely. While more fuel is present at high load, the temperatures are lower at light load and there is a greater availability of fuel that has mixed beyond its lean combustion limit and thus can only react slowly.

Unburned hydrocarbon emissions from diesel engines are primarily a light load problem. At heavy loads the in-cylinder temperatures are high enough that the fuel readily burns to complete products. At light loads, fuel on the periphery of the fuel spray mixes with the large excess of air in the chamber and never reaches the temperature or air–fuel ratio needed for rapid combustion. This fuel will be emitted as unburned or partially burned hydrocarbons. Engines with the greatly retarded timing needed for NO_x control may also have difficulty keeping the fuel–air mixture in the piston bowl because the piston may be well down on its expansion stroke while fuel injection is still underway. This allows the fuel–air mixture to enter the crevice above the top compression ring and evade combustion in manner that is similar to spark-ignited engines.

As mentioned earlier, NO_x emissions are primarily dependent on in-cylinder temperatures. Since these temperatures are higher when the engine is operating at full load, the emissions of NO_x will be higher under these conditions. Diesel fuel injection timing is generally retarded to keep NO_x emissions low, in a manner that is similar to spark timing retard in spark-ignited engines. EGR can be used very effectively to reduce NO_x in diesel engines, especially if the EGR is cooled before it is mixed with the intake air. The cooling is usually accomplished using engine coolant so a portion of the exhaust energy is added to the engine's heat rejection load. EGR is usually accompanied by an increase in exhaust particulates.

Electronically controlled engines can vary the injection timing corresponding to speed, load, or other operating variables following detailed maps. This allows NO_x to be controlled with minimum impact on fuel economy and particulate emissions. NO_x is maximized when the fuel and air are mixed rapidly and combustion occurs near TDC. This is the condition that provides best conditions for minimizing soot production and maximizing its subsequent oxidation. These conflicting effects give rise to the phenomenon known as the NO_x-particulate tradeoff. Those measures taken to minimize NO_x (timing retard, EGR, lower swirl, etc.) tend to increase particulates and the converse is also true. Higher fuel injection pressures with smaller injec-

tor nozzle holes and lower intake air temperatures tend to move the NO_x–particulate tradeoff to more favorable operating points where both pollutants are reduced.

Exhaust gas recirculation can be problematic with diesel engines because the intake manifold pressure is frequently at a higher pressure than the exhaust manifold. Some systems direct the exhaust from upstream of the turbine to upstream of the compressor, which forces the exhaust gas to pass through the compressor. Other approaches use throttling to lower the pressure of the air entering the compressor so that exhaust can be drawn in from an ambient pressure source after the turbine.

Most diesel engines are equipped with turbochargers that allow demands for increased power to be met while still maintaining the air–fuel ratio at values that ensure low emissions. To meet NO_x emission standards, highly-rated engines use heat exchangers known as intercoolers or aftercoolers to reduce the temperature of the compressed air from the turbocharger compressor. Using ambient air as the exchange fluid for the intercoolers is the norm for most applications. Further improvements in engine air supply can be obtained from the use of variable geometry turbocharging. These turbochargers are equipped with variable area turbine nozzles so the exhaust velocity entering the turbine can be optimally matched to the engine's speed and load. This provides greater intake air boost pressures over a wider range of operating conditions.

Diesel engines cannot use the three-way catalyst technology that is used for spark-ignited engines because diesel engines always operate with excess air and it is difficult to reduce NO_x under lean conditions. Recent developments in catalyst technology have produced lean NO_x catalysts but their low efficiency has limited their acceptance. Catalytic systems that absorb the NO_x and then periodically release it as harmless gases when the engine is momentarily operated rich have been more successful and may be used in the near future.

10.4.9 Selected Examples of Combustion Engines

Compression Ignition Engine with Twin Turbo Technology (BMW 535d)

The world's first use of twin turbo technology for car diesel engines sets this engine apart from comparable engines. Along with increasing the specific power to 67 kW/l, most notably the speed range has been expanded to approximately 5000 min^{-1}. With a bore of 84 mm and a stroke of 90 mm, the engine design is based on the 3.0 l inline-six 530d. The engine's rated output is 200 kW and thus increased by 25% over its predecessor. Just like the power, the maximum torque was raised to 560 N m. The engine weight was increased by 14 kg, while specific consumption at maximum output was reduced by 7 g/kW h to 233 g/kW h compared to engines years older.

Crankcase and Transmission. The crankcase cast from pearlitic gray cast iron (GG25+) is based on the *deep skirt concept* already proven in preceding models. The side panels of the crankcase (crankcase skirts) are very deep. A special head design of the skirt area achieves more stiffness. The viscous damper first used in the 530d is used again in the 535d too. The damping effect is generated by varying shear forces in a highly viscose fluid in a narrow gap between the housing and swivel flywheel rim.

Mixture Formation and Combustion. The proven concept of BMW direct injection engines has also been adopted in this generation of engine. A central perpendicular injection nozzle and two intake and two exhaust ducts per cylinder are located on the cylinder head. One of the two intake ports is a swirl duct and the other a tangential duct. The two exhaust ducts are still combined in the cylinder head.

To reduce raw emissions, combustion has been concentrated in the outer zones of the piston combustion bowl. Moreover, the engine's compression ratio has been reduced from 17 : 1 (530d) to 16.5 : 1 by further optimizing the piston combustion bowl geometry.

Injection System. The injection system of the 535d is based on the second generation common rail system already used in the 530d with a maximum injection pressure of 1600 bar. The flow was elevated in the 530d by 20%. This injection system supports up to five injections with minimal injection intervals between injections per combustion cycle. The induction-side high-pressure pump's volume control generates maximum pressure as required. A micro-blind hole injection nozzle with six spray holes is used. Fuel consumption in the New European Driving Cycle (NEDC) test cycle is 8 l/100 km.

Exhaust System. The particle filter is an integral part of the exhaust system of the Euro-4 package. A second-generation filter with catalytically coated SiC substrate is used. With a 4.5 l volumetric capacity, the particle filter has a considerably longer service life than the first generation filter. Two exhaust temperature sensors and

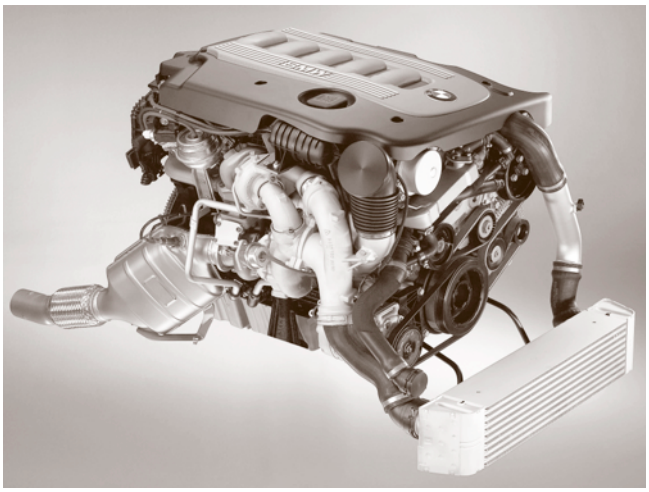

Fig. 10.99 BMW 535d

a pressure sensor are integrated in the exhaust gas line to monitor filter status. A temperature sensor integrated at the inlet of the upstream primary catalytic converter measures the exhaust gas temperature crucial for regenerating the particle filter.

Operating Principle of Twin Turbo Technology. Along with different supercharging concepts (multi-stage supercharging, a combination of mechanical and exhaust gas turbo charging) BMW favored the twin exhaust gas turbocharging after several tests.

This system consists of two differently sized turbochargers arranged in the induction and exhaust system branch as illustrated in Fig. 10.100. At lower speed ranges, the compressor bypass and the exhaust butterfly valve are closed as a result of which the entire exhaust mass flow is conducted through the small turbine. In this operating range, only the small turbocharger regulates the supercharging pressure. When the desired supercharging pressure is reached, the exhaust butterfly valve opens. The compressor bypass valve remains closed and part of the exhaust mass flow is conducted to the large turbine. The large compressor functions as a precompressor for the subsequent small compressor, which achieves supercharging pressures at average speeds (maximum supercharging pressure of 2850 mbar at 2500 min^{-1}).

From a certain speed onward, the small compressor can no longer generate additional supercharging pressure and throttles the induction mass flow. Depending on the load and upwards approximately 3000 min^{-1}, the compressor bypass and the exhaust butterfly valve open synchronously so that only the large turbocharger regulates the supercharging pressure supported by the waste gates.

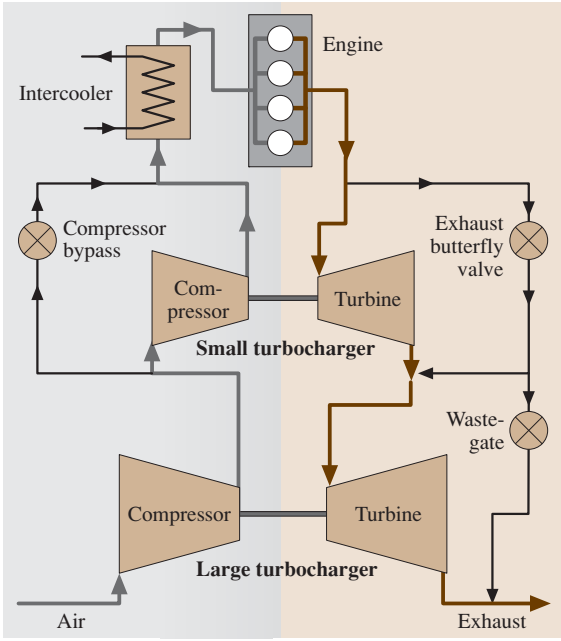

Fig. 10.100 Operating principle of twin turbo technology

Direct Injection Gasoline Engine with Downsizing-Concept and Dual Supercharging (VW 1.4l TSI)

This engine constitutes a logical contribution to downsizing modern gasoline engines. The direct injection FSI and dual supercharging used for the first time in this form achieve a power of 125 kW from only 1.4 l of displacement. Thus, the compressor, disengageable from the exhaust turbocharger, already reaches the maximum torque of 125 N m at an absolute supercharging pressure of 2.5 bar at low speeds. Along with increasing power, this downsizing concept most notably satisfies the requirement of low consumption of 7.2 l/100 km.

Basic Engine. The TSI unit is based on the four cylinder 1.4 l (66 kW) FSI engine used in the Golf V with a bore of 76.5 mm and a stroke of 75.6 mm and a compression ratio of 10 : 1. A basic reason for selecting this engine is the 1.4 l engine's modular design. Many modules could be carried over as a result of which the engineering was limited to a new cylinder crankcase and a water pump with an integrated magnetic clutch for engaging the mechanical supercharger.

The crankcase has an open deck (an open water jacket in the direction of the cylinder head) and deep skirt design (side panels far below the crankcase). Along with the advantage of simpler manufacturing, the open deck variant reduces cylinder barrel deformation when the cylinder head is bolted together. In order to withstand the high mean pressures of 21.7 bar in every operating situation, the material used is GJL (lamellar graphite cast iron), thus achieving a very low weight of 29 kg.

Transmission. Above all, great importance was attached to the engine acoustics. As opposed to the 1.4 l 66 kW, a steel crankshaft with 23% more stiffness was used for the TSI. This improves engine sound quality.

Calculation and development tools make it possible to develop a piston for use in a supercharged engine with a specific power of 90 kW/l. This light metal piston's combustion chamber bowl has a pronounce edge to control the flow. In order to provide the piston sufficient operational stability, oil ducts bolted into the main oil gallery inject with approximately 2 bar against the hot outlet side of the piston.

Finally, the piston pin diameter was enlarged because of the considerably higher ignition pressure.

Injection. The TSI engine is being used for the first time with a multiple hole, high-pressure injection valve with six fuel outlet bores. The nearly unlimited arrangement of the injection valve's spray makes it possible to form the fuel injection spray. Among other things, this not only optimally homogenizes the mixture but also prevents wetting of the intake valve when there is early injection. This reduces the hydrocarbons (HC) emissions.

The TSI injection pressure raised to 150 bar is generated by an adapted high-pressure pump. Compared to the FSI, its significant features include a longer cam stroke, the use of a roller tappet and the forged aluminum housing, all of which made it pos-

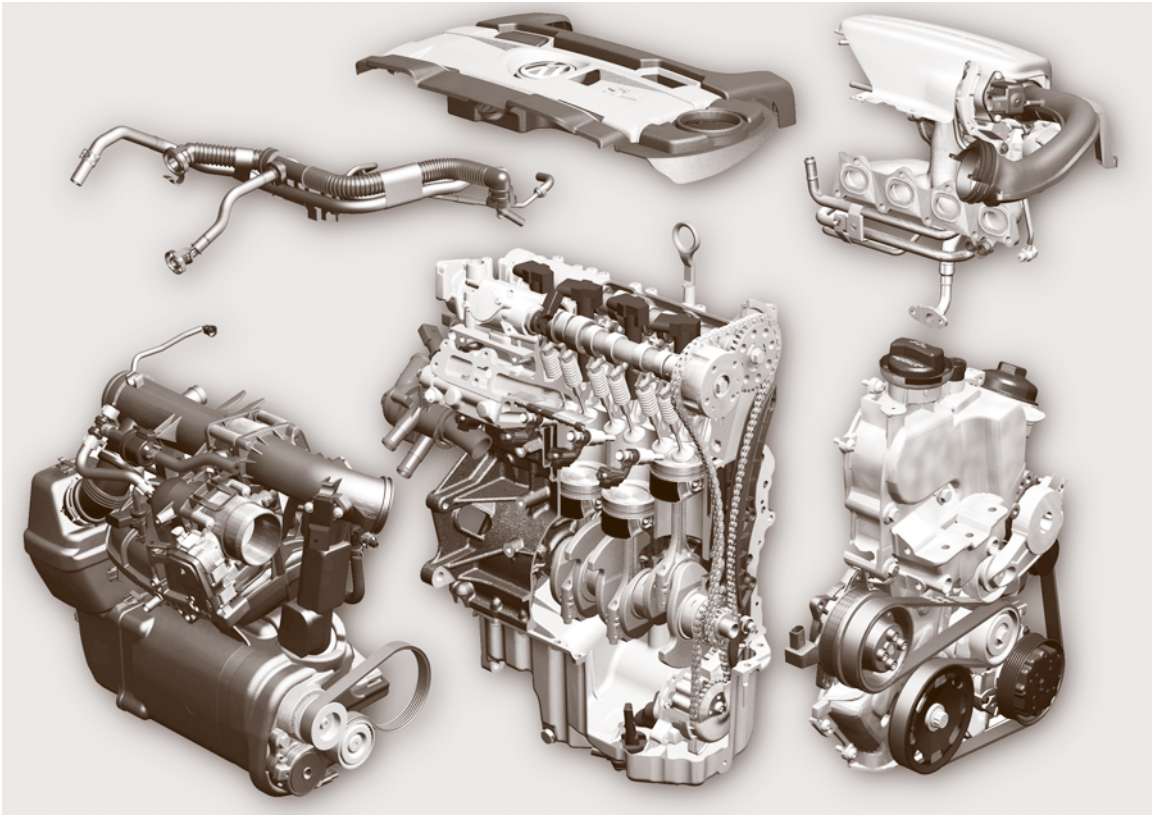

Fig. 10.101 VW 1.4l TSI

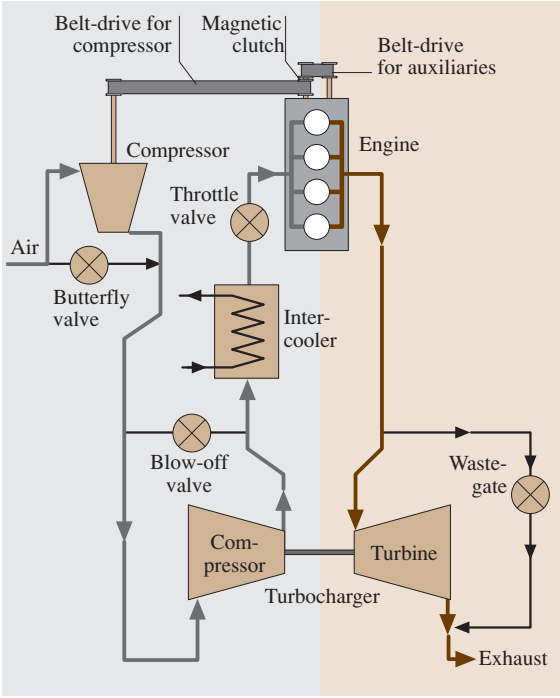

Fig. 10.102 Principle of twin supercharging

sible to approximately double the pump's mechanical stability.

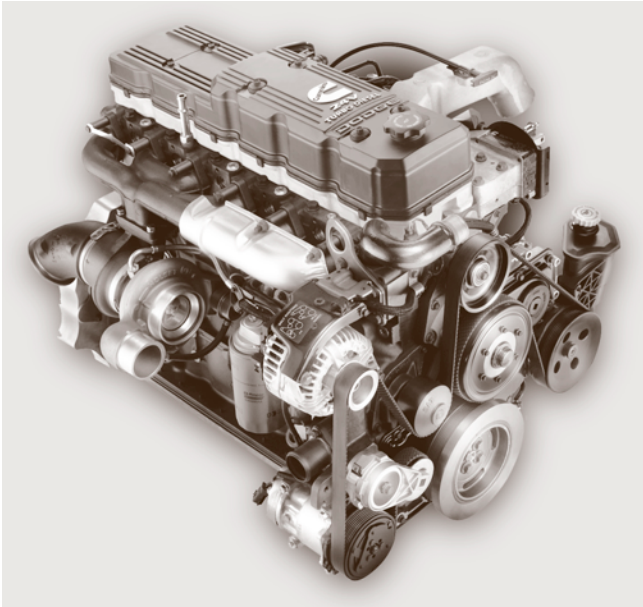

Fig. 10.103 Cummins 600 turbo diesel

Supercharging. Twin supercharging (see Fig. 10.102) basically consists of a Roots supercharger, an exhaust turbocharger and a butterfly valve.

Dependent on the engine map, the magnetic clutch on the water pump connects the compressor to the crankshaft. Inside the compressor is a countershaft transmission, which supplies a high torque above all when starting and in the low speed range. The butterfly valve enables a smooth transition between pure compressor and turbocharger operation.

By using the two charger units, maximum torque can already be produced at 1250–6000 min^{-1}. Since the exhaust gas turbocharger is designed for high efficiency, not enough boost pressure is available in the low speed range. Here, the compressor engages and bypasses the so-called *turbo lag*. At a speed of 3500 min^{-1}, the magnetic clutch disengages the compressor and the butterfly valve opens completely. From this point onward, the exhaust gas turbocharger alone produces the necessary boost pressure.

Diesel Engine for Heavy-Duty Pickups (Cummins 600 Turbo Diesel)

With 325 HP at 2900 min^{-1}, the Cummins 600 turbo is one of the most powerful engines available for the pickup truck market. Available as the engine in the Dodge Ram heavy-duty pickup, this diesel engine already generates a peak torque of 810 N m (600 ft-lbs) at 1600 min^{-1}. However, weighing 544 kg, the 600 Turbo's average consumption has dropped about 2% below that of the earlier model.

This engine consist of 30% fewer parts than comparable V8 engines in its performance class. Consequently, not only assembly time is cut but fewer repair costs are incurred because of its increased service life and durability.

Basic Engine and Transmission. Based on the B series, an agricultural machine engine sold over three million times, the Interact System B (ISB) was developed with an EGR radiator and a supercharging system. Predominantly used in medium-weight commercial vehicles, this engine series is the basic engine for the 600 Turbo diesel. A bore of 102 mm and a stroke of 120 mm produce a displacement of 5.9 l. This inline-six's compression ratio is 17.3 : 1. Push rods control the valves of the bottom-mounted camshaft.

The engine block is manufactured of cast steel and has a correspondingly high stiffness. Along with prolonging service life, this most notably reduces noise emissions.

The transmission is also designed to have a long service life. Not only the crankshaft optimized for weight and stiffness but also the forged fracture-split connection rods contribute to this.

These measures lead to considerably long running times so that an overhaul is only expected after an average of 350 000 miles.

Induction System and Cylinder Head. To enable an optimal turbocharge cycle, the Cummins 600 turbo diesel is equipped with four valves per cylinder. The redesigned intercooler as well as the turbocharger's enlarged compressor wheel and housing achieve an optimal air flow during the induction phase.

Reinforced inconel exhaust valves and cobalt stellite exhaust valve seats are used to increase the engine's service life.

Injection and Combustion. The 600 turbo diesel engine employs a Bosch high-pressure common-rail injection system. This system enables pilot injection before main injection. Thus the ignition delay time of the subsequent main injection is reduced considerably and combustion runs more gently, ultimately producing less combustion noise.

The injector is arranged centrally between the four valves and supports the target values for high efficiency and low emissions.

Exhaust System and Turbocharger. An *in-cylinder solution* and an oxidation catalyst reduce particulate and nitrogen oxide emissions considerably. A newly engineered piston combustion bowl likewise reduces pollutants.

Its compliance with the 2004 emission standards makes it possible to dispense with an external EGR line, which would add over 50 components to the engine's configuration and consequently make it more prone to failure. An expensive soot filter can be dispensed with for the same reasons.

A turbocharger with electronically controlled waste gate is integrated to further reduce emissions and reach the maximum power of 325 HP.

To spare the brake system when driving downhill, the Cummins 600 turbo diesel engine is equipped with an additional exhaust valve. It is closed as required and reduces the exhaust gas mass flow coming from the cylinder. This increases the in-cylinder pressure as a result of which the piston works against a stronger back pressure during the compression phase and crankshaft rotation is delayed.

Modern V8 Gasoline Engine with Variable Valve Timing

This engine is descended from the modular V8 and V10 engine family (MOD for short), developed by Ford in 1991. The engines are variably designed in terms of their cylinder heads (two-, three- or four-valve cylinder heads) and their use (trucks and cars). In conjunction with the six speed automatic transmission, electronically controlled throttle, variable valve timing and other state of the art engine technologies, it was possible to develop an engine that satisfies the requirement for greater power while simultaneously reducing gasoline consumption.

This engine is currently used in the Ford Explorer and a slightly modified version is used in the Ford Mustang.

Basic engine. The basic engine is a 4.6 l unit. The eight cylinders arranged in a V shape have a bore of 90.2 mm and a stroke of 90 mm. This engine also has a cylinder angle of 90° often used for V8 engines (compensation for higher-order inertial forces and moments).

Depending on its vehicle use, the cylinder block is made of aluminum (Ford Mustang) or cast iron (Ford Explorer).

Cylinder Head, Induction Pipe and Exhaust Manifold. In contrast to the central crankcase, the cylinder head in the Ford Explorer as well as the Mustang is made of

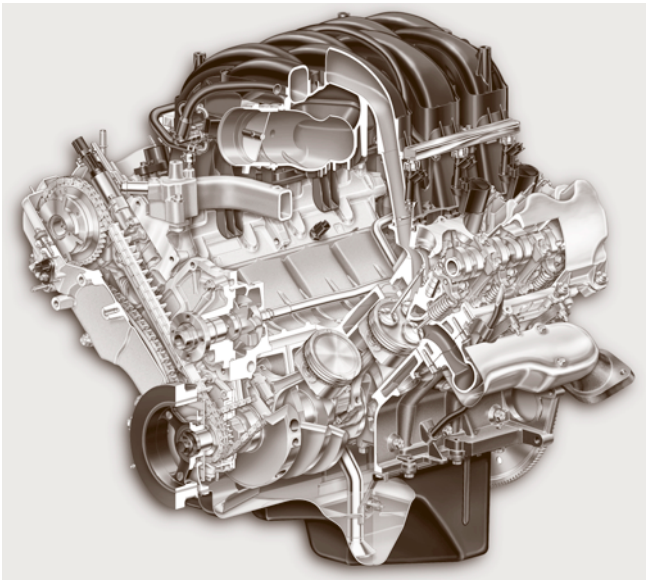

Fig. 10.104 Ford 4.6l single overhead camshaft (SOHC) 90° V8-engine (illustration courtesy of the Ford Motor Company)

aluminum. The three valve cylinder head is lighter and smaller than the four valve variant. The new cylinder head enables a higher compression ratio of 9.8 : 1 when 87 octane fuel is used.

The large dual intake ports create a direct path to the intake valves for enhanced flow behavior at high rpm. At low rpm and engine loads, a processor-controlled charge motion control valve (CMCV) in the induction line closes shortly behind the injection nozzle. This considerably increases the flow velocity in the induction tract as well as the in-cylinder flow resulting in a more ignitable and faster combustible mixture. Consequently, in conjunction with the variable valve timing, an optimal charge motion characteristic can be achieved in the induction tract. As a result, fuel consumption drops by 10% compared to the predecessor model.

In addition, the flow conditions in the longitudinally optimized intake manifold could be noticeably improved and a discharge of combusted gases from the cylinder accelerated.

Due to their mass inertia, extremely light intake and outlet valves make high engine speeds possible and simultaneously reduce fuel consumption through their enhanced frictional properties.

To minimize valve gear noise, the cam covers were made of magnesium.

Ignition System. The three-valve technology allowed arranging the spark plugs centrally in the cylinder head. This results in three advantages:

- The central position to the cylinder produces a symmetrical flame with complete fuel combustion. Since the proportion of uncombusted fuel is negligible, the engine can generate more power while simultaneously reducing emissions (uncombusted hydrocarbons).
- The narrow and more-oblong design of the spark plugs make it possible to enlarge the valve diameters. This results in better engine performance and lower fuel consumption.
- A new powertrain control module (PCM) controls the ignitions more precisely, which ultimately manifests itself in higher efficiency.

Variable Camshaft Timing (VCT). After two- and four-valve engines in the modular engine family have been put in the widest variety of vehicles, a 24 valve cylinder head in the V8 variable valve timing is being implemented for the first time in 2005.

A single overhead camshaft per cylinder bank and low profile roller-finger followers with low friction activate the intake and exhaust valves. The powertrain control module electromagnetically changes the oil flow for the hydraulic cam timing mechanism, which enables the camshaft to rotate opposite the drive sprockets. The mechanism can switch between fully advanced and fully retarded timing in only a few milliseconds.

VCT achieves an angular camshaft control of 50° CA. The *dual-equal* camshaft timing developed by Ford changes the intake and exhaust valve timing simultaneously. This system provides decisive advantages over fixed timing in the engine's complete speed range. Short seat timing at low speeds causes the cylinder pressure to drop less strongly as a result of which a high torque is generated. The slight valve overlap also reduces emissions. The seat timing increases at high speeds. The greater charge mass in the cylinder also increases engine performance.

This synchronous control of the timing enables constructing the cylinder head less complexly and with less weight than fully variable systems in which the intake valve is controlled separately from the exhaust valve.

11. Pressure Vessels and Heat Exchangers

Ajay Mathur

This chapter is intended to present an overview of Pressure Vessels/Heat Exchangers and covers basic design concepts, Loadings & testing requirements relevant to these equipment. Design criteria, fabrication, testing & certification requirement of various Standards/Codes adopted in different countries are discussed on a comparitive basis to bring out similarities of features.

In order to complete the overview, a brief discussion is provided on commonly used Materials of construction and their welding practises along with updates on the on-going developments in this area.

The author is a Mechanical engineering graduatefrom M.S University-Baroda (India) & has over 20 years experience in design and fabrication of Pressure Vessels, exchangers, Skid mounted plants and Fired Heater modules for Refinery, petrochemical Nuclear & chemical plants in India & abroad.

11.1 Pressure Vessel – General Design Concepts

Pressure vessels are closed structures, commonly in the form of spheres, cylinders, cones, ellipsoids, toroids and/or their combinations and which contain liquid or gases under pressure. There are various other requirements such as end closures, openings for inlet/outlet pipes, internal/external attachments for support and other accessories.

11.1.1 Thin-Shell Pressure Vessel

When the thickness of the vessel is less than about one tenth of its mean radius, the vessel is called a thin-walled vessel and the associated stresses resulting from the contained pressure stress are called membrane stresses. The membrane stresses are assumed to be uni-

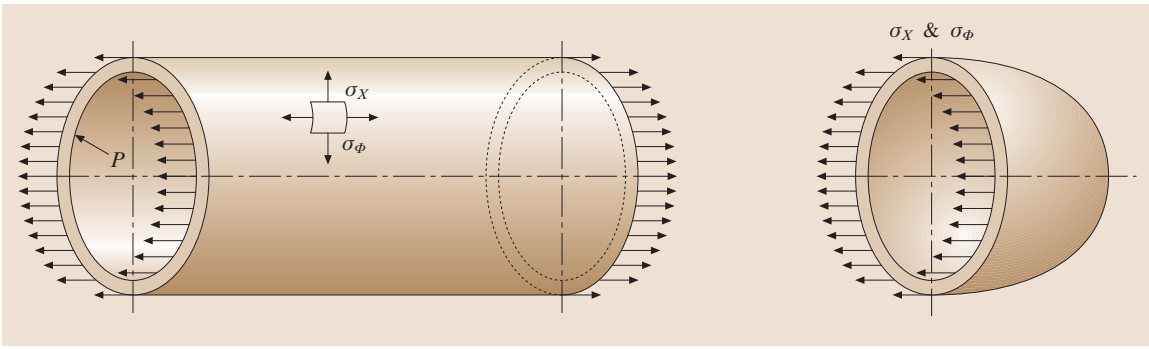

Fig. 11.1 Cylindrical shell with hemispherical heads

form across the vessel wall and act tangential to the surface.

Vessels Under Internal Pressure

The membrane stresses due to internal pressure are derived from application of equilibrium conditions to an appropriate element cut from the vessel shell, which in turn has been considered as a *symmetrically loaded shell of revolution*. Figure 11.1 shows the resulting membrane stress for a thin-walled cylindrical shell, both in the axial axis (called the *meridional* stress) and circumferential direction (also called the *hoop stress*), and the corresponding formulae are tabulated in Table 11.1. It can be seen that the thickness of the cylindrical vessel will be decided based on hoop stress, which is governing since its value is double than that of meridional stress.

In the case of a spherical shell, the circumferential stress is identical in all directions and its magnitude is half the hoop stress of a cylinder of the same radius.

Because the thin shell is assumed to offer no resistance to bending, radial stresses, if present, are small compared to membrane stresses and are generally ignored. This implies that the thin-shell analysis considers only biaxial stresses and therefore follows the *maximum stress theory*, wherein stress failure depends on the numerical magnitude of the principal stresses ignoring stresses in other directions.

Table 11.1 General vessel formula

Part	Stress formula	Thickness d	
		Inside radius	Outside radius
Shell			
Longitudinal direction	$\sigma_x = \frac{PR_m}{2d}$	$\frac{PR_i}{2SE+0.4P}$	$\frac{PR_0}{2SE+1.4P}$
Circumferential stress	$\sigma_\Phi = \frac{PR_m}{d}$	$\frac{PR_i}{SE-0.6P}$	$\frac{PR_0}{SE+0.4P}$
Heads			
Hemisphere longitudinal stress =circumflex stress	$\sigma_x = \sigma_\Phi = \frac{PR_m}{2d}$	$\frac{PR_i}{2SE-0.2P}$	$\frac{PR_0}{2SE+0.8P}$
Ellipsoidal		$\frac{PD_iK}{2SE-0.2P}$	$\frac{PD_0K}{2SE+2P(K-0.1)}$
2:1 semiellipsoidal		$\frac{PD_i}{2SE-0.2P}$	$\frac{PD_0}{2SE+1.8P}$
100%–6% torispherical		$\frac{0.885PL_i}{SE-0.1P}$	$\frac{0.885L_0}{SE+0.8P}$
Torispherical $L/r < 16.66$		$\frac{PL_iM}{2SE-0.2P}$	$\frac{PL_0M}{2SE+P(M-0.2)}$
Cone			
Longitudinal	$\sigma_x = \frac{PR_m}{2d\cos\alpha}$	$\frac{PD_i}{4\cos\alpha(SE+0.4p)}$	$\frac{PD_0}{4\cos\alpha(SE+1.4P)}$
Circumferential	$\sigma_\Phi = \frac{PR_m}{2d\cos\alpha}$	$\frac{PD_i}{2\cos\alpha(SE-0.6P)}$	$\frac{PD_0}{2\cos\alpha(SE+0.4P)}$

Vessels Under External Pressure

Thin-walled vessels under external pressure fail at stresses much lower than the yield strength due to the instability of the shell. In addition to the physical properties of the material of construction at the operating temperature, the principal factors governing the instability and the critical (collapsing) pressure P_c are geometrical, namely the unsupported shell length L, the shell thickness t and the outside diameter D_o. The solution to the theoretical elastic formula for the critical pressure at which the cylinders would collapse under external pressure depends on the number of lobes at collapse, which is a cumbersome exercise. To eliminate the dependency on the number of lobes, American Society of Mechanical Engineers (ASME) codes have adopted a simplified procedure using geometric charts developed for the critical stress ratio v/s L/D_o for different values of the D_o/t ratios. This critical stress ratio in turn is related to the collapsing ratio for a particular material in another chart, thus an estimate for the maximum allowable pressure may be determined for a given geometry. Several trials can be made to achieve an optimum solution for shell thickness, and maximum unsupported length (or stiffener spacing) for a given external pressure.

11.1.2 Thick-Walled Pressure Vessel

The membrane stresses used for evaluation of thin shells cannot be used for thick-walled vessels (with a thickness greater than their mean radius) subjected to internal pressure, since the radial stresses are significant and the stress distribution in the vessel walls varies across the thickness. The stress distribution across the thickness

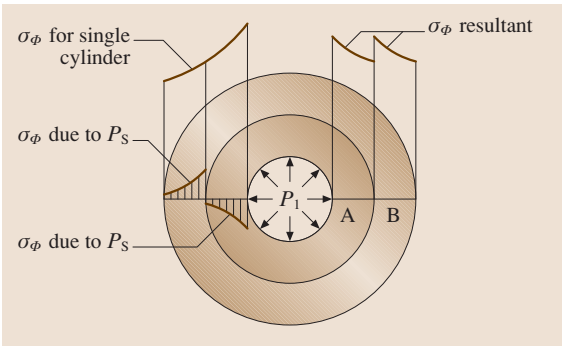

Fig. 11.3 Resultant stresses in a shrink-fitted multiwall vessel

for a vessel for internal and external pressure conditions are shown in Fig. 11.2a,b.

From Fig. 11.2, it is evident that the maximum circumferential stress occurs at the inside surface of the cylinder; however it is tensile in nature for internal pressure conditions and compressive in the case of external pressure. As per Lame's solution,

$$\sigma_\Phi = (+)\frac{PR_i^2}{R_o^2 - R_i^2}\left(1 + \frac{R_o^2}{R_i^2}\right), \tag{11.1}$$

$$\sigma_r = (-)\frac{PR_i^2}{R_o^2 - R_i^2}\left(1 - \frac{R_o^2}{R_i^2}\right), \tag{11.2}$$

the magnitude of stress for a thick-walled vessel is a function of the ratio of the outer to the inner radii.

Prestressing is a manufacturing technique by which compressive stresses are produced in the inside shell of a multilayer/multiwall vessel and/or tensile stresses are created on the outside shell of this vessel operating

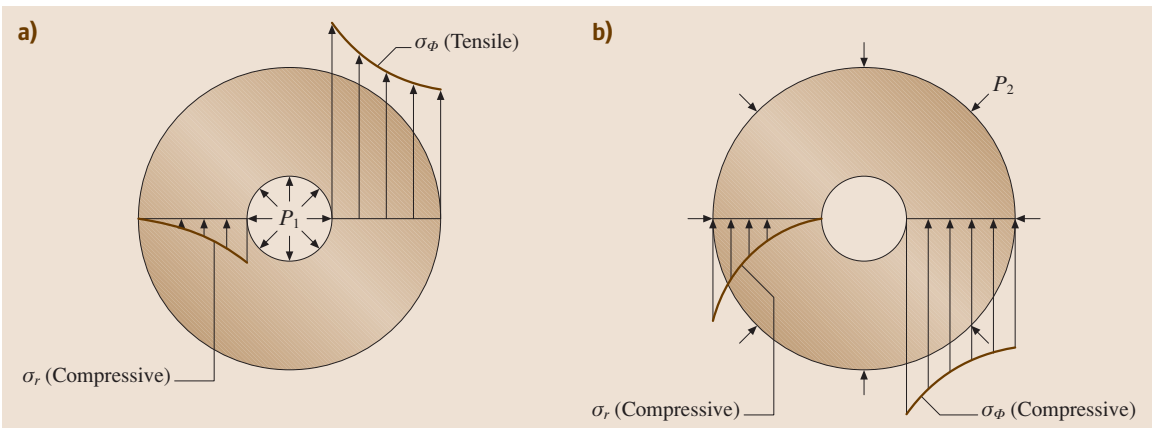

Fig. 11.2a,b Stress distribution for a thick shell: **(a)** internal pressure, **(b)** external pressure

under internal pressure. The prestresses so created help to neutralize the stress peaks in the existing stress distribution, making the material stress almost uniformly throughout the thickness, as shown in Fig. 11.3. This also considerably reduces the required wall thickness.

Prestressing is carried out by the following methods:

- shrink-fitting outer layers over the core, inner layer(s)
- wire/coil wrapping
- autofrettage

A detailed introduction to the basic theory of membrane stress and its application to commonly encountered elements of pressures vessels is presented in [11.1]. However, a brief discussion on other vessels components such as heads, nozzles and flanges is covered below.

11.1.3 Heads

There are three general categories of heads (also called dished ends):

Hemispherical: These dished ends are analyzed as the thin-walled spherical shells discussed earlier.

Ellipsoidal: Ellipsoidal heads are developed by the rotation of a semi-ellipse and have a 2:1 ratio of major R to minor axis h. These heads are the most frequently used end closures in vessel design, particularly for internal pressures greater than 10 bars and also for bottom heads of tall, slender columns.

Torispherical: Torispherical heads have a meridian formed of two circular arcs, a knuckle section with radius r, and a spherical crown segment with a crown radius of L. The maximum crown radius equals the inside diameter, which gives the same maximum membrane stress in the crown region as in the cylindrical region. The minimum knuckle radius is 6% of the crown radius, although a 10% knuckle is the most commonly used.

11.1.4 Conical Heads

A conical head is generated by the rotation of a straight line intersecting the axis of rotation at an angle, α, which is the half-apex angle of the formed cone.

The formulae for computing the thickness of different types of heads under both internal and external pressure are provided in Table 11.1.

There is a failure phenomenon in the knuckle region due to tangential stress under compression, which can occur through elastic buckling (circumferential wrinkles) at a stress much lower than the yield strength or through plastic buckling. A reliable analysis for predicting buckling failure has been introduced in the harmonized pressure vessel standard EN 13445, which will be discussed later.

11.1.5 Nozzles

Nozzles or openings are provided in pressure vessels to satisfy certain process requirements such as inlet or outlet connections, manholes, hand holes, vents and drains etc. These may be located on the shell or head according to the functional requirement and could be circular, elliptical or rectangular in shape. The basic construction of a nozzle connection consists of essentially short pieces of pipes welded to the vessel wall at an opening made in the wall. The other side would normally be a flanged end suitable for connection to the corresponding piping or to bolt on the blind cover (as in the case of a manhole). The complete nozzle may also be formed by rolling or forging to the required shape.

In addition to weakening of the vessel wall, the nozzle opening also causes discontinuity in the wall and creates stress concentration at the edges of the opening. This is compensated by providing reinforcement pads around the nozzle necks, which are suitably attached to the vessel wall. Rules are provided in every pressure vessel code to calculate the reinforcement requirement for all nozzles. At times, additional thickness is provided at the base of the nozzle wall itself; such nozzles are called self-reinforced nozzles.

11.1.6 Flanges

Tall columns are usually constructed in detachable sections for ease of fabrication, transportation, erection, assembly, and internal maintenance. Like the nozzles and the piping system, these sections (or heads) must be provided with end flanges with an arrangement for easy bolting and dismantling as required. A flanged joint therefore consists of a pair of flange; each is attached to one of the components to be joined and is held securely in place by a series of bolt or studs. A gasket is interposed between the two adjoining flange face. The joint must have structural integrity with (zero) min-

imum leakage during service. Several configurations of flanges in various construction materials and a large variety of gaskets are available; the selection is mainly dependent upon the service requirements.

The main consideration for the design of a flanged joint are:

1. to ensure a positive contact pressure at the gasket flange interface to prevent leakage in service. The gasket must be able to withstand the required sealing force,
2. the gasket sealing force is to be provided by bolt tightening without overstressing,
3. to ensure the structural integrity of flange sections and minimize flange deflections.

11.1.7 Loadings

Loadings or forces are the *causes* of stress in pressure vessels. It is important to identify areas *where* and *when* these forces are applied to pressure vessels. The stresses produced by these loads, which could be *general* or *local* are additive and define the overall state of stress in the vessel or its component. The combined stresses are then compared to the allowable stress defined by the pressure vessel code.

An outline of the various categories and types of loadings is summarized in Tables 11.2, 3, respectively.

11.1.8 External Local Loads

Stresses caused by external local loads at the points of attachment to the vessel must be assessed to keep these stresses within the prescribed limits. These loads are usually significant at nozzles, the vessel support region, at brackets, lifting lugs, and saddle supports for horizontal vessels. Since the contact area of the attachment is relatively small compared to the vessel area, a simplified form of the interface force distribution between the vessel and the support is assumed. The analysis is based on elastic stress analysis and stress categorization is used to compare the resultant stresses.

This approach is used in annexure G of the PD 5500 code and in the Welding Research Council (WRC) bulletins WRC 107 and 297 used while in the design of the ASME code. In 1991 the WRC published another bulletin, WRC 368, for the evaluation of shell and nozzle stresses due to internal pressure.

The analytical solution for evaluating localized stresses in the shell wall above the saddle supports for a horizontal vessel is based on the method developed by Zick and published in 1951.

The method used in the harmonized standard EN 13445-3 (clause 16) for evaluating nozzle loads is based on limit load analysis. This standard provides separate rules for calculating line loads for lifting eyes, supporting brackets, and saddle supports.

11.1.9 Fatigue Analysis

Vessels undergoing cyclic service and repeated loading may fail in fatigue due to progressive fracture of localized regions. The behavior of metals under fatigue conditions varies significantly from the normal stress–strain relationship. Damage accumulates dur-

Table 11.2 Categories of loadings

General loads	Local loads
General loads are applied more or less continuously across a vessel section	Local loads are due to reactions from supports, internals, attached piping and equipment such as mixers, platforms etc.
Examples	**Examples**
• Pressure loads – internal or external pressure (design, operating, hydrotest and hydrostatic head of liquid) • Moment loads – due to wind, seismic, erection and transportation • Compressive/tensile loads – due to dead weight, installed equipment, ladder, platform, insulation, piping and vessel contents • Thermal loads – skirt head attachment	• Radial load – inwards or outwards • Shear load – longitudinal or circumferential • Torsional load • Tangential load • Moment load – longitudinal or circumferential • Thermal loads

ing each cycle of loading and develops at localized regions of high stress until subsequent repetitions finally result in visible cracks, which grow, join, and spread.

Localized stresses at abrupt changes in sections such as at the head junction or a nozzle opening, misalignment, defects during fabrication, and thermal gradients are probable causes for fatigue failure. Special attention should be paid to manufacturing tolerances, nondestructive testing, and in-service inspection of vessels designed for fatigue.

All pressure vessel codes have established specific criteria for determining when a vessel must be designed for fatigue. Each code has adopted a methodology for carrying out fatigue analysis based on the use of fatigue curves obtained from test specimens. The fatigue design rules of some of the pressure vessel codes are discussed later.

11.2 Design of Tall Towers

11.2.1 Combination of Design Loads

The shell thickness of tall columns as computed based on internal or external pressure is not usually sufficient to withstand the combined stresses produced by the operating pressure plus weight, and wind or seismic loads. Combined stresses in the longitudinal direction σ_L due to pressure P, dead weight W and applied moment M, with W and M taken at the elevation under consideration, are calculated as follows:

1. On the windward side

$$\sigma_L = \left(\frac{PD}{4d}\right) + \left(\frac{4M}{\pi D^2 d}\right) - \left(\frac{W}{\pi Dd}\right), \quad (11.3)$$

$$d = \frac{\left[(PD/4) + (4M/\pi D^2) - (W/\pi D)\right]}{\text{allowable stress}}. \quad (11.4)$$

2. On the leeward side

$$\sigma_L = \left(\frac{PD}{4d}\right) - \left(\frac{4M}{\pi D^2 d}\right) - \left(\frac{W}{\pi Dd}\right). \quad (11.5)$$

For the design of a particular vessel, the value of the moment derived from either the wind or seismic loads is used in these expressions. This is due to the assumption that the wind and seismic loads are not expected to occur simultaneously and therefore the higher moment of the two is considered to be governing. These loads are based on site-specific data, which is obtained from one of the following national standards as applicable to the installation site.

Code for Wind Loads

- American Society of Civil Engineers (ASCE) 7, formerly American National Standards Institute (ANSI) A58.1
- Uniform building code (UBC)
- National building code (NBC)
- British standard (BS) 6399

Code for Seismic Loads

- ASCE-7
- UBC/NBC
- International building code (IBC) 2000
- Response spectrum data

Tall cylindrical vessels are normally designed to be self-supporting; they are supported on cylindrical or conical skirts with base rings resting on concrete foundations, firmly fixed to the foundations by anchor bolts. Detailed analytical methods for computing the thickness of the skirt components and sizing of the anchor bolts can be found in [11.2, 3], which also provide procedures for other types of supports such as lugs, legs, and rings due to wind and seismic loads.

11.2.2 Wind-Induced Deflection

A sustained wind pressure will cause tall columns to deflect with the wind. Most engineering specifications limit the deflection to 150 mm per 30 m of column height. The vessel is assumed to be a cantilever beam firmly fixed to the concrete pedestal and individual deflections induced by wind load and moments are calculated for each varying section of the vessel using the deflection formula for cantilever beams. The total deflection is then calculated using the method of superposition.

11.2.3 Wind-Induced Vibrations

Wind-induced vibrations can be caused by vortex shedding, the magnitude of which is dependent on wind velocity and vessel diameter. Vortex shedding results in severe oscillations, excessive deflections, structural damage and even failure. When the natural frequency

Table 11.3 Types of loadings

Steady loads	Non-Steady loads
These loads are long term and continuous	These loads are short term and variable
Examples	**Examples**
• Internal/external pressure • Dead weight • Vessel contents • Loading due to attached piping and equipment • Loading to and from vessel supports • Thermal loads • Wind loads	• Shop and field hydrotest • Earthquake • Erection • Transportation • Upset, emergency • Thermal loads • Startup, shutdown

of a column or stack coincides with the frequency of vortex shedding, the amplitude of vibrations is greatly magnified. After a vessel has been designed statically, it is necessary to determine if the vessel needs to be investigated dynamically for vibrations. Detailed methods for determination the need for dynamic analysis and a method for carrying out this dynamic analysis are provided in [11.3].

11.3 Testing Requirement

11.3.1 Nondestructive Testing (NDT)

NDT of the raw material, components, and finished vessel is important from the safety point of view. The most widely used methods of examination for plates, forgings, castings and welds are briefly described below.

Radiographic examination is done either by X-rays or gamma rays. The former has greater penetrating power, but the later is more portable. Single-wall or double-wall techniques are used for tubular components. Penetrameters, or image quality indicators, check the sensitivity of a radiographic technique to ensure that any defect will be visible.

Ultrasonic techniques use vibrations with a frequency between 0.5 and 20 MHz transmitted to the metal by a transducer. The instrument sends out a series of pulses, which are seen on a cathode ray screen after being reflected from the other end of the member. Reflections either from a crack or inclusion in the metal (or weld) can be detected on the screen; based on the magnitude and position of the signal, the location of the flaw can be ascertained.

Liquid penetrant examination involves wetting the surface with a colored fluid that penetrates open cracks. After wiping out excess fluid, the surface is coated with a developer fluid, which reveals the liquid that has penetrated the cracks. Another system uses a penetrant that becomes florescent under ultraviolet light.

Magnetic particle examination, which can only be used on magnetic material, is carried out by passing magnetic flux with the help of a probe through the part to be tested. Fine magnetic particles, which are dusted over the surface, tend to concentrate at the edge of the crack. To pick up all the cracks, the area is probed in two directions.

11.3.2 Destructive Testing of Welds

In contrast to the NDT methods, which are essentially predictive techniques, the mechanical integrity of welds is checked by testing sample test plates called *production test coupons*. The coupons are welded along with the actual vessel joint (usually a longitudinal seam) and thus are representative of the actual welding techniques employed for the vessel. The following tests are normally carried out on the test piece:

1. Tensile testing, which includes transverse tensile and all-weld tensile tests
2. Bend test – transverse bend/side bending
3. Macro-etching, hardness, impact testing
4. Intergranular corrosion test (IGC) for austenitic stainless-steel material/welds
5. Ferrite checking

11.4 Design Codes for Pressure Vessels

In modern competitive industry, new process plants are being set up rapidly and existing units are continually revamped, modernized and refurbished for the chemical, petrochemical, pharmaceutical, energy, refinery, and nuclear industries all over the globe. A variety of equipment is needed for the storage, handling and processing of hydrocarbons and chemicals in these processing plants. Unfired pressure vessels such as storage tanks, Horton spheres, mounded bullets, reactors, autoclaves, distillation/fractionating columns, and heat exchangers are some of the basic components of any such process plant.

Various codes specifying the requirements for the design, material, fabrication, inspection, and testing of pressure vessels have been written and adopted as national standards in various countries. Most the international pressure vessels have been developed with a higher degree of technical similarity between them. Core area such as vessel class, design criteria and requirements for independent inspection and certification are based on similar (but not identical) guiding principles.

A compilation of websites of various organizations, associations, technical standards, and current European Union (EU) legislation relating to pressure equipment sector is presented in [11.4].

The subsequent subsections present a brief discussion of the key features of some of the international pressure vessel codes.

11.4.1 ASME Boiler and Pressure Vessel Code

The ASME boiler and pressure vessel code, section VIII, published by the American Society of Mechanical Engineers, also known as ASME International, is a widely accepted code in the USA and 80 other countries in the world. The code is written by voluntary engineering talent and is constantly upgraded by the corresponding committee members to include the latest developments in material and design methodology.

ASME section VIII is written against a well-defined theoretical background and is divided into three subdivisions: 1, 2 and 3. The important design rules of both the codes are summarized in the respective appendices of each code. The contents of the three divisions are organized to cover specific pressure ranges, as illustrated in Table 11.4.

As can be seen from the code comparison table, division 2 permits higher working stresses at the expense of stringent material testing and more-careful quality control. In addition to detailed design rules division 2 provides for discontinuities, fatigue, and other stress analysis considerations, which are based on maximum shear stress theory. Division 2 also contains rules for vessels with layered construction (multiwalled vessels)

Fatigue Analysis

Clause AD-160 of division 2 provides several methods for exempting fatigue evaluations. If the cyclic operation does not meet all the conditions of AD-160 a fatigue evaluation method as per appendix 5 or 6 is added. The stress ranges are first determined for the specified cyclic operation and then, using fatigue curves presented in appendix 5, the associated number of allowable cycles and Miner's rule are used to determine the life fraction and cumulative damage. Fatigue curves up to 370 °C for carbon/low-alloy steel and 430 °C for austenitic stainless steel are provided in the code.

Division 3, which is a comparatively recent publication, provides a state-of-the art code and is intended for high-pressure applications where fatigue and fracture dominate.

11.4.2 PED Directive and Harmonized Standard EN 13445

The early phase of development of design codes and associated legislation in the pressure equipment sector was done predominantly at the national level. In view of the substantial economic potential of this sector, a need was felt in the European community to introduce a uniform and harmonized regulatory framework within the EU. The objective of the common legislation mechanism promulgated through directives was to minimize, if not eliminate, trade barriers between EU member states for pressure equipment, at the same time meeting essential safety requirements stipulated by the new directives.

Of the several European directives enforced since 1987, the Pressure Equipment Directive (PED) (97/23/EC) and the Simple Pressure Vessel (SPV) Directive (87/404/EEC) are the two principal instruments for the pressure equipment sector. The approach of the directives includes the identification of the product, prescription of the essential safety requirements (ESRs) to be met by technical standards, demonstration of conformity and CE marking. Technical standards adopted by the European Committee for Standardiza-

Table 11.4 Comparison of various divisions of ASME codes vis-à-vis EN13445

	Section VIII division I	Section VIII division II	Section VIII division III	EN 13445 part 3
First publication	< 1940	1968	1997	2002
Units adopted	řF and ksi			°C and N/mm^2
Pressure limits	Upto 3000 psig	No limits, usually + 600 psig	No limits, usually from 10 000 psig	For gas-ps up to 3000 bar and/or ps* V up to 3000 bar L For liquid-ps up to 1000 bar and/or ps* V up to 10 000 bar L
Design factor				
Tensile strength	3.5	3.0		Ferritic/normalized steel – 2.4 Austenitic steel – 3
Yield strength	1.5	1.5	Yield based with reduction factor for yield to tensile ratio less than 0.7	Ferritic/normalized steel – 1.5 Austenitic steel – 1.5 or 1.2 (depending on rupture elongation)
Average stress for 1% creep in 100 000 h	1.0	1.0		Guidelines for design in creep range are under development
Allowable stress calculated by	Committee and provided in Tables in section II C for individual grades and products			Designer
Testing groups	NDE requirement dependent on weld efficiency factor	Stringent NDE requirement	NDE requirement is even more stringent than Division 2	Classified from I to IV in decreasing extent of NDT
Hydrostatic test	1.3 × design pressure	1.25 × design pressure	1.25 × design pressure	Greater of 1.43 × allowable pressure and 1.25 × temperature-adjusted pressure

Table 11.5 EN 13445:2002 *Unfired pressure vessels* – a quick reference

Reference	Title	Contents/special features
EN 13445-1:2002	General	Scope, extent of testing with respect to weld joint coefficient, material grouping, etc.
EN 13445-2:2002	Materials	Materials listed include steels with sufficient ductility, cast iron and aluminium. Permitted or tabulated design stress are not provided. List of normative annexures are provided which include technical, inspection and delivery condition. Material listed in CE harmonized product standard can be used for that product. Material listed in CE harmonized material standard, if appropriate to the product. European approval of material (EAM) required for materials not listed in the harmonized standards. Particular material appraisal (PMA) required for material not listed in the harmonized standards or approved via EAM.
EN 13445-3:2002	Design	See Table 11.6 listing features for individual components.
EN 13445-4:2002	Fabrication	Provides weld designs, tolerances, production testing, post-weld heat treatment and repair requirements.
EN 13445-5:2002	Inspection and testing	Specifies nondestructive testing, pressure testing, marking and documentation requirement for noncyclic operation and special provisions for cyclic operations.
EN 13445-6:2002	Requirement for design and fabrication of pressure vessels and pressure parts constructed of spheroidal graphite cast iron.	
CR 13445-7:2002	Supporting standard for guidance on the use of the conformity procedures.	
prEN 13445-8	Additional requirement for pressure vessels of aluminium and aluminium alloys.	

Table 11.6 A quick summary of EN 13445 part 3

Type of analysis	Component	Special features
Design by formulae for non-cyclic loading (used in clauses 7 to 16) (full pressure cycles less than 500 cycles)	Dished ends	Additional formulae for knuckle and knuckle buckling
	Cones and conical ends	Based on limit analysis
	Opening in shells	Pressure area method
	Opening in flat ends	Replacement of section modulus
	Flanges	Modified Taylor forge method, alternate method also provided based on limit load analysis carrying out detailed assessment of flange–bolt–gasket system, useful for joints where bolt loads are monitored
	Weld joint efficiency	Linked to testing group I/II/III/IV
	Tubesheets	In addition to traditional method, new method using limit analysis approach in which edge loads and restraints are addressed, is provided Allowable tube loads are calculated
	Bellows	Covers both thin- and thick-walled bellows Rules are based on Expansion Joint Manufacturer's Association (EJMA) standards
	Rectangular vessels	Covers both unreinforced and reinforced vessels where outside stiffeners are attached
	Non-pressure local loads	Local loads are assessed by comparison with allowable loads calculated based on limit load analysis
Design by formulae for cyclic loading (used in clauses 17 and 18) (full pressure cycles exceeding 500 cycles)	Simplified fatigue analysis (clause 17)	Fatigue strength calculated using fatigue curves, which are more conservative than those used in detailed fatigue analysis for the unwelded region Table is provided for selecting stress factor for various design configurations
	Detailed fatigue analysis (clause 18)	Correction factors depending upon temperature, thickness, mean stress and surface finish are applied on fatigue curves Cumulative damage calculated as per Miner's rule Guidance provided on bending stress calculations due to misalignment of weld and recommendation given for weld-toe grinding
Design by analysis (covered by annexes B and C)	Direct route (annex B)	New route based on Eurocode (for steel structure), which overcomes the shortcomings of the familiar stress categorization method, addresses failure modes directly by way of design checks under the influence of *actions* (all imposed thermo-mechanical quantities including pressure, thermal and environmental) using partial safety factor depending on nature of single action or combination of actions
	Stress categorization route (annex C)	Based on categorization of stresses into primary, secondary and peak stress and comparing the same with specified limits, Stress classification table is provided for given component and its location depending upon the source load to help list and allocate stress category

tion (CEN/CENELEC), which provide means for the user to comply with the ESRs of the PED, are called *harmonized standards*.

EN 13445:2002 Unfired Pressure Vessel is a major harmonized product standard within the CEN pressure equipment portfolio. The standard utilizes expertise and best practices from across the European member states as well other internationally accepted standards. The adoption of the first issue of this standard, published in 2002, was preceded by discussions between experts who took nearly 10 years to achieve a major technical convergence.

The various sections of EN 13445 along with a brief description of the respective contents are tabulated in Table 11.5, while Table 11.6 summarizes the essential features of the design rules for various pressure vessel components, as covered in part 3 of EN 13445. An excellent presentation of the background to the rules of EN 13445 part 3 is available [11.5].

11.4.3 PD 5500

PD 5500:2000, the *specification for unfired fusion welded pressure vessels*, is a recent replacement for BS 5500:1997. It was issued under the status of a published document (PD) in anticipation of simultaneous release of the harmonized standard EN 13445 for pressure equipment in Europe.

Table 11.7 Summary of the salient features of ASME, PD 5500 and the AD code

Information	ASME section VIII division 1		PD 5500		AD Merkblätter	
	Part	Summary	Section	Summary	Section	Summary
Responsibilities	UG-99	Responsibilities listed for manufacturer and authorized inspector (AI)	1.4	Responsibilities for code compliance is on manufacturer	Druckbehälter VO	Authorized inspector to issue final vessel certification
Certification	UG-115 to 120	Manufacturer to have *certificate of authorization* to construct ASME stamped vessel	1.4	Code compliance is documented by use of form *X* issued by manufacturer and counter signed by AI	Druckbehälter VO	Authorized inspector to issue final vessel certification
Construction categories	–	–	3.4	Three categories with different material and NDT requirement are defined	HP 0	Four testing groups I, II, III and IV are defined
Joint types	UW-3	Defines A, B, C, D category with different NDT requirements; UW-12 gives joint efficiencies	5.6.4	Defines A and B welded joints, with different NDT requirements		
Weld joint details	UW-12, UW-13, UW-16	Shows typical weld joints for guidance and are not mandatory	E.1(1)–E.1(6)	Shows typical weld joints for guidance and are not mandatory		
Welder's approval	UW-28, 29, 48	Weld procedure specification (WPS), procedure qualification record (PQR) and welder's qualification are required	5.2, 5.3	WPS, PQR and welder's qualification are required	HP 2/1	WPS, PQR and welder's qualification are required
Permissible materials	UG-4, UG-10	UG-4 refers to materials specified in ASME section II	2.1.2	This sections references British standard materials	W0 to W13 for metallic and N series for non-metallic material	W0 to W13 cover all types of alloyed/unalloyed steel, castings, forgings, clad steel bolts and nuts but do not include gaskets
Material identification	UG-94	Material for all pressure parts is marked and certified for traceability	4.1.2	Positive material identification is required for all pressure parts		
NDT techniques	UW-51 to 53, UW-11, UW-42	NDT techniques are detailed in ASME section V	5.6.4	Ultrasonic testing (UT) and radiographic testing (RT) testing both are acceptable	HP 5/3	DIN standards are referenced for all NDT techniques
Assembly tolerance	UG-80, UW-33	Tolerances for circularity and alignment are specified	4.2.3	Tolerances for circularity and alignment are specified		
Pressure testing	UG-99, UW-50	Test pressures are specified along with other requirements of testing	5.8.1	Test pressures are specified along with other requirements of testing	HP 8/2, HP 30	
Heat treatment	UCS-56				HP 7/1 to HP 7/4	

Though PD 5500 does not currently have formal status as a harmonized standard and compliance with its technical requirement does not qualify presumption of conformity to PED, it does include information showing how its technical content would comply with the ESR of the directive.

Fatigue Analysis

Annexure C of the code presents criteria for exemption from fatigue analysis. A simplified fatigue analysis using design curves can be done using conservative estimates of the stress range due to pressure changes and thermal gradients. By using appropriate an design curve

to obtain allowable cycles and satisfying a cumulative damage rule, a simplified analysis can be done.

A detailed analysis is required if the specified criterion is not satisfied. Detailed methods for determining stresses due to pressure, thermal gradient, and piping loads based on using stress concentration factors are provided in annexure G. Based on the individual stresses thus obtained, the maximum principal stress range for each individual cycle is determined and fatigue evaluation is done as per annexure C.

The fatigue curves are limited to 350 °C for ferritic steel and 430 °C for austenitic stainless steels.

11.4.4 AD Merkblätter

Arbeitgemeinschaft Druckbehälter (AD) Merkblätter regulations are a set of generally accepted rules of technology regarding pressure vessels and contain safety requirement for equipment, design, manufacture and testing, and materials. These regulations are compiled by seven trade associations of Germany, who together form the AD. The AD associations represent a balanced combination of material and pressure vessel manufacturer's, operators, employer's liability insurance, and technical inspectorates.

To a large extent the AD Merkblätter code is based on Deutsches Institut für Normung (DIN) standards and is continuously amended in keeping with technical progress. The associations has published a regulation called AD 2000 conforming to the safety requirement and other stipulations as laid down in the PED, which has been made compulsory in Europe from May 2002 onwards.

A quick summary showing the key technical points of PD 5500 in comparison with the ASME section and AD Merkblätter code are shown in Table 11.7.

11.5 Heat Exchangers

Heat exchangers are devices that transfer heat from a hot to a cold fluid. They are used extensively in processing plants and are given specific names when they serve a special purpose, for example superheaters, condensers, evaporators etc. In a surface-type exchanger, the two process fluids are separated by a physical barrier and the heat is transferred from the warm/hot fluid through the barrier to the cold fluid. Shell-and-tube and plate exchangers are the most commonly used types of surface exchangers.

The construction of shell-and-tube exchangers is broadly divided into the shell side and tube side (also called the channel section). Several small-diameter tubes (on the tube side) are attached to larger pressure vessels (known as the shell side), or parts thereof, called tube sheets. The tubes are distributed within the tube

Table 11.8 Design rules for tube sheets as per different codes

	TEMA	ASME section VIII division 1	EN 13445-3
U tube tubesheet			
Reference section	Section 1999 edition	Appendix AA-1 edition 2001 and UHX-12 edition 2002 (mandatory)	Clause 13 D-2002 (based on Code francais de construction des Appareils a Pression (CODAP)/unifired pressure vessel (UPV) rules)
Assumptions	Perforated tubesheet and unperforated rim not accounted for; the effect of tube sheet attachment with shell/channel not considered	Refined and rational analytical treatment is used after taking into account actual geometry (based on model proposed by F. Osweiller in 2000)	
Ligament efficiency	$0.45 \leq \eta \leq 0.60$	$0.25 \leq \mu \leq 0.35$	
Safety factor	2.6	1.5	2.0
Allowable stress		Stress classification of division 2 appendix 4	Based on primary and secondary stress as per appendix C
Remarks	TEMA approach leads to lower thickness than ASME due to higher ligament efficiency and high safety factor	Higher thickness obtained in ASME rules than UPV/CODAP due to lower allowable stress	

Table 11.8 (cont.)

Fixed/floating tubesheet			
Reference section		Appendix AA-2 edition 1992	Clause 13 E-2002 (based on CODAP/UPV rules)
Assumption	Stiffening effect of tube bundle and weakening effect of tube holes are assumed to counterbalance each other, coefficient F is not dependent on the stiffness ratio X of the axial tube bundle rigidity to the bending rigidity of the tube sheet	Coefficient F is dependent on the stiffness ratio X	Coefficient F is dependent on the stiffness ratio X; the value of F is higher than ASME since tubes are assumed to be uniformly distributed over the whole tube sheet
Remarks	TEMA does not provide the same design margin for all cases, leading to over-thickness for higher X and under-thickness for lower X		

sheet in a certain pattern, the three most common of which are the triangular, square and rotated triangular, and square.

Designs for the joint between the tube and tube sheet vary widely and are chosen to be compatible with the severity of the service conditions. The joint may be expanded, welded, or a combination of both. There are various constructional details of welded joints, the choice of which is based upon service and environment.

Various configurations and designs of shell-and-tube exchangers are covered extensively by the Tubular Exchanger Manufacturers' Association (TEMA).

The principle of mechanical design for most of the components of the heat exchanger is identical to the design of a pressure vessel. However, the design of the tube sheet is typically different because of its constructional geometry. The tube sheet design rules have been rationalized in recent years by various pressure vessel codes, which are summarized in the Table 11.8.

11.6 Material of Construction

11.6.1 Carbon Steel

Steel is an iron alloyed with carbon at a level of 0.05–2.0%. In addition it contains smaller proportions of phosphorus, sulphur, silicon, aluminum, and manganese. These steels are known as plain carbon steels, which are classified as mild-, medium- and high-carbon steels according to the percentage of carbon.

Mild steel has 0.05–0.3% carbon by weight, medium-carbon steel has a carbon content of 0.3–0.6% and high-carbon steel has more than 0.5%, up to a maximum of 2%, carbon content. Mild steels are the most versatile materials for the construction of pressure vessel due to their good ductility and relative ease of forming, rolling, forging, fabrication, and welding. They are also most suited and economic for applications where the rate of corrosion is low. During the manufacture of these steels, silicon and/or aluminum are added to react with dissolved oxygen in the molten metal alloy to form a slag of Al_2O_3/SiO_2, which floats to the top and is removed; the resultant steel is called *killed steel*. A fully killed steel usually contains less than 150 ppm oxygen and at least 0.10% silicon. Besides being cleaner due to the formation of fewer oxides and inclusions, fully killed steels are much easier to weld due to a lower tendency to outgas during welding.

Welding

Mild-steel electrodes are grouped into those with rutile-type flux covering and those with low hydrogen flux covering. Rutile-covered electrodes are used for general fabrication involving thinner sections, lower tensile strength, and in applications where there is no requirement for impact properties. For all other applications, where strength, impact properties, and weld quality are essential, low-hydrogen-type electrodes are employed. The flux covering eliminates sources of potential hydrogen and thus minimizes the chances of clod cracking.

11.6.2 Low-Alloy Steel

Low-alloy steel contains additions of the elements Ni, Cr, Si, Mo, and Mn in amounts totaling less than 5%. The added elements improve mechanical properties, heat treatment response and /or corrosion resistance. The weld ability of low-alloy steels is also good; however since these steels are hardenable by heat treatment, they do require careful attention to welding procedure including pre- and post-weld heat treatment (PWHT) for stress relief, which is discussed later.

The workhorse alloys for pressure vessels, exchanger and heater tubes, and piping for elevated temperature service, usually greater than 250 °C, contain 0.5%–9.0% chromium plus molybdenum. With the increasing chromium content, resistance to high-temperature hydrogen attack, and resistance to sulfidation and oxidation increases.

Developments

There has been an increasing trend towards improved toughness properties and temper embrittlement resistance by restricting levels of impurity elements at the ladle.

To minimize the temper embrittlement of low-alloy steel, the phosphorous content is restricted to 0.010% or lower, while the combined phosphorous–tin content is limited to 0.010%.

The effects of the tramp elements have been addressed by the Bruscato factors X and J, as defined by the following equations:

$$X = \frac{(10\mathrm{P} + 4\mathrm{Sn} + 5\mathrm{Sb} + \mathrm{As})}{100}$$

(all elements in ppm) ,

$$J = (\mathrm{Si} + \mathrm{Mn})(\mathrm{P} + \mathrm{Sn}) \times 10^4 \quad \text{(elements in \%)} .$$

For this reason PWHT is a must for all creep-resisting Cr–Mo-type alloy steels. PWHT also stabilizes and softens the microstructure at the heat-affected zone (HAZ) of the weld. If the base metal is quenched and tempered, higher PWHT temperatures can be specified for improved resistance to creep embrittlement.

Fabrication

In view of the criticality of preheating, post-heating, and PWHT, it is prudent to employ specialized heat-treatment techniques using electrical resistance pads or induction coils,especially for thick piping sections.

11.6.3 NACE standards

The National Association of Corrosion Engineers (NACE) is a worldwide technical organization that studies various aspects of corrosion in refineries, chemical plants and other industrial systems.

NACE standard MR0175, entitled *Sulfide corrosion cracking resistant metallic material for oilfield equipment*, is widely used for applications in sour gas and oil environments. NACE compliance is recommended in systems where there is a likelihood of sulfide cracking due to the presence of a measurable amount of H_2S. Since the susceptibility of carbon, low-alloy and austenitic stainless steel to sulfide corrosion is directly related to strength and hardness level, it these standards recommend that the hardness of the aforementioned plate material should be restricted to 22 HRC (200 BHN). The cold working of these steels during forming/rolling shall be less than 5%. Post-weld heat treatment is to be carried out for carbon steels in the case of greater cold working. A few duplex stainless and some nickel-based alloys are also acceptable according to the NACE criteria, subject to a maximum hardness level of 28 and 35 HRC, respectively.

Welding

All weld procedures must be qualified to meet the same hardness levels standards as specified for the corresponding parent material.

11.6.4 Comparative Standards for Steel

The discussion for carbon steel material and the discussion to follow for other construction materials are generally based on the generic composition of materials without referring to any code of construction. It is difficult to furnish equivalence of any grade of material from one code to another; at best steels grades can be compared based on the closest matching technical requirements. Tables 11.9, 10 list some of the comparable standards for flat and tubular products commonly used in fabrication of pressure vessel.

11.6.5 Stainless Steel

Alloys of iron and carbon with over 12% chromium, which resist rusting under most atmospheric conditions, are called stainless steels. The alloys become more corrosion resistant as the chromium level increases. As more nickel is added, several phases are possible and the alloy may undergo transformation depending on the

Table 11.9 Comparative chart for material standards of flat products (plates) for pressurized use

Harmonized European standard			ASTM	DIN	BS 1501

actual content of Cr–Ni–Fe and C. Gamma or austenitic stainless steel is an iron alloy containing at least 18% Cr and 8% Ni with carbon up to 0.10%. The austenitic structure provides a combination of excellent corrosion resistance, oxidation, and sulfidation resistance with high creep resistance, toughness and strength at temperatures up to 550 °C. The 18Cr–8Ni stainless alloys form a series known as the American Iron and Steel Institute (AISI) type 300 series, with varying amounts of carbon, molybdenum, and titanium added.

The 18–8 series have good formability besides being readily weldable without stress relief; however they can be hardened by cold working. These steels are susceptible to grain-boundary chromium carbide precipitation, known as *sensitization*, when subjected to a temperature range of 535–800 °C. To prevent sensitization, low-carbon grades (C < 0.03%) and stabilized grades with added columbium or titanium are used.

The traditional grades of stainless steel that are extensively used in the fabrication of chemical plant and equipment are AISI 304 type and the 2% molybdenum-bearing 316 types along with their low-carbon versions 304L and 316L or the stabilized grades 321 (with Ti) or 347 (with Cb) where intercrystalline corrosion is to be avoided.

Higher-alloyed grades such as AISI 309 and 310 have a higher chromium content that makes them suitable for high-temperature applications such as furnace liners, preheaters and column trays.

Developments

Newer grades of stainless steel have been developed to overcome the limitations of low 0.2% proof stress, sensitivity to stress and pitting corrosion especially in chloride media, inadequate corrosion in reducing media, and preferential attack on the ferrite phase in strong oxidizing media.

Nitrogen alloyed steel such as AISI 304LN and 316LN have been developed with the addition of 0.2% nitrogen, resulting in improved proof stress by about 15%. Nitrogen alloyed steel finds wide application in the transportation and storage industries.

For reactors, strippers, and condensers in urea service steels with higher chromium and nickel contents with nil ferrite have been developed. Modified compositions of AISI 310 steel such as SANDVIK 2RE69 and Assab 725 LN have been developed for strong oxidizing conditions in fertilizer plants.

For elevated-temperature applications in furnaces, and hydrocarbon and steam reformers, where higher creep strength is also necessary, casting alloys such as HK-40 and IN657 have been developed.

Duplex stainless steels were developed to combine the attractive properties of ferritic and austenitic stainless steels. In simple terms, the ferrite could be said to provide mechanical strength and stress corrosion resistance, while the austenite provides ductility and the two combine to produce a fine-grained, two-phase microstructure with high strength and good corrosion resistance. Of the many alloying elements Cr and Mo enhance the formation of ferrite, while Ni and N stabilize the austenite. Resistance to pitting and crevice corrosion in chloride environments is increased, expressed by the pitting resistance equivalent $PRE_N = \%Cr + 3.3 \times \%Mo + 16 \times \%N$.

This number is used to rank materials according to their expected resistance to pitting corrosion. A 23% Cr Mo-free grade would have a PRE_N value of about 25. Regular Mo-alloyed duplex grades have a PRE_N value of 30–36. Steels having a PRE_N value higher than 40 are normally defined as super-duplex stainless steels.

Welding

Duplex stainless-steel welds with matching composition filler material show high ferrite levels, which has low toughness and poor ductility. Therefore all welding consumables for duplex materials are over-alloyed with nickel, which allows more austenite to form so that the ferrite level in welds is lowered and the welds have good ductility and corrosion resistance. It is recommended to achieve a ferrite content of approximately 22–70%; equivalent to 30–100 FN (ferrite number). In addition to the ferrite count, a corrosion test in ferric chloride is also carried out as per ASTM G48, which gives a good assessment of the corrosion resistance of the weld metal. As per this test, the critical pitting temperature (CPT) is specified at 22 °C for duplex and 35 °C for super-duplex steel.

Preheating of duplex material is not required except where heavy loads on high-ferrite-containing welds may cause cracking. Post-welding solution annealing is required only in cases where the resultant weldment has deteriorated due to detrimental phase transformation and/or has high ferrite levels.

Root passes of nitrogen-alloyed stainless steel are welded with higher-alloyed filler, to compensate for the influence of nitrogen.

Urea-grade stainless steels and steels in high-temperature applications are welded with matching composition electrodes enriched with 4–5% manganese to counteract the tendency for microfissuring.

11.6.6 Ferritic and Martensitic Steels

Ferritic steels are chromium–iron stainless steel with little or no nickel and form a body centric structure unlike the face-centered austenitic steel. When ferritic steels are modified by heat treatment, they become hardened and form *martensitic* steels.

Martensitic steels derive their excellent hardness from the high levels of carbon added to their alloy. The most commonly used martensitic steel is ASTM type 410 stainless steel used for column tray and tower lining in crude service for refinery applications. The increased carbon level in 410 steel results in a much harder martensitic cutlery steel or tool steel type 420.

By increasing the percentage of chromium, transformation hardening is suppressed, as in ASTM types 430 and 446, which are essentially ferritic. These steels are resistant to chloride stress corrosion cracking; however they are subject to ductile–brittle temperature embrittlement, thereby restricting their mechanical properties.

The limiting values for X and J factor are usually specified for welding consumables, although it would be preferable also to restrict these for the base material.

A step-cooling simulation treatment is performed on higher-thickness quench and tempered plates to determine susceptibility to embrittlement phenomenon in terms of meeting the specified shift in the 40 ft – lb charpy V-notch (CVN) transition temperature.

Welding

With increasing base and weld material strength and hardenability, hydrogen diffusibility in the weldment is kept below 5 ml/100 g of deposited weld metal. The flux covering of all electrodes is of the low-hydrogen type and employs binders that give high resistance to moisture absorption. Prior to use, they are dried or baked at the manufacturer's recommended temperature.

Although there are several theories for determining the optimum preheat temperature, the common industrial practice is to use carbon equivalent as guidance to select the temperature, as shown here

CE	Temperature °C
< 0.4	50
< 0.55	100
< 0.70	150
< 0.8	200
< 0.9	250

Maintaining the preheat after welding (also called post-heating) for a specified period (generally 300–350 °C for 30 min) in some cases (say for pipe thicknesses greater than 12 mm with a chromium content of 2–7%) also helps to reduce hydrogen levels, thereby preventing cold cracks and stress corrosion cracking.

Martensitic steels can be welded but caution needs to be exercised as they will produce a very hard and brittle zone adjacent to the weld. Cracking in this zone can occur (particularly in thicker sections) and therefore preheating and PWHT is recommended.

Though ferritic steels are less prone to cracking due to their lower strength and non-hardenability, the weldment suffers from excessive grain growth, sensitization and a lack of ductility. Due to the excessive grain growth problem, only thin-gauge sheets are generally used. Filler material can be of either a similar composition, or alternatively an austenitic grade can be used to help weld toughness and increase ductility.

Table 11.11 lists some of the comparable standards for stainless-steel grades commonly used in the fabrication of pressure vessel.

Developments

Since the ferritic grades do not possess good welding properties, hybrid utility ferritics such as 3CR12 with controlled martensite (dual phase steel) have been developed to overcome these welding difficulties. Using new steel-refining techniques, along with the addition of titanium or niobium, it has been possible to develop extremely corrosion-resistant grades such as *superferritic stainless steel*.

11.6.7 Copper and Nickel Base Alloys

Brass

Brasses are commercially produced with varying percentages of copper and zinc to provide a range of properties depending on the end-use requirements.

Admiralty brass, which is widely used for tubes in water-cooled condensers for low water speeds, is an alloy brass containing 71% Cu, 28% Zn, and 1% Sn. To prevent dezincification, small amounts of arsenic, phosphorous or antimony are added.

At high water speeds and when seawater contains air bubbles, aluminum brass containing 2% Al is more suitable due to the formation of a protective film. For tube plates in condensers and exchangers, it is usual practice to use high-zinc brasses, hot-rolled Muntz metal (60% Cu, 40% Zn) or Naval brass (60% Cu, 39% Zn,

Table 11.11 Comparative chart for various stainless-steel grades

Structure	Hardenability	ASTM 240 Grade	UNS No.	EN 10028-7 Grade	Number	Analysis built up from basic type

		431	S 43100	X4CrNiMo16-5-1	1.4418	Higher Cr and Ni added for improved ductility
Ferritic	Non-hardenable	405	S 40500	X6CrAl13	1.4402	Al added to Cr 12% to prevent hardening
		430	S 43000	X6Cr17	1.4016	Cr 17% basic type
		442	S 44200			Higher Cr to resist oxidation and sulfidation at higher temperature
		446	S 44600			
Precipitation-hardening steel	Age-hardenable	17-7 PH	S 17700	X7CrNiAl17-7	1.4568	
		14-8MoPH	S 13800	X8CrNiMoAl15-7-2	1.4532	

and 1% Sn) to take advantage of higher tensile strength, although the two-phase structure of these alloys cannot be satisfactorily inhibited against dezincification.

Bronze

Bronze is a tin alloy of copper with other elements such as aluminum added for additional properties. Because of the hardening effect of tin, hot-rolled bronze plates have greater strength than brass plates and therefore can be used for tube plates and channel material for exchangers.

Cu–Ni Alloys

Alloys of copper and nickel have historically been used in saltwater condensers as they show better resistance to saltwater than brasses. Increasing nickel content was found to be beneficial and 30% Ni alloy was adopted as the standard for naval vessels. The addition of iron and Mn was found to improve resistance to impingement attack.

These alloys are used as tubes for heat exchangers, saltwater pipelines, and hydraulic lines as well as for several applications in marine and offshore

platform services. Cupronickel tubes are superior to brass in terms of better resistance to dezincification for applications involving higher metal temperature of water-cooled exchangers. They are also excellent materials for tube plates and, because of their good formability and weldability, they can be used in sheet form for the fabrication of heat-exchanger shells and water boxes. Monel, a nickel-copper alloy (67% Ni, 30% Cu) has good resistance to saltwater, and to hydrochloric and hydrofluoric acid under nonoxidizing conditions. Therefore they are excellent material for cladding and trays in towers handling acid vapors.

Other Nickel-based alloys are classified as:

1. Chromium bearing as in Inconel 600, and Hastelloy C-22 and C-276;
2. Containing chromium and molybdenum such as Inconel 625, Hastelloy B, Incoly 825;
3. Precipitation hardening alloys such as Monel K-500, and Inconel 817.

These alloys show excellent resistance to pitting, stress corrosion cracking in chloride environments and retain strength at elevated temperatures. Therefore they are excellent candidates for exchanger tubes, heat-transfer plates for plate heat exchangers (PHE), and pressure coils for steam/hydrocarbon reformers, naphtha-cracking furnaces etc. in the petrochemical and fertilizer industries.

Welding

Gas tungsten arc (GTAW), gas metal arc (GMAW), and shielded metal arc (SMAW) processes are most commonly used for welding brasses and bronze. Whereas thin gauges are welded with GTAW using zinc-free fillers, heavier gauges are joined by a GMAW/SMAW process using zinc-free silicon bronze or aluminum bronze fillers/electrodes. Zinc-free fillers are prescribed since the evolution of zinc fumes makes the weld porous and affects visual observation of the welding process; moreover zinc fumes are extremely hazardous to health. Argon and helium, either individually or in combination, are used for shielding in the case of the GTAW/GMAW process.

Welding consumables for welding of all Cu–Ni-based alloys are available with compositions matching the specific parent material with the generous addition of manganese and/or niobium, which are added intentionally to give resistance to hot cracking and to raise hot strength. Most of these consumables are often used for dissimilar metal welding between the nickel base and most steels or between other ferrous and nonferrous alloys.

Carbon and silicon are controlled to low levels to minimize detrimental precipitates in the weld metal and HAZ for electrodes with specifications matching with some of the high-molybdenum alloys such as Hastelloy C276 and Hastelloy B.

12. Turbomachinery

Meinhard T. Schobeiri

The following chapter consists of two sections. Section 12.1 presents a concise treatment of the theory of turbomchinery stages including the energy transfer in absolute and relative systems. Contrary to the traditional approach that treats turbine and compressor stages of axial, radial or mixed configurations differently, these components are treated from a unifying point of view.

Section 12.2 is dedicated to steady and unsteady performance of gas turbine engines, where the components are treated as generic modules. Thus, any arbitrary power generation or aircraft gas turbine engine with single or multiple shafts can be composed of these modules. Several examples show, how different gas turbine configurations can be constructed and dynamically simulated. Finally, a section about the new generation gas turbines shows, how the efficiency of gas turbines can be improved far beyond the existing level.

This chapter is based on [12.1], where the reader finds detailed explanation of relevant aerodynamic aspects of turbomachines, their component losses and efficiencies, and the design and off-design performance calculations.

12.1 Theory of Turbomachinery Stages

12.1.1 Energy Transfer in Turbomachinery Stages

Energy transfer in turbomachinery is established by means of a number of stages. A *turbomachinery stage* consists of a row of fixed, guide vanes called *stator blades*, and a row of rotating blades termed the *rotor*. To elevate the total pressure of a working fluid, *compressor stages* that partially convert the mechanical energy into potential energy are used. According to the law of conservation of energy, this energy increase requires

an external energy input which must be added to the system in the form of mechanical energy. Figure 12.1 shows a schematic of an axial compressor stage that consists of one stator and two rotor rows. In general, a *compressor component* starts with a rotor row followed by a stator row. Compressor configurations that start with an *inlet guide vane* are also found. To define a unified station nomenclature for the compressor and turbine stages, we identify station number 1 as the inlet of the stator, followed by station 2 as the rotor inlet, and station 3 as the rotor exit. The absolute and relative flow angles are counted counterclockwise from a horizontal line. This convention allows an easier calculation of the off-design behavior of compressor and turbine stages during a transient operation, as we will see later. Different angle conventions are used in the literature [12.2–5]. The working fluid enters the first rotor with an *absolute velocity* in the axial direction (Fig. 12.1b), where it is deflected in the direction of the rotor's leading edge. As a result of the rotational motion of the rotor, a major part of the mechanical energy input is converted into the potential energy of the working medium, causing the total pressure to rise. During the compression process, the absolute velocity within the stator and the relative velocity vector within the rotor decrease. To convert the total energy of a working medium into mechanical energy, *turbine stages* are used. Figure 12.2 exhibits a turbine stage within a multistage environment. As shown, the mean diameter may change from inlet to exit. The continuous increase in flow path cross section is due to the continuity requirement.

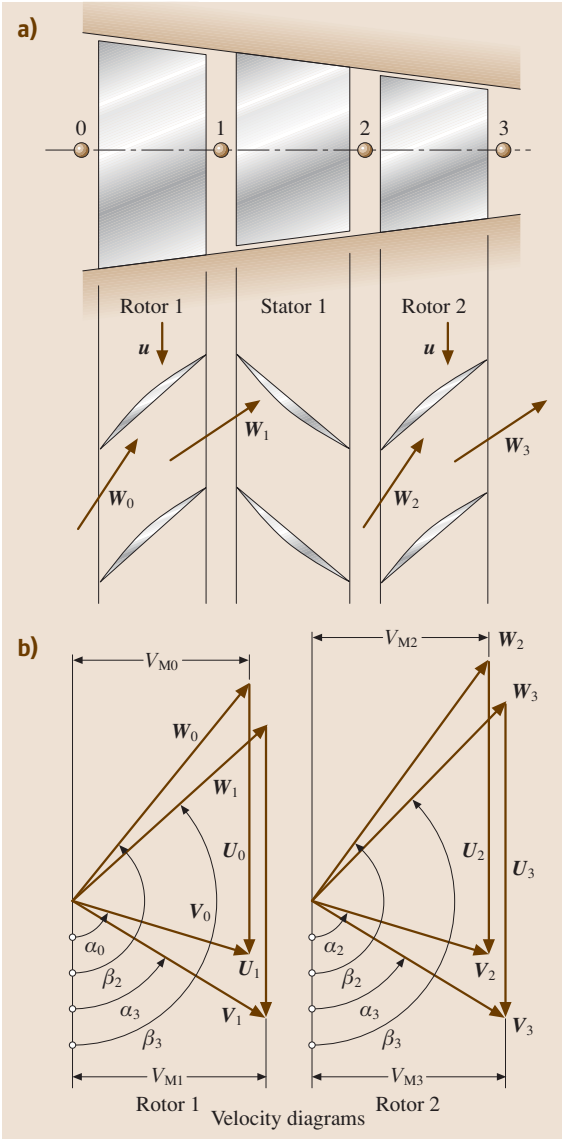

Fig. 12.1 (a) An axial compressor stage with a rotor–stator–rotor configuration and (b) velocity diagrams for the first and second rotor

12.1.2 Energy Transfer in Relative Systems

Since the rotor operates in a relative frame of reference (relative system), the energy conversion mechanism is quite different from that of a stator (absolute system). A fluid particle that moves with a relative velocity $\boldsymbol{W}$ within the relative system that rotates with the angular velocity $\boldsymbol{\omega}$, has an absolute velocity

$$\boldsymbol{V} = \boldsymbol{W} + \boldsymbol{\omega} \times \boldsymbol{R} = \boldsymbol{W} + \boldsymbol{U}, \quad \boldsymbol{\omega} \times \boldsymbol{R} = \boldsymbol{U}\,, \tag{12.1}$$

where $\boldsymbol{R}$ is the radius vector of the particle in the relative system. Introducing the absolute velocity vector $\boldsymbol{V}$ in the equation of motion [12.1, Chap. 3, Eq. (3.37)] and multiplying the results with a relative differential displacement $\mathrm{d}R$, we get the energy equation for an adiabatic steady flow within a relative system

$$\mathrm{d}\left(h + \frac{1}{2}W^2 - \frac{\omega^2 R^2}{2} + gz\right) = 0 \tag{12.2}$$

or the relative total enthalpy

$$H_\mathrm{r} = h + \frac{1}{2}W^2 - \frac{\omega^2 R^2}{2} + gz = \text{const}\,. \tag{12.3}$$

Neglecting the gravitational term, $gz \approx 0$, (12.3) can be written as

$$h_1 + \frac{1}{2}W_1^2 - \frac{1}{2}U_1^2 = h_2 + \frac{1}{2}W_2^2 - \frac{1}{2}U_2^2\,. \tag{12.4}$$

Equation (12.4) is the equation for the energy transformed in a relative system. As can be seen, the transformation of kinetic energy undergoes a change while the transformation of static enthalpy is frame indifferent. With these equations together with the energy balance [12.6] we can analyze the energy transfer within an arbitrary turbine or compressor stage.

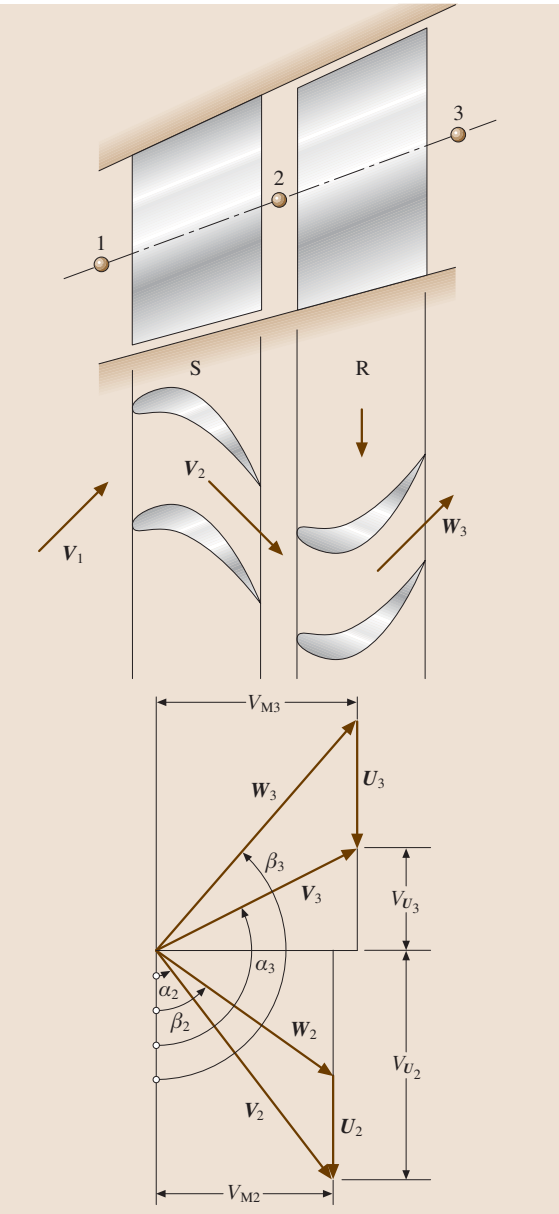

Fig. 12.2 An axial turbine stage with velocity diagram

12.1.3 General Treatment of Turbine and Compressor Stages

In this chapter, compressor and turbine stages are treated from a unified physical point of view. Figures 12.3 and 12.4 show the decomposition of a turbine and a compressor stage into their stator and rotor rows. The primes $'$ and $''$ refer to stator and rotor rows, respectively. As seen, the difference between the isentropic and the polytropic enthalpy difference is expressed in terms of dissipation $\Delta h'_{\mathrm{d}} = \Delta h'_{\mathrm{s}} - \Delta h'$ for turbines and $\Delta h'_{\mathrm{d}} = \Delta h' - \Delta h'_{\mathrm{s}}$ for compressors. For the stator, the energy balance requires that $H_2 = H_1$. This leads to

$$h_1 - h_2 = \Delta h' = \frac{1}{2}\left(V_2^2 - V_1^2\right). \tag{12.5}$$

Moving to the relative frame of reference, the relative total enthalpy $H_{\mathrm{r}2} = H_{\mathrm{r}3}$ remains constant. Thus, the energy equation for the rotor is according to (12.4) (Fig. 12.4)

$$h_2 - h_3 = \Delta h'' = \frac{1}{2}\left(W_3^2 - W_2^2 + U_2^2 - U_3^2\right). \tag{12.6}$$

The stage specific mechanical energy balance requires (Fig. 12.5)

$$\begin{aligned} l_{\mathrm{m}} &= H_1 - H_3 \\ &= (h_1 - h_2) - (h_3 - h_2) + \frac{1}{2}\left(V_1^2 - V_3^2\right). \end{aligned} \tag{12.7}$$

Inserting (12.5) and (12.6) into (12.7) yields

$$l_{\mathrm{m}} = \frac{1}{2}\left[\left(V_2^2 - V_3^2\right) + \left(W_3^2 - W_2^2\right) + \left(U_2^2 - U_3^2\right)\right]. \tag{12.8}$$

Equation (12.8), known as the *Euler turbine equation*, indicates that the stage work can be expressed simply in terms of absolute, relative, and rotational kinetic energies. This equation is equally applicable to turbine stages that *generate* shaft power and to compressor stages that *consume* shaft power. In the case of a turbine stage, the sign of the specific mechanical energy l_{m} is negative, which indicates that energy is removed from the system (power generation). In compressor cases, it is positive because energy is added to the system (power consumption). Before proceeding with velocity diagrams, it is of interest to evaluate the individual kinetic energy differences in (12.8). If we wish to design a turbine or a compressor stage with a high specific mechanical energy l_{m} for a particular rotational speed, then

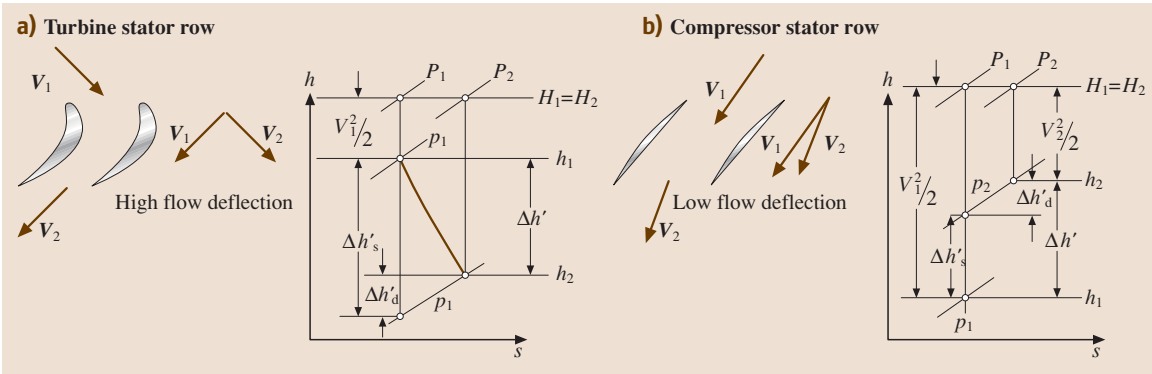

Fig. 12.3a,b Expansion and compression process through a turbine (**a**) and a compressor (**b**) stator row

we have two options:

1. We increase the *flow deflection*, which leads to an increase in $\left(V_2^2 - V_3^2\right)$.
2. We increase the radial difference that leads to a larger $\left(U_2^2 - U_3^2\right)$.

While option 1 is used in axial stages, option 2 is primarily applied to radial stages. These quantities are the characteristics of a stage velocity diagram at the corresponding radial section.

Using the trigonometric relation with the *angle convention* from the velocity diagram in Figs. 12.5 and 12.6, we determine the velocity components and vector relations from

$$
\begin{aligned}
&V_{m2} = W_{m2}\,, \quad V_{m3} = W_{m3}\,,\\
&\boldsymbol{W}_2 = e_1(V_{u2} - U_2) + e_2 V_{m2}\,,\\
&\boldsymbol{W}_3 = -e_1(V_{u3} - U_3) + e_2 V_{m3}\,.
\end{aligned}
\tag{12.9}
$$

In (12.9) V_m, W_m and V_u, W_u are the meridional and circumferential components of the absolute and relative velocities, respectively. The corresponding kinetic energy contributions are determined from

$$
\begin{aligned}
W_2^2 &= \left(V_{u2}^2 + V_{m2}^2\right) + U_2^2 - 2V_{u2}U_2\\
&= V_2^2 + U_2^2 - 2V_{u2}U_2\,,\\
W_3^2 &= V_{u3}^2 + U_3^2 + 2V_{u3}U_3 + V_{m3}^2\,,\\
W_3^2 &= V_3^2 + U_3^2 + 2V_{u3}U_3\,.
\end{aligned}
\tag{12.10}
$$

Incorporating (12.9) and (12.10) into (12.8) yields the *stage specific* work

$$
l_m = U_2 V_{u2} + U_3 V_{u3}\,. \tag{12.11}
$$

Equation (12.11) is valid for axial, radial, and mixed flow turbines and compressors. A similar relation is obtained from the scalar product of moment of momentum and the angular velocity. In conjunction with the equation of moment of momentum, one finds in the

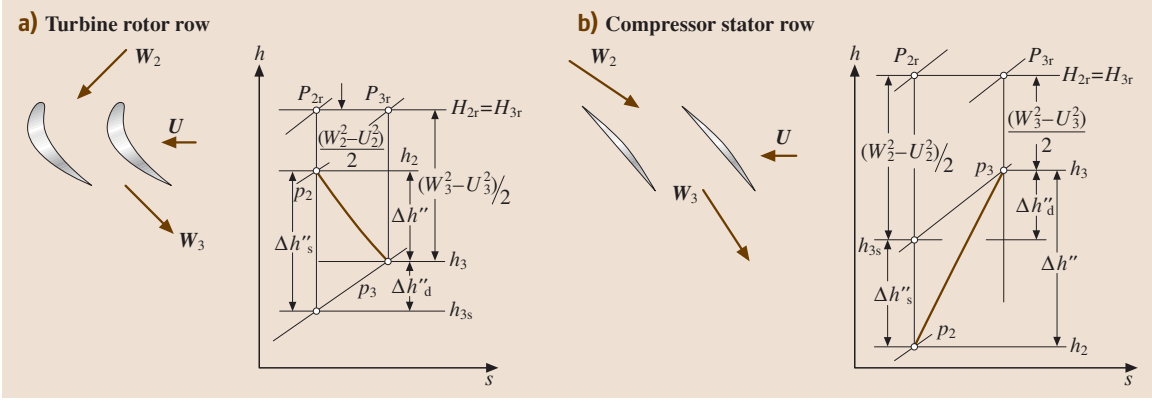

Fig. 12.4a,b Expansion and compression process through a turbine (**a**) and a compressor (**b**) rotor row

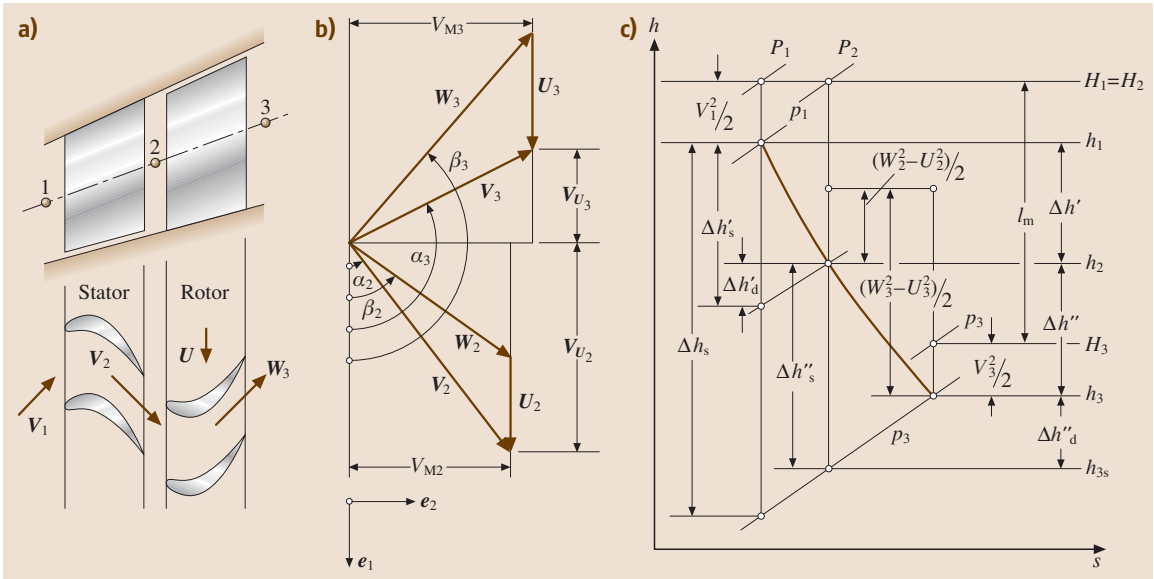

Fig. 12.5a–c A compressor stage (a) with the velocity diagram (b) and the expansion process (c). The direction of the unit vector $\boldsymbol{e}_1$ is identical with the rotational direction

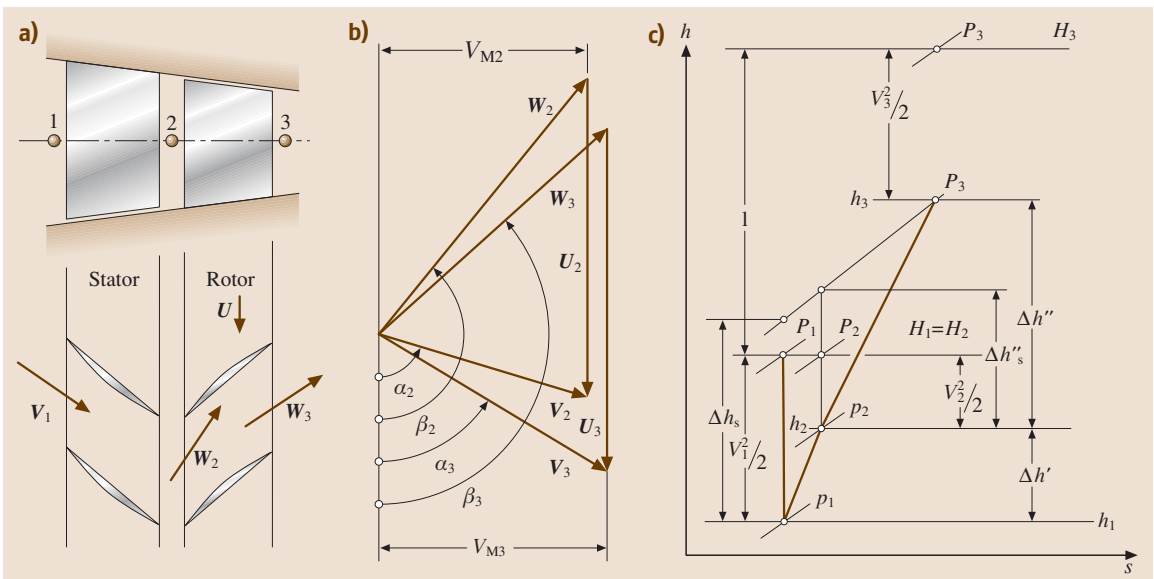

Fig. 12.6a–c A compressor stage (a) with the velocity diagram (b) and the expansion process (c). The direction of the unit vector $\boldsymbol{e}_1$ is identical with the rotational direction

literature $l_m = U_2 V_{u2} - U_3 V_{u3}$. In order to avoid confusion that may arise from different signs, it should be pointed out that the negative sign is the result of the formal derivation of the conservation law of moment of momentum. This negative sign implies that V_{u1} and V_{u2} point in the same direction. The unified angle convention introduced in Figs. 12.1 and 12.2, however, takes the actual direction of the velocity components with regard to a predefined coordinate system.

12.1.4 Dimensionless Stage Parameters

Equation (12.11) exhibits the direct relation between the specific stage work l_m and the kinetic energies. The velocities from which these kinetics energies are built can be taken from the corresponding stage velocity diagram. The objective of this chapter is to introduce dimensionless stage parameters that completely determine the stage velocity diagram. These stage parameters exhibit unified relations for compressor and turbine stages, respectively.

Starting from a turbine or compressor stage with constant mean diameter and axial components (Fig. 12.7) we define the dimensionless stage parameters that describe the stage velocity diagram of a *normal stage* introduced by *Traupel* [12.3]. A normal stage is encountered within the high-pressure (HP) part of multistage turbines or compressor components and is characterized by $U_3 = U_2$, $V_3 = V_1$, $V_{m1} = V_{m3}$, and $\alpha_1 = \alpha_3$. The similarity of the velocity diagrams allows the same blade profile to be used throughout the HP turbine or compressor, thus significantly reducing manufacturing costs. We define the stage flow coefficient ϕ as the ratio of the meridional velocity component and the circumferential component. For this particular case, the meridional component is identical with the axial component

$$\phi = \frac{V_{m3}}{U_3} \,. \tag{12.12}$$

The stage flow coefficient ϕ in (12.12) is a characteristic of the mass flow behavior through the stage. The *stage load coefficient* λ is defined as the ratio of the specific stage mechanical energy l_m and the exit circumferential kinetic energy U_3^2. This coefficient directly relates the flow deflection given by the velocity diagram with the specific stage mechanical energy

$$\lambda = \frac{l_m}{U_3^2} \,. \tag{12.13}$$

The stage load coefficient λ in (12.13) describes the work capability of the stage. It is also a measure for the stage loading. The *stage enthalpy coefficient* Ψ represents the ratio of the isentropic stage mechanical energy and the exit circumferential kinetic energy U_3^2

$$\Psi = \frac{l_s}{U_3^2} \,. \tag{12.14}$$

The stage enthalpy coefficient represents the stage isentropic enthalpy difference within the stage. Furthermore, we define the *stage degree of reaction* r which is the ratio of the static enthalpy difference used in the rotor row divided by the static enthalpy difference used in the entire stage

$$r = \frac{\Delta h''}{\Delta h'' + \Delta h'} \,. \tag{12.15}$$

The degree of reaction r indicates the portion of energy transferred in the rotor blading. Using (12.5) and (12.6), we arrive at

$$r = \frac{\Delta h''}{\Delta h' + \Delta h''} = \frac{W_3^2 - W_2^2 + U_2^2 - U_3^2}{W_3^2 - W_2^2 + U_2^2 - U_3^2 + V_2^2 - V_1^2} \,. \tag{12.16}$$

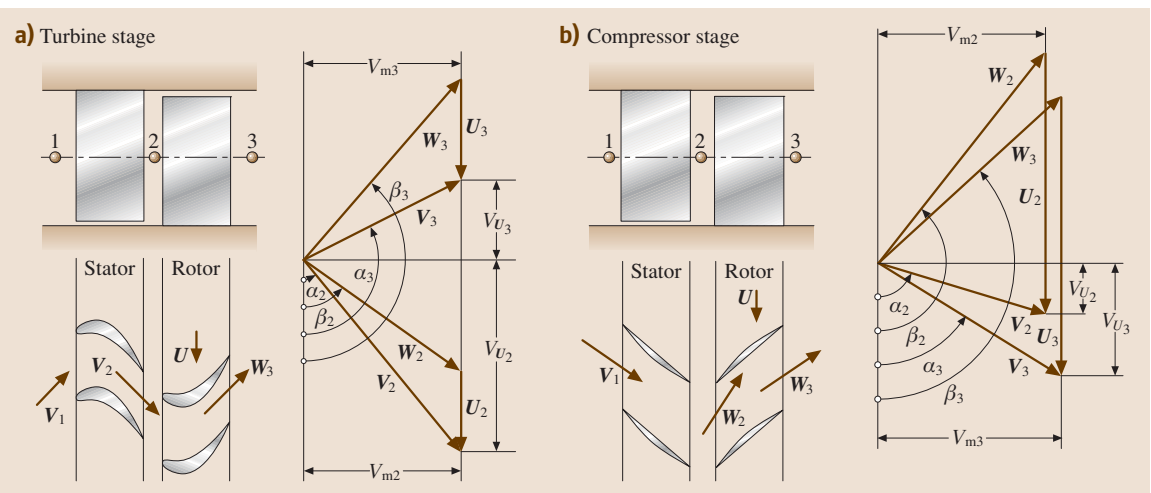

Fig. 12.7a,b Turbine (a) and compressor (b) stages with corresponding velocity diagrams

Since for the stage type under consideration, $V_1 = V_3$ and $U_2 = U_3$, (12.16) can be simplified as

$$r = \frac{W_3^2 - W_2^2}{W_3^2 - W_2^2 + V_2^2 - V_3^2} \,. \tag{12.17}$$

The velocity vectors and the corresponding kinetic energies are determined from the stage velocity diagram in connection with the angle and direction convention as follows

$$\begin{aligned} V_2 &= e_1(W_{u2} + U_2) + e_2 W_{m2} \,, \\ V_2^2 &= (W_{u2} + U_2)^2 + W_{m2}^2 \,, \\ V_3 &= e_1(W_{u3} + U_3) + e_2 W_{m3} \,, \\ V_3^2 &= (W_{u3} + U_3)^2 + W_{m3}^2 \,, \end{aligned} \tag{12.18}$$

since $U_2 = U_3 = U$,

$$V_2^2 - V_3^2 = W_2^2 - W_3^2 + 2UW_{u2} + 2UW_{u3} \,. \tag{12.19}$$

Using (12.18) and (12.19), (12.17) gives

$$r = \frac{W_3^2 - W_2^2}{2U(W_{u2} + W_{u3})} = \frac{W_{u3}^2 - W_{u2}^2}{2U(W_{u2} + W_{u3})} \,. \tag{12.20}$$

Rearranging (12.20) yields the final relationship for the particular stage we introduced above

$$r = \frac{1}{2}\frac{W_{u3} - W_{u2}}{U} \,. \tag{12.21}$$

12.1.5 Relation Between Degree of Reaction and Blade Height for a Normal Stage Using Simple Radial Equilibrium

In axial flow compressors or turbines, the working fluid has a rotational and translational motion. The rotating fluid is subjected to centrifugal forces that must be balanced by the pressure gradient in order to maintain the radial equilibrium. Consider an infinitesimal sector of an annulus with unit depth containing the fluid element which is rotating with tangential velocity V_u.

The centrifugal force acting on the element is shown in Fig. 12.8. Since the fluid element is in radial equilibrium, the centrifugal force is obtained from

$$\mathrm{d}F = \mathrm{d}m\frac{V_u^2}{R} \tag{12.22}$$

with $\mathrm{d}m = \rho R\,\mathrm{d}R\,\mathrm{d}\phi$. The centrifugal force is kept in balance by the pressure forces

$$\frac{\mathrm{d}\rho}{\mathrm{d}R} = p\frac{\mathrm{d}p}{\mathrm{d}\rho}\frac{V_u^2}{R} \,. \tag{12.23}$$

This result can also be obtained by decomposing the Euler equation of motion [12.1, Chap. 3, Eq. (3.46)] for inviscid flows into its three components in a cylindrical coordinate system. The Euler equation is expressed as

$$\boldsymbol{V} \cdot \nabla \boldsymbol{V} = -\frac{1}{\rho}\nabla p \,. \tag{12.24}$$

In the radial direction

$$V_r\frac{\partial V_r}{\partial R} + V_u\frac{\partial V_r}{R\partial\varphi} + V_z\frac{\partial V_r}{\partial z} - \frac{V_u^2}{R} = -\frac{1}{\rho}\frac{\partial p}{\partial R} \,. \tag{12.25}$$

The assumptions needed to arrive at (12.23) are

$$\frac{\partial V_r}{\partial R} \simeq 0 \,, \text{ axial symmetric: } \frac{\partial V_r}{\partial \varphi} = 0 \,, \quad \frac{\partial V_r}{\partial z} \simeq 0 \,. \tag{12.26}$$

With these assumptions, (12.24) yields

$$\frac{1}{\rho}\frac{\partial p}{\partial R} = \frac{V_u^2}{R} \,. \tag{12.27}$$

Equation (12.27) is identical with (12.23). Calculation of a static pressure gradient requires additional information from the total pressure relation. For this purpose, we apply the Bernoulli equation neglecting the gravitational term

$$P = p + \frac{1}{2}\rho V^2 = p + \frac{1}{2}\rho\left(V_u^2 + V_{ax}^2\right) \,. \tag{12.28}$$

Using (12.28), the change in radial direction is

$$\frac{\mathrm{d}p_0}{\mathrm{d}R} = \frac{\mathrm{d}p}{\mathrm{d}R} + \rho V_u\frac{\mathrm{d}V_u}{\mathrm{d}R} + \rho V_{ax}\frac{\mathrm{d}V_{ax}}{\mathrm{d}R} \,. \tag{12.29}$$

If the stagnation or total pressure $P = p_0 = \text{const}$ and $V_{ax} = \text{const}$, (12.29) yields

$$\frac{\mathrm{d}p}{\mathrm{d}R} + \rho V_u\frac{\mathrm{d}V_u}{\mathrm{d}R} = 0 \,, \quad \text{or} \quad \frac{\mathrm{d}p}{\mathrm{d}R} = -\rho V_u\frac{\mathrm{d}V_u}{\mathrm{d}R} \,. \tag{12.30}$$

Equating (12.30) and (12.23) results in

$$V_u\frac{\mathrm{d}V_u}{\mathrm{d}R} + \frac{V_u^2}{R} = 0 \tag{12.31}$$

or

$$\frac{\mathrm{d}V_u}{V_u} + \frac{\mathrm{d}R}{R} = 0 \,. \tag{12.32}$$

The integration of (12.32) leads to $V_u R = \text{const}$. This type of flow is called free vortex flow and fulfills the requirement to be potential flow, $\nabla \times V = 0$. We use

this relation to rearrange the specific stage mechanical energy

$$l_m = U_2 V_{u2} + U_3 V_{u3} = \omega(R_2 V_{u2} + R_3 V_{u3}) \,. \quad (12.33)$$

At station 2 the swirl is $R_2 V_{u2} = \text{const} = K_2$; likewise at station 3 the swirl is $R_3 V_{u3} = K_3$. Since $\omega = \text{const}$, the specific stage mechanical energy is constant

$$l_m = (K_2 + K_3)\omega = \text{const} \,. \quad (12.34)$$

Equation (12.34) implies that, for a stage with constant spanwise meridional components and constant total pressure from hub to tip, the specific stage mechanical energy is constant over the entire blade height. To express the degree of reaction in the spanwise direction, we replace the enthalpy differences in (12.15) by pressure differences. For this purpose we apply the first law for an adiabatic process through stator and rotor blades expressed in terms of $\Delta h'' = \bar{v}'' \Delta p''$ and $\Delta h' = \bar{v}' \Delta p'$. This leads to

$$r = \frac{\bar{v}'' \Delta p''}{\bar{v}'' \Delta p'' + \bar{v}' \Delta p'} = \frac{\Delta p''}{\Delta p'' + \frac{\bar{v}'}{\bar{v}''} \Delta p'} \simeq \frac{p_2 - p_3}{p_1 - p_3} \,. \quad (12.35)$$

In (12.35), the ratio of specific volumes was approximated as $\bar{v}'/\bar{v}'' \simeq 1$. This approximation is admissible for low Mach number ranges. Considering $R_2 V_{u2} = \text{const}$, the integration of (12.23) for station 1 from an arbitrary diameter R to the mean diameter R_m yields

$$(p_1 - p_{m1}) = \frac{\rho}{2} (V_{um})_1^2 \left(1 - \frac{R_m^2}{R^2}\right)_1 \,. \quad (12.36)$$

At station 2 we have

$$(p_2 - p_{m2}) = \frac{\rho}{2} (V_{um})_2^2 \left(1 - \frac{R_m^2}{R^2}\right)_2 \quad (12.37)$$

and finally, at station 3 we arrive at

$$(p_3 - p_{m3}) = \frac{\rho}{2} (V_{um})_3^2 \left(1 - \frac{R_m^2}{R^2}\right)_3 \,, \quad (12.38)$$

with $(R_m)_1 = (R_m)_2 = (R_m)_3$ and $V_{um3} = V_{um1}$. Introducing (12.36)–(12.38) into (12.35), we finally arrive at a simple relationship for the degree of reaction

$$\frac{1 - r}{1 - r_m} - \frac{R_m^2}{R^2} \,. \quad (12.39)$$

From a turbine design point of view, it is of interest to estimate the degree of reaction at the hub and tip radius by inserting the corresponding radii into (12.39). As a result, we find

$$\frac{1 - r_h}{1 - r_m} = \left(\frac{R_m}{R_h}\right)^2 \,, \quad \frac{1 - r_t}{1 - r_m} = \left(\frac{R_m}{R_t}\right)^2 \,. \quad (12.40)$$

Equation (12.40) represents a simple radial equilibrium condition which allows the calculation of the inlet flow angle in a radial direction by integrating (12.32)

$$V_u R = \text{const} \,, \quad R = \frac{\text{const}}{V_u} \,. \quad (12.41)$$

This leads to the determination of the inlet flow angle in a spanwise direction as

$$\frac{R_m}{R} = \frac{\cot \alpha_1}{\cot \alpha_m} \,. \quad (12.42)$$

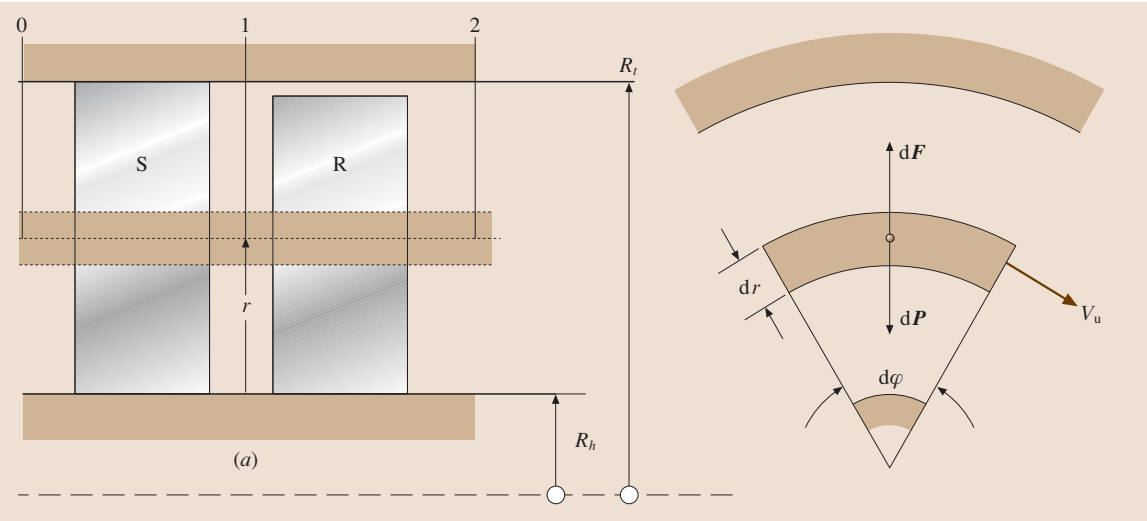

Fig. 12.8 Explanation for simple radial equilibrium

12.1.6 Effect of Degree of Reaction on the Stage Configuration

The distribution of degree of reaction can also be obtained simply by using the velocity ratio for r. If, for example, the degree of reaction at the mean diameter is set at $r = 50\%$, (12.40) immediately calculates r at the hub and tip for the simple radial equilibrium condition $V_u R = \text{const}$, as presented above. It should be mentioned that for a turbine a negative degree of reaction at the hub may lead to flow separation and is not desired. Likewise, for a compressor, r should not exceed the value of 100%. The value of r has major design consequences. For turbine blades with $r = 0$, as shown in Figs. 12.9a and 12.10, the flow is deflected in the rotor and exit velocity vectors have the same magnitude but opposite directions. The entire stage static enthalpy difference is partially converted within the stator row. Note that the flow channel cross section remains constant. For $r = 0.5$, shown in Fig. 12.9b, a fully symmetric blade configuration is established. Figure 12.9c shows a turbine stage with $r > 0.5$. In this case, the flow deflection inside the rotor row is much greater than the one inside the stator row. Figure 12.10 shows the flow deflection within a high-speed rotor cascade. In the past, mainly two types of stages were common designs in steam turbines. The stage with a constant pressure across the rotor blading ($p_2 = p_3$), called an *action stage*, was used frequently. This turbine stage was designed such that the exit absolute velocity vector V_3 was swirl free. It is most appropriate for the design of single-stage turbines and as the last stage of a multistage turbine. The *exit loss*, which corresponds to the kinetic energy of the exiting mass flow, becomes a minimum by using a swirl-free absolute velocity. The stage with $r = 0.5$ is called the *reaction stage*.

12.1.7 Effect of the Stage Load Coefficient on Stage Power

The stage load coefficient λ defined in (12.13) is an important parameter, which describes the capability of the stage to generate/consume shaft power. A turbine stage with low flow deflection, and thus low specific stage load coefficient λ, generates lower specific mechanical energy. To increase the stage mechanical energy l_m, blades with higher flow deflection are used that produce higher stage load coefficient λ. The effect of an increased λ is shown in Fig. 12.11, where three different bladings are plotted.

The top blading with the stage load coefficient $\lambda = 1$ has lower deflection. The middle blading has a moderate flow deflection and moderate $\lambda = 2$, which delivers twice as much stage power as the top blading. Finally, the bottom blading with $\lambda = 3$ delivers three times the stage power as the first one. In the practice of turbine design, among other things, two major parameters must be considered: the specific load coefficients and the stage polytropic efficiencies.

Lower deflection generally yields higher stage polytropic efficiency, but many stages are needed to produce the required turbine power. However, the same turbine

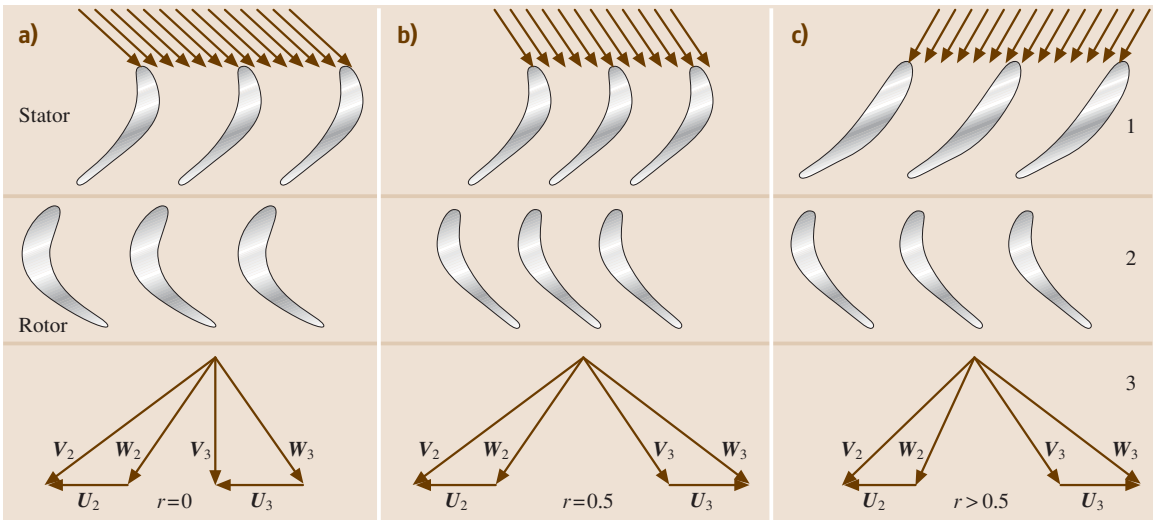

Fig. 12.9a–c Effect of degree of reaction on the stage configuration

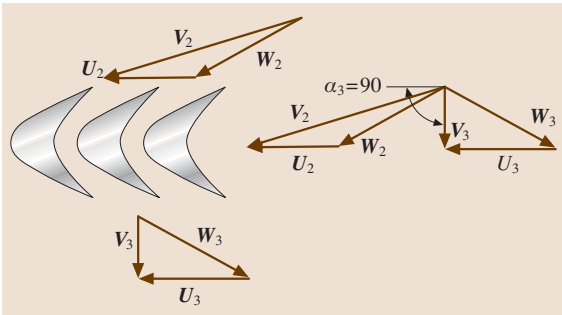

Fig. 12.10 Flow through a high-speed turbine rotor with a degree of reaction $r = 0.0$, note that $\alpha_3 = 90°$ and $|\boldsymbol{W}_2| = |\boldsymbol{W}_3|$

power may be established by a higher stage flow deflection, and thus a higher λ, at the expense of the stage efficiency. Increasing the stage load coefficient has the advantage of significantly reducing the stage number, thus lowering the engine weight and manufacturing cost. In aircraft engine design practice, one of the most critical issues besides the thermal efficiency of the engine is the thrust-to-weight ratio. Reducing the number of stages may lead to a desired thrust-to-weight ratio. While a high turbine stage efficiency has top priority in power generation steam and gas turbine design, the thrust-to-weight ratio is the major parameter for aircraft engine designers.

12.1.8 Unified Description of a Turbomachinery Stage

The following sections treat turbine and compressor stages from a unified standpoint. Axial, mixed flow, and radial flow turbines and compressors follow the same thermodynamic conservation principles. Special treatments are indicated when dealing with aerodynamic behavior and loss mechanisms. While turbine aerodynamics is characterized by negative (favorable) pressure gradient environments, the compression process operates in a positive (adverse) pressure gradient environment. As a consequence, partial or total flow separation may occur on compressor blade surfaces, leading to partial stall or surge. On the other hand, with the exception of some minor local separation bubbles on the suction surface of highly loaded low-pressure turbines blades, a turbine normally operates without major flow separation or breakdown. These two distinctively different aerodynamic behaviors are due to the different pressure gradient environments. Turbine and compressor cascade aerodynamics and losses are extensively treated in [12.1, Chaps. 7 and 16]. In this section, we will first present a set of algebraic equations that describes turbine and compressor stages with constant mean diameter and then extend the approach to general cases where the mean stage diameter changes.

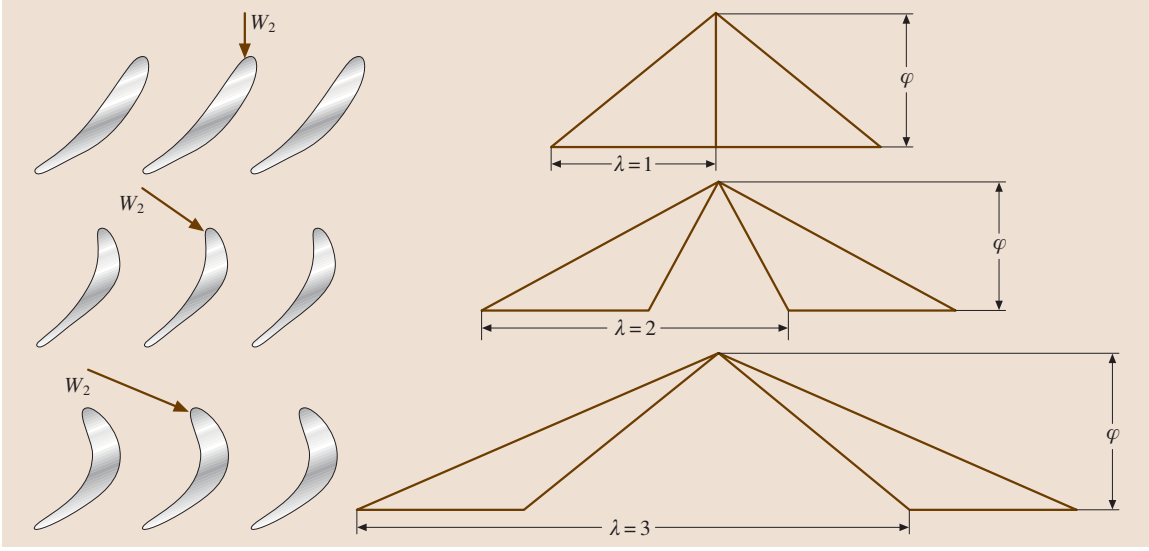

Fig. 12.11 Dimensionless stage velocity diagram to explain the effect of the stage load coefficient λ on flow deflection and blade geometry, $r = 0.5$

Unified Description of Stages with Constant Mean Diameter

For a turbine or compressor stage with constant mean diameter (Fig. 12.7), we present a set of equations that describe the stage by means of dimensionless parameters such as stage flow coefficient ϕ, stage load coefficient λ, degree of reaction r, and the flow angles. From the velocity diagram with the angle definition in Fig. 12.7, we obtain the flow angles

$$\begin{aligned}\cot\alpha_2 &= \frac{U_2 + W_{u2}}{V_{ax}} = \frac{1}{\phi}\left(1 + \frac{W_{u2}}{U}\right)\\ &= \frac{1}{\phi}\left(1 - r + \frac{\lambda}{2}\right),\\ \cot\alpha_3 &= -\frac{W_{u2} - U_2}{V_{ax}} = -\frac{1}{\phi}\left(\frac{W_{u3} - U}{U}\right)\\ &= \frac{1}{\phi}\left(1 - r - \frac{\lambda}{2}\right). \end{aligned} \tag{12.43}$$

The other flow angles can be found similarly, thus we summarize

$$\cot\alpha_2 = \frac{1}{\phi}\left(1 - r + \frac{\lambda}{2}\right), \tag{12.44}$$

$$\cot\alpha_3 = \frac{1}{\phi}\left(1 - \frac{\lambda}{2} - r\right), \tag{12.45}$$

$$\cot\beta_2 = \frac{1}{\phi}\left(\frac{\lambda}{2} - r\right), \tag{12.46}$$

$$\cot\beta_3 = -\frac{1}{\phi}\left(\frac{\lambda}{2} + r\right). \tag{12.47}$$

The stage load coefficient can be calculated from

$$\lambda = \phi(\cot\alpha_2 - \cot\beta_3) - 1\,. \tag{12.48}$$

The velocity diagram of the last stage of a compressor or a turbine differs considerably from the normal stage. As mentioned in the previous section, to minimize the *exit losses*, the last stage usually has an exit flow angle of $\alpha_3 = 90°$. Figure 12.12 compares the velocity diagram of a normal stage with the one in the last stage of the same turbine component. As shown, by changing the exit flow angle to $\alpha_3 = 90°$ a substantial reduction in exit velocity vector V_3, and thus the exit kinetic energy V_3^2, can be achieved. This subject is treated in [12.1, Chap. 7] in detail.

Generalized Dimensionless Stage Parameters

Now we extend the foregoing consideration to compressor and turbine stages where the diameter, circumferential velocities, and meridional velocities are not constant. Examples are axial flow turbine and compressors (Figs. 12.5 and 12.6), radial inflow (centripetal) turbines (Fig. 12.13), and centrifugal compressors (Fig. 12.14).

In the following, we develop a set of unifying equations that describes the above axial turbine and compressor stages, as well as the centripetal turbine and centrifugal compressor stages shown in Figs. 12.13 and 12.14. We introduce new dimensionless parameters

$$\mu = \frac{V_{m2}}{V_{m3}}\,,\quad \nu = \frac{R_2}{R_3} = \frac{U_2}{U_3}\,,\quad \phi = \frac{V_{m3}}{U_3}\,,\quad \lambda = \frac{l_m}{U_3^2}\,,$$
$$r = \frac{\Delta h''}{\Delta h' + \Delta h''}\,, \tag{12.49}$$

with V_m, U from the velocity diagrams and $\Delta h'$ and $\Delta h''$ as the specific static enthalpy difference in the rotor and stator, respectively. The dimensionless parameters μ represents the meridional velocity ratio for the stator and rotor, respectively, ν is the circumferential velocity ratio, ϕ is the stage flow coefficient, λ is the stage load coefficient, and r is the degree of reaction. Introducing these parameters into the equations of continuity, moment of momentum, and the relation for degree of reaction, the stage is completely defined by a set of four

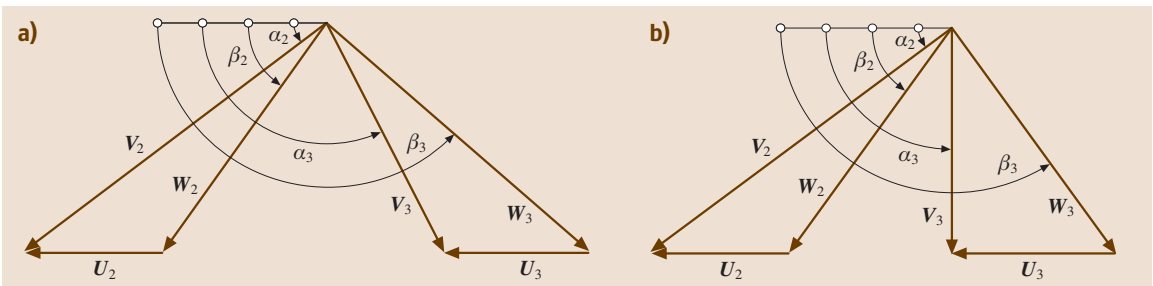

Fig. 12.12a,b Turbine stage velocity diagrams: **(a)** for a normal stage, and **(b)** for the last stage of a multistage turbine

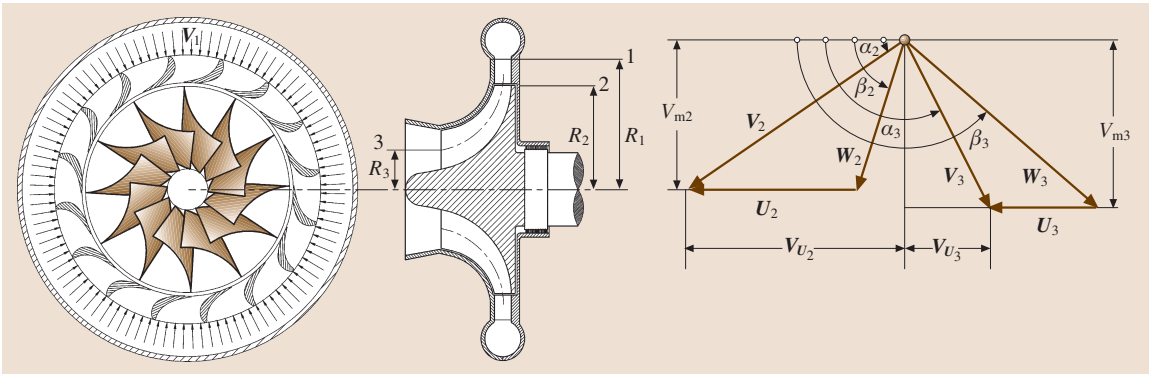

Fig. 12.13 A centripetal turbine stage with cross section and velocity diagram

equations

$$\cot\alpha_2 - \cot\beta_2 = \frac{\nu}{\mu\,\phi}\,, \tag{12.50}$$

$$\cot\alpha_3 - \cot\beta_3 = \frac{1}{\phi}\,, \tag{12.51}$$

$$r = 1 + \frac{\phi^2}{2\lambda}\left[1 + \cot^2\alpha_3 - \mu^2\left(1 + \cot^2\alpha_2\right)\right], \tag{12.52}$$

$$\lambda = \phi(\mu\nu\cot\alpha_2 - \cot\beta_3) - 1\,. \tag{12.53}$$

While (12.50), (12.51) and (12.53) are exact, (12.52) is only an approximation. However, its exact value can be obtained by solving equation system (12.54). The system of (12.50–12.53) contains nine unknown stage parameters. To find a solution, five parameters must be guessed. Appropriate candidates for the first guess are: the diameter ratio, $\nu = R_2/R_3 = U_2/U_3$, the stator and rotor exit angles α_2 and β_3, the exit flow angle α_3, and the stage degree of reaction r. In addition, the stage flow coefficient ϕ can be estimated by implementing the information about the mass flow and using the continuity equation. Likewise, the stage load coefficient λ can be estimated for turbine or compressor stages by employing the information about the compressor pressure ratio or turbine power. Once the five parameters are guessed, the rest of the four parameters are determined by solving the above equation system. In this case, the four parameters calculated fulfill the conservation laws for the particular compressor or turbine blade geometry for which the five stage parameters were guessed. This preliminary estimation of stage parameters, however, is considered the first iteration toward an optimum design. A subsequent loss and efficiency calculation, presented in [12.1, Chap. 8], will clearly show if the guessed parameters were useful or not. In fact, a few iterations are necessary to find the optimum configuration that fulfills the efficiency requirement set by

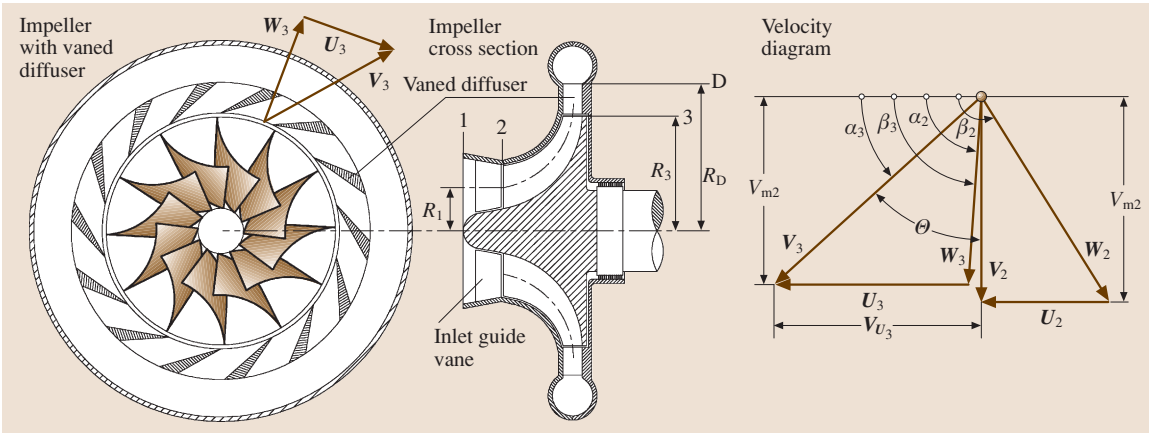

Fig. 12.14 A centrifugal compressor stage with cross section and velocity diagram

the compressor or turbine designer. Equations (12.50–12.53) can be expressed in terms of the flow angles α_2, α_3, β_2, and β_3, which lead to a set of four nonlinear equations

$$\begin{aligned}
&\mu^2\phi^2(1-\nu^2)\cot^2\alpha_2 + 2\mu\nu\,\phi\,\lambda\cot\alpha_2 - \lambda^2 \\
&\quad - 2(1-r)\lambda + (\mu^2-1)\phi^2 = 0\,, \\
&\phi^2(1-\nu^2)\cot^2\alpha_3 + 2\phi\,\lambda\cot\alpha_3 + \lambda^2 \\
&\quad - 2(1-r)\lambda\nu^2 + (\mu^2-1)\phi^2\nu^2 = 0\,, \\
&(1-\nu^2)(\mu\,\phi\cot\beta_2 + \nu)^2 + 2\nu\,\lambda(\phi\,\mu\cot\beta_2 + \nu) - \lambda^2 \\
&\quad - 2(1-r)\lambda + (\mu^2-1)\phi^2 = 0\,, \\
&(1-\nu^2)(\phi\cot\beta_3 + 1)^2 + 2\lambda(\phi\cot\beta_3 + 1) + \lambda^2 \\
&\quad - 2(1-r)\lambda\nu^2 + (\mu^2-1)\phi^2\nu^2 = 0\,.
\end{aligned} \tag{12.54}$$

12.1.9 Special Cases

Equations (12.50–12.54) are equally valid for axial, radial, and mixed flow turbine and compressor stages. Special stages with corresponding dimensionless parameters are described as special cases as listed below.

Case 1: Constant Mean Diameter

In this special case, the diameter remains constant, leading to the circumferential velocity ratio of $\nu = U_2/U_3 = 1$. The meridional velocity ratio is $\mu = V_{m2}/V_{m3} \neq 1$. The flow angles expressed in terms of other dimensionless parameters are

$$\begin{aligned}
\cot\alpha_2 &= \frac{1}{\phi\,\mu}\left[\frac{\lambda}{2} + (1-r) - (\mu^2-1)\frac{\phi^2}{2\lambda}\right], \\
\cot\alpha_3 &= \frac{1}{\phi}\left[-\frac{\lambda}{2} - (1-r) - (\mu^2-1)\frac{\phi}{2\lambda}\right], \\
\cot\beta_2 &= \frac{1}{\mu\,\phi}\left[\frac{\lambda}{2} + (1-r) - (\mu^2-1)\frac{\phi^2}{2\lambda} - 1\right], \\
\cot\beta_3 &= \frac{1}{\phi}\left[-\frac{\lambda}{2} + (1-r) - (\mu^2-1)\frac{\phi}{2\lambda} - 1\right].
\end{aligned} \tag{12.55}$$

The stage load coefficient is calculated from

$$\lambda = \phi(\mu\cot\alpha_2 - \cot\beta_3) - 1 \quad \text{for } \nu = 1 \text{ and } \mu \neq 1\,. \tag{12.56}$$

Case 2: Constant Mean Diameter and Meridional Velocity Ratio

In this special case, the circumferential and meridional velocities are equal, leading to $\nu = U_2/U_3 = 1$, $\mu = V_{m2}/V_{m3} = 1$. The flow angles are calculated from

$$\begin{aligned}
\cot\alpha_2 &= \frac{1}{\phi}\left(\frac{\lambda}{2} - r + 1\right), \\
\cot\alpha_3 &= \frac{1}{\phi}\left(-\frac{\lambda}{2} - r + 1\right).
\end{aligned} \tag{12.57}$$

The stage load coefficient is calculated from

$$\lambda = \phi(\cot\alpha_2 - \cot\beta_3) - 1 \quad \text{for } \nu = 1 \text{ and } \mu = 1\,. \tag{12.58}$$

The generalized stage load coefficient for different μ, ν-cases can be summarized as

$$\begin{aligned}
\lambda &= \phi[\mu\nu\cot\alpha_2 - \cot\beta_3] - 1 \quad \text{for } \nu \neq 1 \text{ and } \mu \neq 1\,, \\
\lambda &= \phi[\mu\cot\alpha_2 - \cot\beta_3] - 1 \quad \text{for } \nu = 1 \text{ and } \mu \neq 1\,, \\
\lambda &= \phi[\nu\cot\alpha_2 - \cot\beta_3] - 1 \quad \text{for } \nu \neq 1 \text{ and } \mu = 1\,, \\
\lambda &= \phi[\cot\alpha_2 - \cot\beta_3] - 1 \quad \text{for } \nu = 1 \text{ and } \mu = 1\,.
\end{aligned} \tag{12.59}$$

12.1.10 Increase of Stage Load Coefficient: Discussion

Following the discussion in Sect. 12.1.3 regarding the increase of the specific stage mechanical energy and the subsequent discussion in Sect. 12.1.8, we proceed with (12.53), where the stage load parameter λ is expressed in terms of μ and ν and the blade angle α_2 and β_3 as

$$\lambda = \phi(\mu\nu\cot\alpha_2 - \cot\beta_3) - 1\,. \tag{12.60}$$

The effect of flow deflection on the stage load coefficient of axial flow turbines was already discussed in Sect. 12.1.8. As we saw, turbine blades can be designed with stage load coefficients λ as high as 3 or more. In turbine blades with high λ and Reynolds numbers $\mathrm{Re} = V_{exit}\,c/\nu > 150\,000$, the governing strong negative pressure gradient prevents major separation from occurring in the flow. However, if the same type of blade operates at lower Reynolds numbers, flow separation that results in a noticeable increase of profile losses may occur. For high-pressure turbines (HPT), the strong favorable pressure gradient within the blade channels prevents major separation from occurring in the flow. However, low-pressure turbine (LPT) blades, particularly those of aircraft gas turbine engines that operate at low Reynolds numbers (cruise conditions up to $\mathrm{Re} = 120\,000$), are subjected to laminar flow separation and turbulent reattachment. While axial turbine blades can be designed with relatively high positive λ,

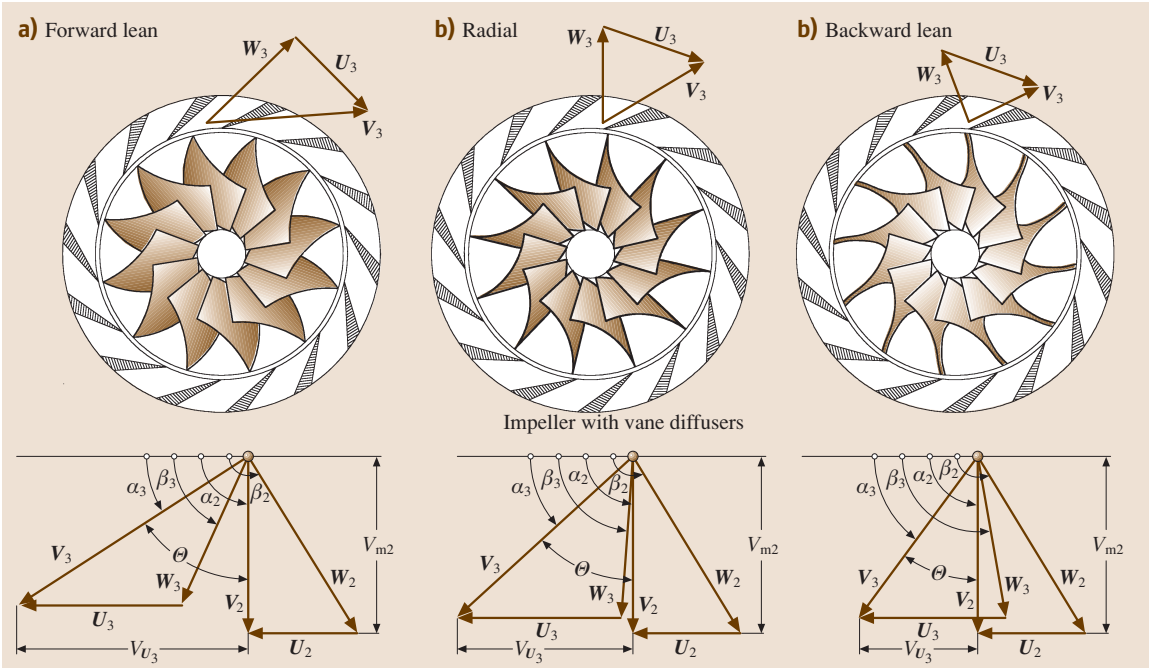

Fig. 12.15a–c Centrifugal compressor stage with velocity diagrams: **(a)** forward lean, **(b)** radial zero lean, and **(c)** backward lean

the flow through axial compressor blade channels is susceptible to flow separation, even at relatively low λ. This is primarily due to a positive pressure gradient in the streamwise direction that causes the boundary layer to separate once a certain deflection limit or a *diffusion factor* (see [12.1, Chap. 16]) has been exceeded. To achieve a higher λ, and thus a higher stage pressure ratio, a smaller diameter ratio $\nu = D_2/D_3 = U_2/U_3$ can be applied. Using a moderate diameter ratio range of $\nu = 0.85 - 0.75$ results in a mixed flow configuration. At a lower range of ν, such as $\nu = 0.75 - 0.4$, a centrifugal compressor configuration is designed.

Figure 12.15 shows, schematically, three centrifugal compressors with three different exit flow angles and the corresponding velocity diagrams. Figure 12.15a shows a centrifugal impeller in which the trailing edge portion is forward leaning with a negative lean angle of $\Delta\beta = \beta_3 - 90° < 0$. The reference configuration Fig. 12.15b shows an impeller with a radial exit flow angle $\beta_3 = 90°$ and thus $\Delta\beta = 0$. Finally, Fig. 12.15c shows an impeller with a backward-leaned trailing edge portion with a positive lean angle of $\Delta\beta = \beta_3 - 90° > 0$. All three

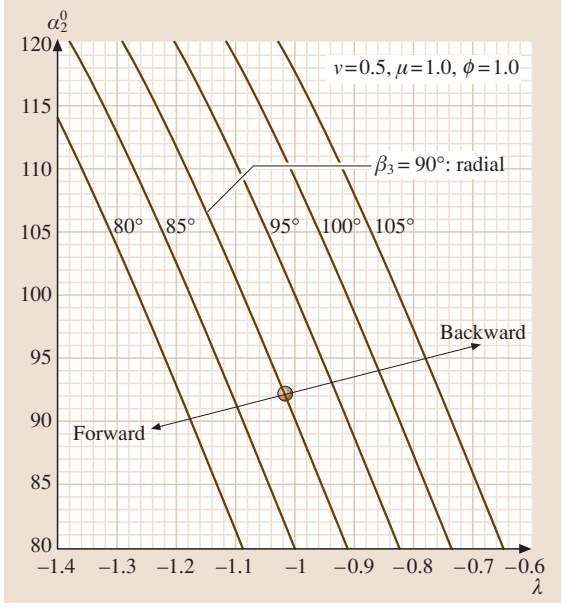

Fig. 12.16 Influence of lean angle on λ: forward lean with $\beta_3 < 90°$, backward lean $\beta_3 > 90°$, and zero lean $\beta_3 = 90°$

impellers have the same diameter ratio ν and the same rotational speed ω. The λ-behavior of these impellers is shown in Fig. 12.16, where the relative exit flow angle is varied in the range of $\beta_3 = 80° - 105°$. As shown, forward lean results in higher deflection Θ, larger ΔV_u, and thus higher negative λ, which is associated with a higher profile loss. Backward lean, however, reduces the flow deflection Θ and ΔV_u. As a result, the stage load coefficient λ is reduced. For the comparison, the radial exit case with $\beta_3 = 90°$ is plotted. In calculating the stage load coefficient λ, the influence of the radius ratio $\nu = R_2/R_3 = U_2/U_3$ on the stage load coefficient becomes clear.

12.2 Gas Turbine Engines: Design and Dynamic Performance

A gas turbine engine is a system that consists of several turbomachinery components and auxiliary subsystems. Air enters the compressor component, which is driven by a turbine component that is placed on the same shaft. Air exits the compressor at a higher pressure and enters the combustion chamber, where the chemical energy of the fuel is converted into thermal energy, producing combustion gas at a temperature that corresponds to the turbine inlet design temperature. The combustion gas expands in the following turbine component, where its total energy is partially converted into shaft work and exit kinetic energy. For power generation gas turbines, the shaft work is the major portion of the above energy forms. It covers the total work required by the compressor component, the bearing frictions, several auxiliary subsystems, and the generator. In aircraft gas turbines, a major portion of the total energy goes toward generation of high exit kinetic energy, which is essential for thrust generation.

Gas turbines are designed for particular applications that determine their design configurations. For power generation purposes, the gas turbine usually has a *single spool*. A spool combines a compressor and a turbine that are connected together via a shaft. Figure 12.17 exhibits a single-spool power generation gas turbine, where a 14-stage compressor shares the same shaft with a three-stage turbine.

While in power generation gas turbine design the power-to-weight ratio does not play an important role, the thrust-to-weight ratio is a primary parameter in designing an aircraft gas turbine. High-performance aircraft gas turbine engines generally have twin-spool or multispool arrangements. The spools are usually rotating at different angular velocities and are connected with each other aerodynamically via air or combustion gas. Figure 12.18 exhibits a typical high-performance twin-spool aircraft gas turbine with a *ducted front fan* as the main thrust generator. Gas turbine engines with power capacities less than 20 MW might have a *split shaft* configuration that consists of a *gas generation spool* and a *power shaft*. While the turbine of the gas generation spool provides the shaft work necessary to drive the compressor, the power shaft produces the net power. In addition to the above design configurations, a variety of engine derivatives can be constructed using a core engine as shown in Fig. 12.19.

12.2.1 Gas Turbine Processes, Steady Design Operation

Starting with the single-spool power generation gas turbine that consists of a multistage compressor, a combustion chamber, and a turbine, the h–s diagram is shown in Fig. 12.20a.

The compression process from 1 to 2 is accomplished by the compressor with a polytropic efficiency η_{pol} that can be accurately calculated using the row-by-row or stage-by-stage methods discussed in [12.6]. The combustion process from 2 to 3 is associated with certain total pressure loss coefficient ζ_{comb}, thus it is not considered isobaric. The expansion process from 3 to 4 causes an entropy increase that is determined by the turbine efficiency. Figure 12.20b shows the h–s diagram for a twin-spool aircraft engine. In contrast to the single-spool engine, the compression process is accomplished by two compressors that are operating at two different angular velocities. Air enters the low-pressure (LP) compressor driven by the LP turbine and is compressed from 1 to 2. Further compression from 2 to 3 occurs in the high-pressure compressor (HP compressor) driven by the HP turbine. After addition of fuel in the combustion chamber, the fist expansion occurs in the HP turbine, whose power exactly matches the sum of the HP compressor power and the power required to compensate bearing frictions. The second expansion in the LP turbine matches the power by the LP compressor, bearing friction, and the auxiliary subsystems. In off-design operation, there is always a dynamic

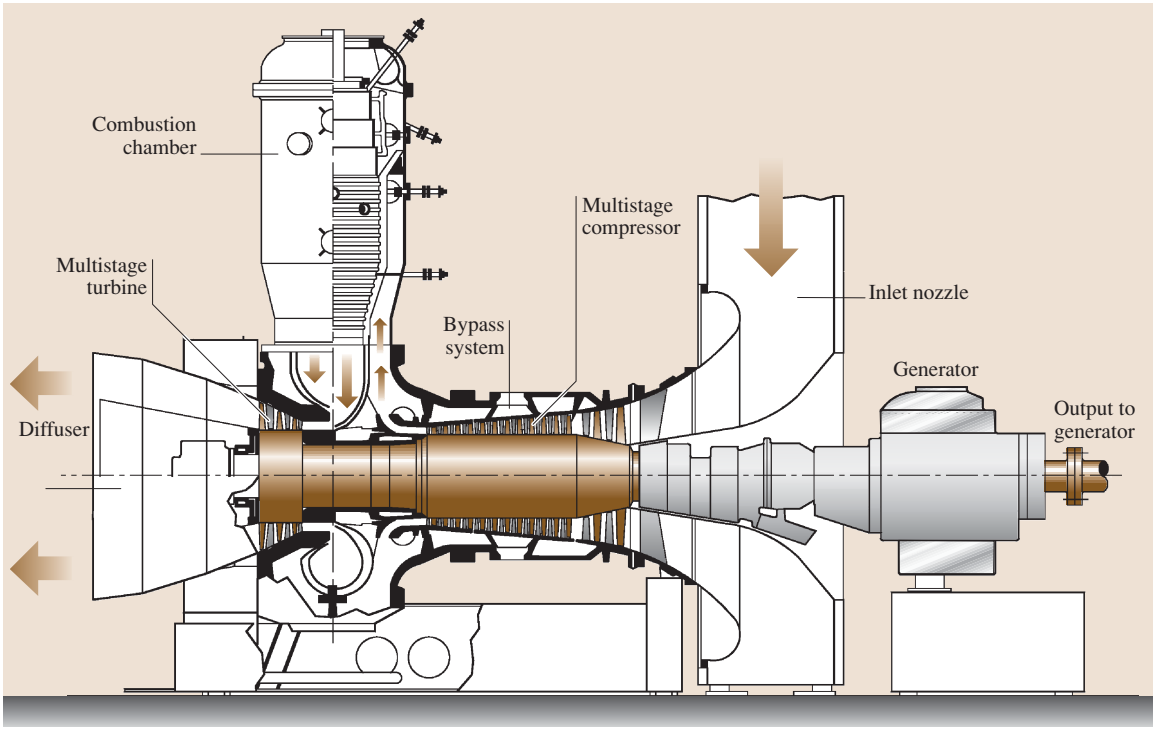

Fig. 12.17 A single-spool power generation gas turbine BBC-GT9

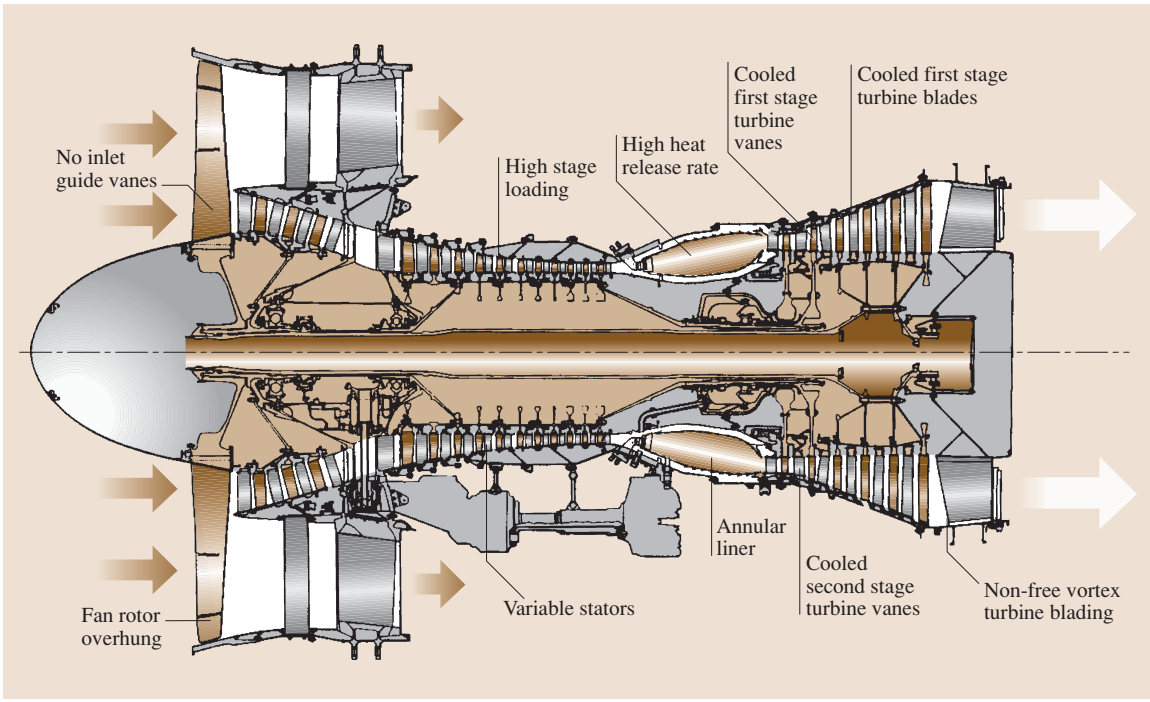

Fig. 12.18 A twin-spool Pratt & Whitney high-bypass-ratio aircraft engine with multistage compressors and turbines

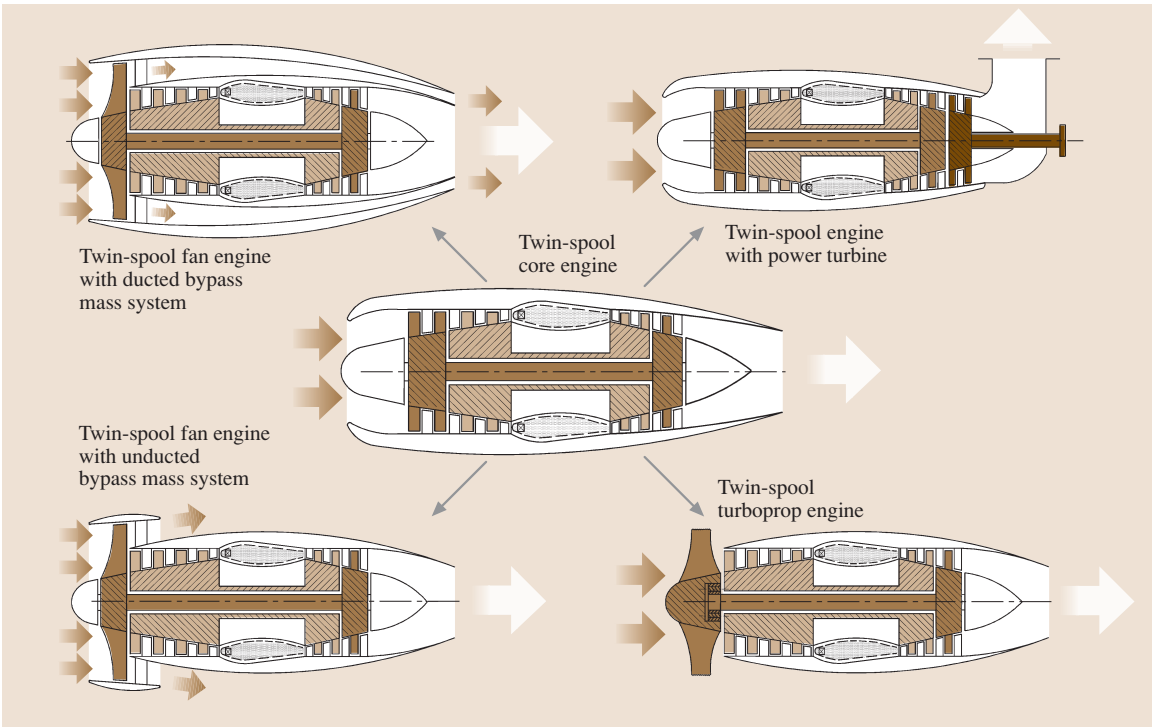

Fig. 12.19 Schematic of a twin-spool core engine with its derivatives

mismatch between the turbine and compressor power that changes the spool rotational speed. This dynamic mismatch is brought to an equilibrium by taking appropriate control measures, as discussed in the following sections. As mentioned briefly, small gas turbines may have a split shaft configuration, as shown in Fig. 12.21. The single-spool gas generator unit provides the power turbine with combustion gas that has the required pressure and temperature to produce the power. As seen in Fig. 12.21a, the specific turbine enthalpy difference is $\Delta h_T \approx \Delta h_C$, leaving the remaining enthalpy difference Δh_{PT} for power generation.

Figure 12.21b shows the h–s diagram of a high-efficiency power generation gas turbine. The schematic cross section of this gas turbine is shown in Fig. 12.25. It consists of a multistage compressor C and a combustion chamber CC1, providing a lean combustion gas that expands in a single-stage reheat turbine (RT). The exhaust gas from the RT enters the second combustion chamber CC2, where the remaining fuel is added to ensure a stoichiometric combustion. It expands in the multistage turbine, which produces the major portion of power. As seen in the following sections, the implementation of the reheat process substantially increases the thermal efficiency of gas turbines. The underlying thermodynamic principles of this concept is the reheat process, which has been very well known in steam turbine design for more than a century. However, in gas turbine design, adding a second combustion chamber to a conventionally designed gas turbine seemed to be associated with unforeseeable problems. Based on design experiences with *compressed air energy storage* (CAES) gas turbines with two combustion chambers, *Brown Boveri* designed and successfully manufactured the first series of power generation gas turbines with a reheat stage and two combustion chambers.

Gas Turbine Process

Accurate prediction of the thermal efficiency of a gas turbine engine requires knowledge of the compressor, combustion chamber, and turbine efficiencies as well as the bearing losses and the losses in auxiliary systems. Furthermore, detailed knowledge of the amount of mass flows with their extraction and injection pressures for cooling the turbine blades and the rotor discs are necessary. In addition, a detailed gas table that accounts for thermodynamic properties of humid air as well as the properties of the combustion gas must be implemented

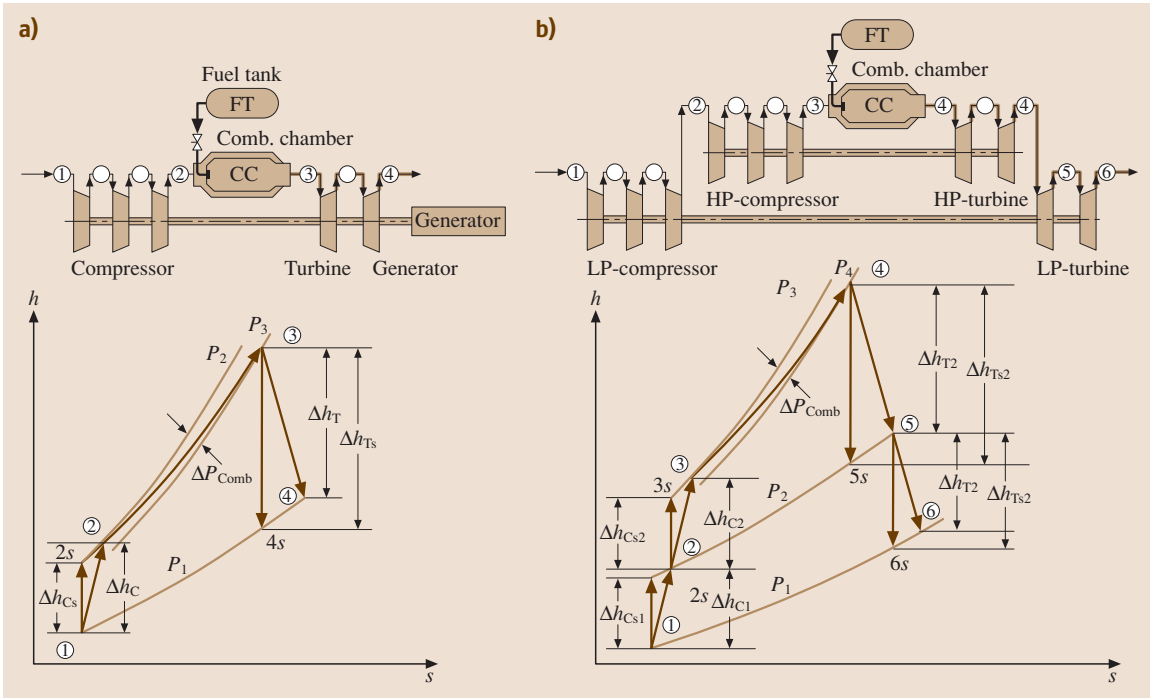

Fig. 12.20a,b *h–s* diagram of **(a)** a single-spool power generation gas turbine and **(b)** a twin-spool aircraft engine

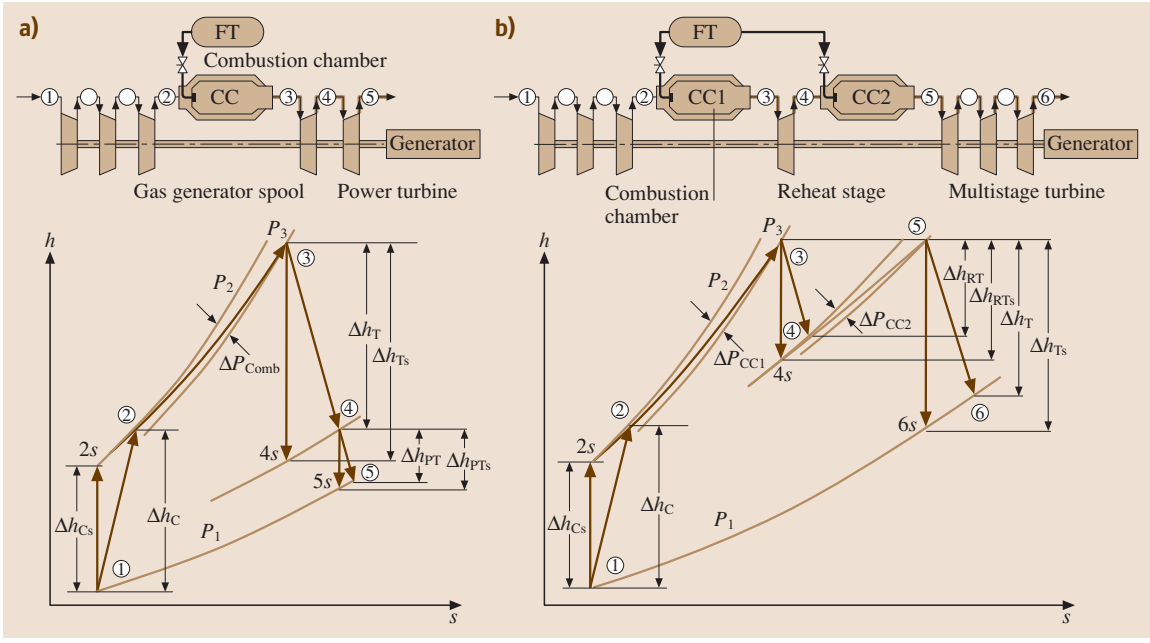

Fig. 12.21a,b *h–s* diagram of **(a)** a single-spool power generation gas turbine with a power shaft and **(b)** a single-spool power generation gas turbine with a reheat stage and two combustion chambers

into the calculation procedure. Assuming that air and combustion gas are calorically perfect gases results in significant errors. Figure 12.22 exhibits a schematic diagram that shows in detail the extraction of different cooling mass flows and their injection locations.

Mass flow through P1 extracted from plenum 3 cools the rotor and does not participate in power generation; mass flows through P2 and P3 cool the second and first turbine stages and remain in the system; and finally, mass flow through P4 reduces the combustion chamber exit temperature before it enters the turbine. At stations 6–8 and 11 humid air is mixed with combustion gas resulting in a local change of water-to-air and fuel-to-air ratios, therefore changing the entire thermodynamic properties including the special gas constant R. In the absence of the above information, reasonable assumptions relative to component efficiencies can be made to qualitatively determine the thermal efficiency and its tendency with regard to parameter variation. In the following section, a simple thermal efficiency calculation procedure is derived that is appropriate for varying different parameters and qualitatively determining their impacts on thermal efficiency.

The gas turbine with its corresponding process is sketched in Fig. 12.23. It consists of a compressor, a recuperator, a combustion chamber, and a turbine. Exhaust gas from the turbine is diverted into the recuperator, heating up the compressed air before entering the combustion chamber. The individual processes are compression, expansion, fuel addition and combustion, and heat exchange in the recuperator. The compressor and turbine enthalpy differences are calculated from

$$h_2 - h_1 = \frac{h_{2s} - h_1}{\eta_c} ,$$
$$h_3 - h_4 = (h_3 - h_{4s})\eta_T . \qquad (12.61)$$

We introduce the following definitions for the recuperator air and gas side (RA, RG), as well as combustion chamber (CC) pressure loss coefficients

$$\zeta_{RA} = \frac{\Delta P_{RA}}{P_2} , \text{ with } \Delta P_{RA} = P_2 - P_5 ,$$
$$\zeta_{RG} = \frac{\Delta P_{RG}}{P_1} , \text{ with } \Delta P_{RG} = P_4 - P_6 ,$$
$$\zeta_{CC} = \frac{\Delta P_{CC}}{P_2} , \text{ with } \Delta P_{CC} = P_5 - P_3 . \qquad (12.62)$$

The thermal efficiency is defined as

$$\eta_{in} = \frac{L_{net}}{\dot{Q}_{in}} = \frac{L_T - L_C}{\dot{Q}_{in}} = \frac{\dot{m}_T l_T - \dot{m}_C l_C}{\dot{Q}_{in}} . \qquad (12.63)$$

The specific net power is calculated from

$$\frac{L_{net}}{\dot{m}_1} = \frac{L_T - L_c}{\dot{m}_1} = \frac{\dot{m}_3 l_T - m_1 l_C}{\dot{m}_1} = (1+\beta) l_T - l_c , \qquad (12.64)$$

with the fuel air ratio $\beta = \dot{m}_f / \dot{m}_1$. Replacing the specific turbine power l_T by the enthalpy difference from

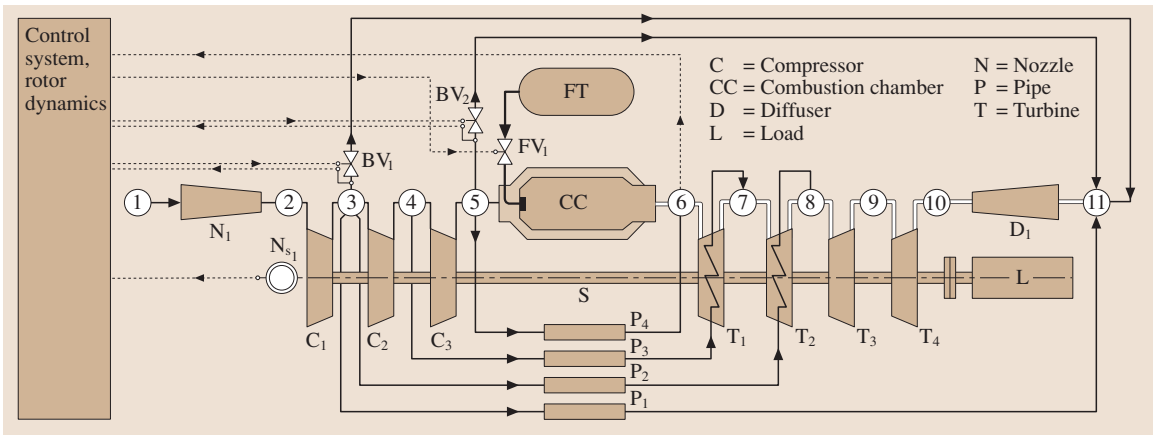

Fig. 12.22 Schematic of a single-spool gas turbine illustrating the mass flow extraction from compressor for different cooling purposes

(12.61), we find

$$\frac{\dot{m}_3}{\dot{m}_1} l_T = (1+\beta)(h_3 - h_4) = \eta_T (1+\beta)(h_3 - h_{4s}) ,$$
$$\frac{\dot{m}_3}{\dot{m}_1} l_T = \eta_T (1+\beta) \bar{c}_{PT} (T_3 - T_{4s}) ,$$
$$\frac{\dot{m}_3}{\dot{m}_1} l_T = \eta_T (1+\beta) \bar{c}_{PT} T_3 \left(1 - \frac{T_{4s}}{T_3}\right) . \qquad (12.65)$$

Equation (12.65) expresses the isentropic enthalpy difference in terms of a product of averaged specific heat at constant pressure and the isentropic temperature difference. The specific heat in (12.65) exhibits an averaged value between the two given temperatures

$$\bar{c}_{PT} = \frac{h_3 - h_{4s}}{T_3 - T_{4s}} . \qquad (12.66)$$

The temperature ratio in (12.65) can be related to the pressure ratio by

$$\frac{T_3}{T_{4s}} = \left(\frac{p_3}{p_4}\right)^{\left(\frac{k-1}{k}\right)_T} = \pi_T^{\left(\frac{k-1}{k}\right)_T} = \pi_T^{m_T} ,$$
$$\text{with } m_T \equiv \left(\frac{k-1}{k}\right)_T . \qquad (12.67)$$

With (12.67), (12.65) becomes

$$\frac{\dot{m}_3}{\dot{m}_1} l_T = \eta_T (1+\beta) \bar{c}_{PT} T_3 \left(1 - \pi_T^{-m_T}\right) . \qquad (12.68)$$

Because of the pressure losses across the combustion chamber, the turbine and compressor pressure ratios are not the same ($\pi_T \neq \pi_c$). Implementing the pressure losses of the combustion chamber and recuperator air side, we find

$$\pi_T = \frac{p_3}{p_4} = \frac{p_2 - \Delta p_{RA} - \Delta p_{CC}}{p_1 + \Delta p_{RA}}$$
$$= \frac{p_2}{p_1} \left(\frac{1 - \zeta_{RA} - \zeta_{CC}}{1 + \zeta_{RA}}\right) = \pi_c \frac{1 - \zeta_{RA} - \zeta_{CC}}{1 + \zeta_{RA}} . \qquad (12.69)$$

We set the fraction on the right-hand side of (12.69) as

$$\epsilon = \frac{1 - \zeta_{RA} - \zeta_{CC}}{1 + \zeta_{RA}} \qquad (12.70)$$

and arrive at

$$\pi_T = \epsilon \pi_c , \text{ for } \epsilon = 0, \zeta_{RA} = \zeta_{CC} = \zeta_{RA} = 0$$
$$\text{and for } \epsilon > 0 \; \zeta_{RA} \neq 0 , \; \zeta_{CC} \neq 0 . \qquad (12.71)$$

For parameter variation, the following values may be used: $\zeta_{RA} \simeq \zeta_{RG} = 2\text{–}8\%$ and $\zeta_{CC} \simeq 5\text{–}10\%$. Following exactly the same procedure defined by (12.64)–(12.71), we find the compressor specific work as

$$l_C = \frac{1}{\eta_C} \bar{c}_{Pc} T_1 \left(\pi_C^{m_C} - 1\right) , \text{ with } m_C = \left(\frac{k-1}{k}\right)_C . \qquad (12.72)$$

Inserting (12.68) and (12.72) into (12.64), we arrive at

$$\eta_{th} = \frac{\eta_T \bar{c}_{PT} T_3 \left[1 - (\epsilon \pi_c)^{-m_T}\right](1+\beta)}{\bar{c}_{PCC} T_1 \left[(1+\beta)\frac{T_3}{T_1} - \frac{T_5}{T_1}\right]}$$
$$- \frac{\frac{1}{\eta_c} \bar{c}_{Pc} T_1 \left(\pi_c^{m_c} - 1\right)}{\bar{c}_{PCC} T_1 \left[(1+\beta)\frac{T_3}{T_1} - \frac{T_5}{T_1}\right]} . \qquad (12.73)$$

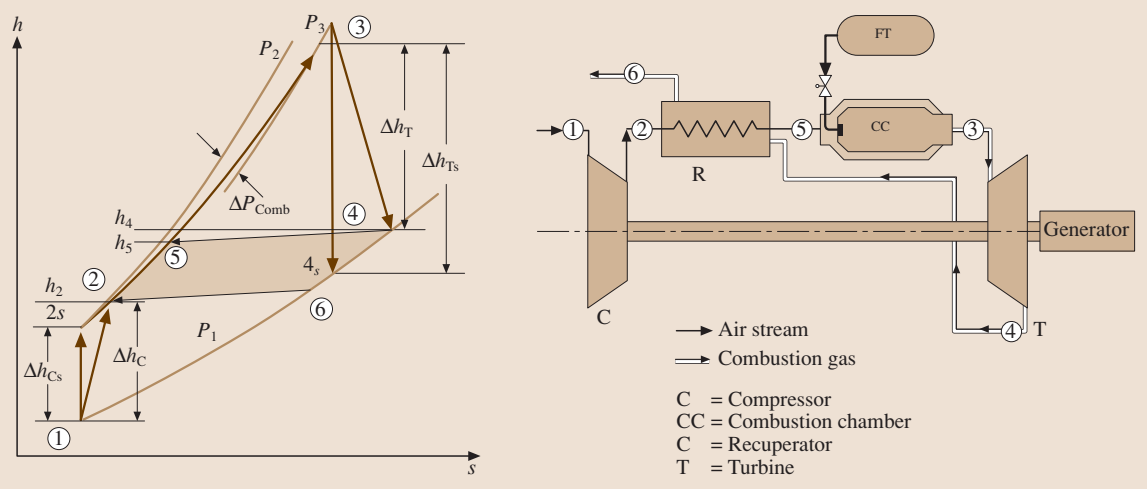

Fig. 12.23 Simple sketch of a gas turbine with recuperator

The turbine inlet temperature T_3 and the environmental temperature T_1, and thus their ratio T_3/T_1, is considered as a known parameter. This parameter can also be used for parametric studies. Therefore it is desirable to express the ratio T_5/T_1 in terms of T_3/T_1. We find this ratio by utilizing the recuperator effectiveness η_R

$$\eta_R = \frac{h_5 - h_2}{h_4 - h_2} \simeq \frac{T_5 - T_2}{T_4 - T_2} \,. \tag{12.74}$$

From the compressor and turbine energy balance in (12.61) we find

$$\begin{aligned} T_2 &= T_1 + (T_{2s} - T_1)\frac{1}{\eta_c} = T_1 + T_1\left(\pi_c^{m_c} - 1\right)\frac{1}{\eta_c} \,, \\ T_4 &= T_3 - (T_3 - T_{4s})\eta_T = T_3 - T_3\left[1 - (\epsilon\pi_c)^{-m_T}\right]\eta_t \,. \end{aligned} \tag{12.75}$$

Equation (12.75) in dimensionless form yields

$$\begin{aligned} \frac{T_2}{T_1} &= 1 + \frac{1}{\eta_c}\left(\pi_c^{m_c} - 1\right) \,, \\ \frac{T_4}{T_1} &= \frac{T_3}{T_1} - \frac{T_3}{T_1}\eta_T\left[1 - (\epsilon\pi_c)^{-m_T}\right] \,. \end{aligned} \tag{12.76}$$

Introducing the temperature ratio $\theta = T_3/T_1$, the temperature ratio T_4/T_1 (12.76) becomes

$$\frac{T_4}{T_1} = \theta\left\{1 - \left[1 - (\epsilon\pi_c)^{-m_T}\right]\eta_T\right\} \,. \tag{12.77}$$

To determine the temperature ratio T_5/T_1, we rearrange (12.74) to obtain

$$\frac{T_5}{T_1} = \eta_R\left(\frac{T_4}{T_1} - \frac{T_2}{T_1}\right) + \frac{T_2}{T_1} \,. \tag{12.78}$$

Using (12.76) and (12.77), (12.78) can be rearranged to

$$\begin{aligned} \frac{T_5}{T_1} = \eta_R\Bigg(&\theta\left\{1 - \left[1 - (\epsilon\pi_c)^{-m_T}\right]\epsilon_T\right\} - 1 \\ &- \frac{1}{\eta_c}\left(\pi_c^{m_c} - 1\right)\Bigg) + 1 + \frac{1}{\eta_c}\left(\pi_c^{m_c} - 1\right) \,. \end{aligned} \tag{12.79}$$

Introducing (12.79) and the definition $\theta = T_3/T_1$ into (12.73), the thermal efficiency equation for a gas turbine with a recuperator is written as

$$\begin{aligned} \eta_{th} = &\Bigg(\bar{c}_{PT}\eta_T\theta\left[1 - (\epsilon\pi_c)^{-m_T}\right](1+\beta) \\ &- \frac{1}{\eta_c}\bar{c}_{Pc}\left(\pi_c^{m_c} - 1\right)\Bigg) \\ &\times\Bigg(\bar{c}_{PCC}\Big\{\theta(1 + \beta - \eta_R) \\ &- \left[1 + \frac{1}{\eta_c}\left(\pi_c^{m_c} - 1\right)\right](1 - \eta_R) \\ &+ \theta\eta_R\eta_T\left[1 - (\epsilon\pi_c)^{-m_T}\right]\Big\}\Bigg)^{-1} \,. \end{aligned} \tag{12.80}$$

From (12.80) special cases are obtained. Setting $\eta_R = 0$ gives the thermal efficiency of a gas turbine without recuperator. The ideal case the of Brayton cycle is obtained by setting all loss coefficients equal to zero, all efficiencies equal to unity, and $\bar{c}_{PC} = \bar{c}_{PCC} = c_{PT} = \text{const}$. Equation (12.80) properly reflects the effects of individual parameters on the thermal efficiency and can be used for preliminary parameter studies. As an example, Fig. 12.8 shows the effect of pressure ratio, the turbine inlet temperature, and the component efficiency on thermal efficiency for two different cases. As Fig. 12.24 shows, for each turbine inlet temperature, there is one optimum pressure ratio. For temperature ratios up to $\theta = 3.5$ pronounced efficiency maxima are visible within a limited π-range. When approaching higher inlet temperature, however, this range widens significantly.

For a gas turbine without recuperator, the thermal efficiency (the solid curves in Fig. 12.24) shows that, for $\theta = 4.0$, increasing the pressure ratio above 15 does not yield a noticeable efficiency increase. However, this requires the compressor to have one or two more stages. The temperature ratio $\theta = 4.0$ corresponds to a turbine inlet temperature of $T_3 = 1200\,\text{K}$ at a compressor inlet temperature of $T_1 = 300\,\text{K}$.

The dashed curves in Fig. 12.24 indicate that tangibly higher thermal efficiencies at a substantially lower pressure ratio can be achieved by utilizing recuperators. This is particularly advantageous for small gas turbines (so called *microturbines*) with power ranging from 50 to 200 kW. The required low maximum pressure ratio can easily be achieved by a single-stage centrifugal compressor. Comparing cases 1 and 2 in Fig. 12.24 shows that thermal efficiency reduces if low-efficiency components are applied.

Improvement of Gas Turbine Thermal Efficiency

The above parameter study indicates that, for a conventional gas turbine with a near-optimum pressure ratio with or without a recuperator, the turbine inlet temperature is the parameter that determines the level of thermal efficiency. For small-size gas turbines, the recuperator is an inherent component of the gas turbine. For large power generation gas turbines, however, this is not a practical option. Using a recuperator in a large gas turbine requires a significantly lower pressure ratio, which results in a large-volume recuperator and turbine. As a result, in order to improve the thermal efficiency of conventional gas turbines, increasing the turbine inlet temperature seems to be the only option left. Considering this fact, in the past three decades,

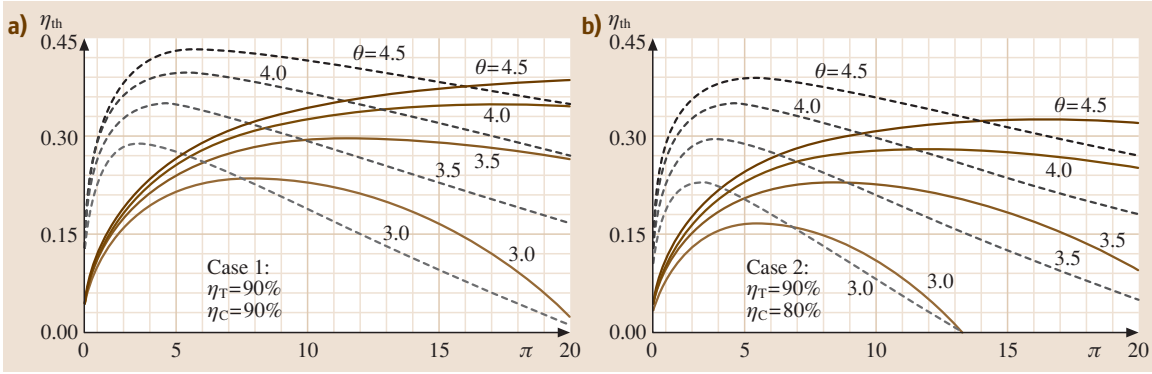

Fig. 12.24a,b Thermal efficiency as a function of pressure ratio with turbine inlet temperature ratio as a parameter for **(a)** a gas turbine with a recuperator (*dashed curves*) and **(b)** without a recuperator (*solid curves*). $\eta_R = 0.75$, $\zeta_{CC} = 0.05$, $\zeta_{RA} = \zeta_{RG} = 0.03$, for case 1 and case 2. In case 2 the turbine efficiency is lowered from 90% to 80%

gas turbine manufacturer have been concentrating their efforts on introducing more sophisticated cooling technologies, which are essential for increasing the turbine inlet temperature of conventional gas turbines.

To improve the thermal efficiency substantially without a significant increase in turbine inlet temperature, the well-known reheat principle as a classical method for thermal efficiency augmentation is applied. Although this standard efficiency improvement method is routinely applied in steam turbine power generation, it did not find its way into aircraft and the power generation gas turbine design. The reason for this was the inherent problem of integrating a second combustion chamber into a conventionally designed gas turbine engine. This issue raised a number of unforeseeable design integrity and operational reliability concerns. ABB (formerly Brown Boveri & Cie) was the first to develop a gas turbine engine with one reheat stage turbine followed by a second combustion chamber and a multistage turbine (Fig. 12.25).

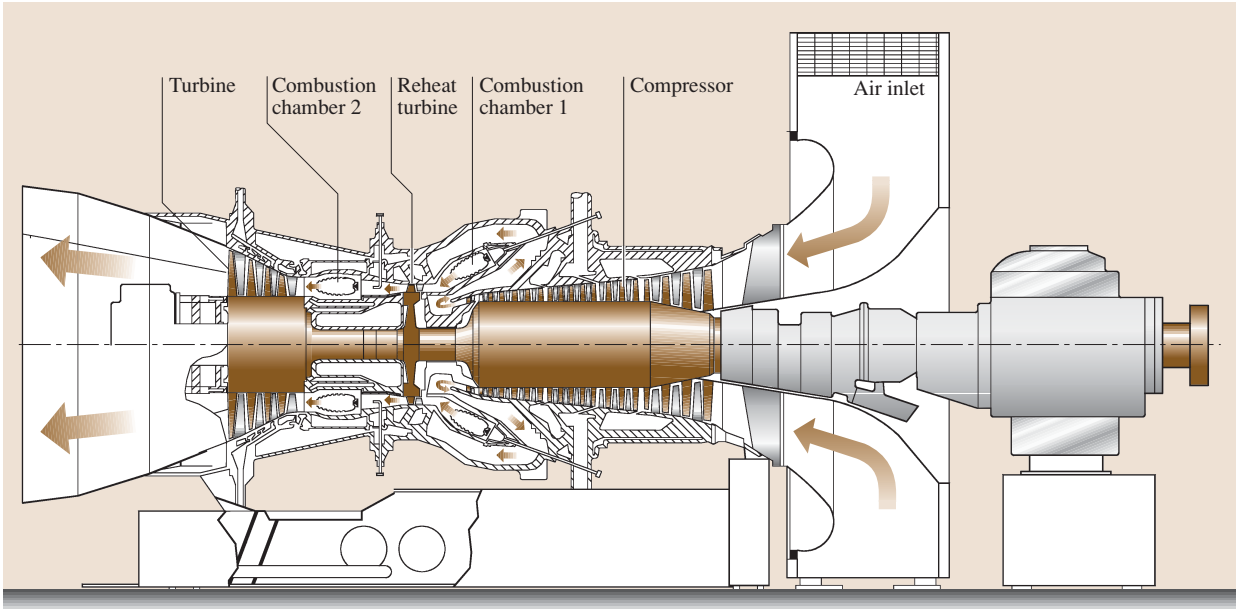

Fig. 12.25 A schematic cross section of the GT-24 gas turbine engine with a single-stage reheat turbine and a second combustion chamber

A comparative study in [12.7] emulates, among others, two conceptually different power generation gas turbine designs utilizing components whose detailed aerodynamic performance characteristics were known. The first is a conventional gas turbine, whereas the second one has a reheat turbine stage and a second combustion chamber resembling the GT-24 [12.8]. Starting from a given environmental condition (pressure, temperature) and a consolidated turbine inlet temperature $T_{3BL} = 1200\,°C$ for both engines (Fig. 12.26a) the thermal efficiency is determined by the compressor pressure ratio and the compressor and turbine polytropic efficiencies η_c and η_T and is plotted in Fig. 12.27a. As curve 1 shows, for the given pressure ratio, which is not identical with the optimum pressure ratio, an efficiency of $\eta_{th} = 35\%$ is calculated. Substantial efficiency improvement is achieved by introducing a single-stage reheat principal, as applied to the GT-24. Details of the process are sketched in Fig. 12.26b with the baseline process as the reference process. The bright dotted area in Fig. 12.26b translates into the efficiency improvement, which in the case of the GT-24 resulted in efficiency improvement of 5.5% above the baseline efficiency. A detailed dynamic engine simulation of the GT-24 gas turbine engine with GETRAN© [12.9] verified a thermal efficiency of $\eta_{th} = 40.5\%$ plotted in Fig. 12.27a, curve 2. This tremendous efficiency improvement was achieved despite the facts that (a) the compressor pressure ratio is much higher than the optimal one for baseline engine and (b) the introduction of a second combustion chamber inherently causes additional total pressure losses. Further calculation showed that introducing a third combustion chamber would only result in a marginal improvement of 1–1.5% thermal efficiency, which does not justify the necessary research and development efforts to integrate a third combustion chamber. The specific work comparison is plotted in Fig. 12.27b, which shows a significant increase in specific work. Additional efficiency improvement requires a technology change. Major improvement can be achieved by using the ultrahigh-efficiency gas turbine (UHEGT) technology [12.8]. This technology eliminates the combustion chambers altogether and places the combustion process inside the stator blade passages (Sect. 12.2.6).

12.2.2 Nonlinear Gas Turbine Dynamic Simulation

The continuous improvement of efficiency and performance of aircraft and power generation gas turbine systems during the past decades has led to engine designs that are subject to extreme load conditions. The engine components operate near their aerodynamic, thermal, and mechanical stress limits. Under these circumstances, any adverse dynamic operation causes excessive aerodynamic, thermal, and subsequent mechanical stresses that may affect the engine safety, and reliability if adequate precautionary actions are not taken. Considering these facts, an accurate predic-

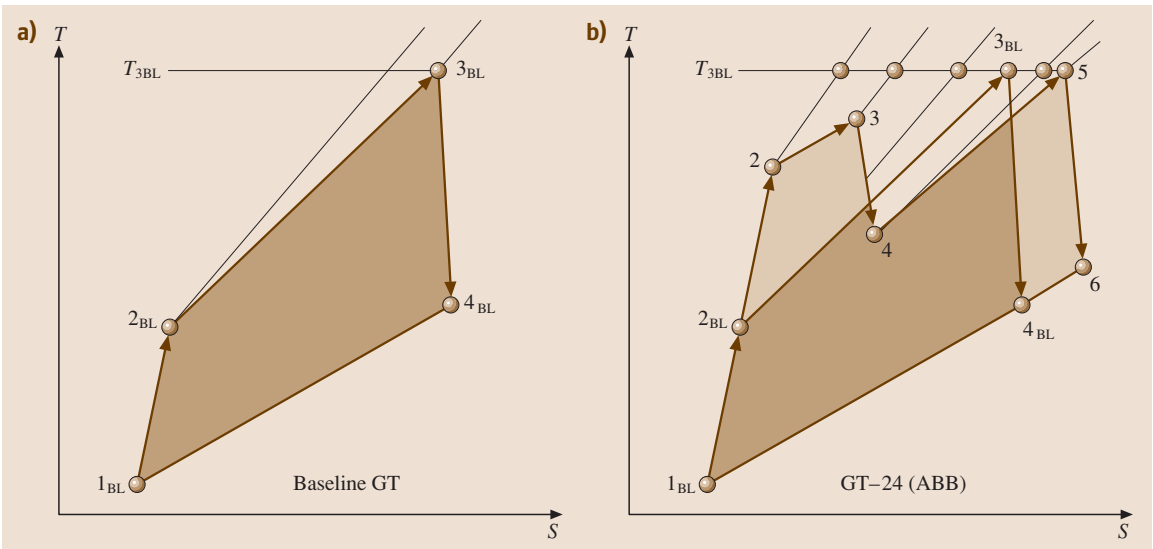

Fig. 12.26a,b Comparison of (a) a conventional baseline gas turbine process (b) with the GT-24 process after [12.7]

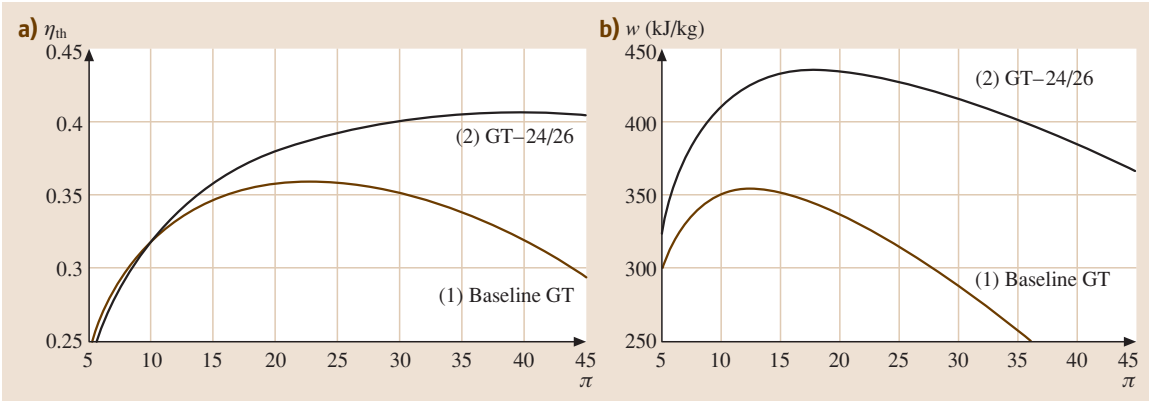

Fig. 12.27a,b Comparison of efficiency and specific work between a conventional baseline gas turbine and GT-24: **(a)** efficiency, **(b)** specific work

tion of the above stresses and their cause is critical at the early stages of design and development of the engine and its components. This section focuses on the simulation of the dynamic behavior of gas turbine engines and their components. The simulation spectrum encompasses single- and multispool gas turbine engines, turbofan engines, and power generation gas turbine engines. The simulation concept is based on a generic modularly structured system configurations. This concept is discussed in detail in [12.6], where the gas turbine components are represented by individual modules described mathematically by systems of differential equations. Based on these and other necessary modules, a generic concept is presented that provides the reader with necessary tools for developing computer codes for simulation of arbitrary engine and plant configurations ranging from single-spool thrust generation to multispool thrust/power generation engines under adverse dynamic operating conditions. It can easily be extended to rocket engines, combined cycles, cogeneration cycles, and steam power plants. In [12.6] a multilevel system simulation treats different degrees of complexity ranging from global adiabatic simulation to a detailed diabatic one. The dynamic behavior of the subject engine is calculated by solving a number of systems of partial differential equations which describe the unsteady behavior of the individual components. Accurate prediction of the dynamic behavior of the engine and the identification of critical parameters by using the method enables the engine designer to take appropriate steps using advanced control systems. The method may also be used to proof the design concept of the new generation of high-performance engines. The modular structure of the concept enables the user to independently develop new components and integrate them into the simulation code. As representative examples, four different case studies are presented that deal with dynamic simulation of a compressed air energy storage gas turbine, different transient cases with single- and multispool thrust, and power generation engines were simulated. The transient cases range from operating with a prescribed fuel schedule, to extreme load changes and generator shut down.

12.2.3 Engine Components, Modular Concept, and Module Identification

A schematic component arrangement and modeling of a twin-spool core engine is shown in Fig. 12.28. The corresponding modules are implemented into the engine modular configuration schematic in Fig. 12.29. Figures 12.30 and 12.31 show the lists of components with their corresponding modular representations and symbols that are described by the method presented in [12.6]. They exhibit the basic components essential for generically configuring any possible aero- and power generation gas turbine engines. These modules are connected with each other with a plenum, which is a coupling component between two or more successive components. As briefly explained in [12.6], the primary function of the plenum is to couple the dynamic information of entering and exiting components such as mass flow, total pressure, total temperature, fuel-to-air ratio, and water-to-air ratio. After entering the plenum a mixing process takes place, where the aforementioned quantities reach their equilibrium values. These values are the same for all outlet components.

A survey of power and thrust generation gas turbine engines has led to the practical conclusion that any arbitrary aircraft or power generation gas turbine engine and its derivatives, regardless of configuration, i. e., number of spools and components, can be generically simulated by arranging the components according to the engine configuration of interest. The nonlinear dynamic method presented in [12.6] is based on this generic, modularly structured concept that simulates the transient behavior of existing and new engines and their derivatives. The modules are identified by their names, shaft number, and inlet and outlet plena. This information is vital for automatically generating the system of differential equations representing individual modules. Modules are then combined into a complete system which corresponds to the engine configuration. Each module is physically described by the conservation laws of thermo-fluid mechanics which result in a system of nonlinear partial differential or algebraic equations. Since an engine consists of a number of components, its modular arrangement leads to a system containing a number of sets of equations. The above concept can be systematically applied to any aircraft or power generation gas turbine engine.

The general application of the modular concept is illustrated in Figs. 12.28 and 12.29. The twin-spool engine shown in Fig. 12.28 exemplifies the modular extension of the single-spool base engine. It consists of two spools with shafts S_1 and S_2, on which the low- and high-pressure components such as compressors and turbines are assembled. The two shafts are coupled by the working media air and combustion gas. They rotate with different speeds, which are transferred to the control system by the sensors Ns_1 and Ns_2. Air enters the inlet diffuser D_1, which is connected with the multistage compressor assembled on S_1, and is decomposed in several compressor stages C_{1i}. The first index (1) refers to the spool number and the second index i marks the number of the compressor stage. After compression in the S_1 compressor stage group, the air enters the second compressor (HP compressor) assembled on the S_2 shaft, which consists of stages C_{21}–C_{25}. In the combustion chamber (CC_1) high-temperature combustion gas is produced by adding the fuel from the tank FT. The gas expands in the high-pressure turbine that consists of stages T_{21}–T_{23}. When exiting from the last stage of the HP turbine, the combustion gas enters the low-pressure turbine, consisting of stages T_{11}–T_{13} and is expanded

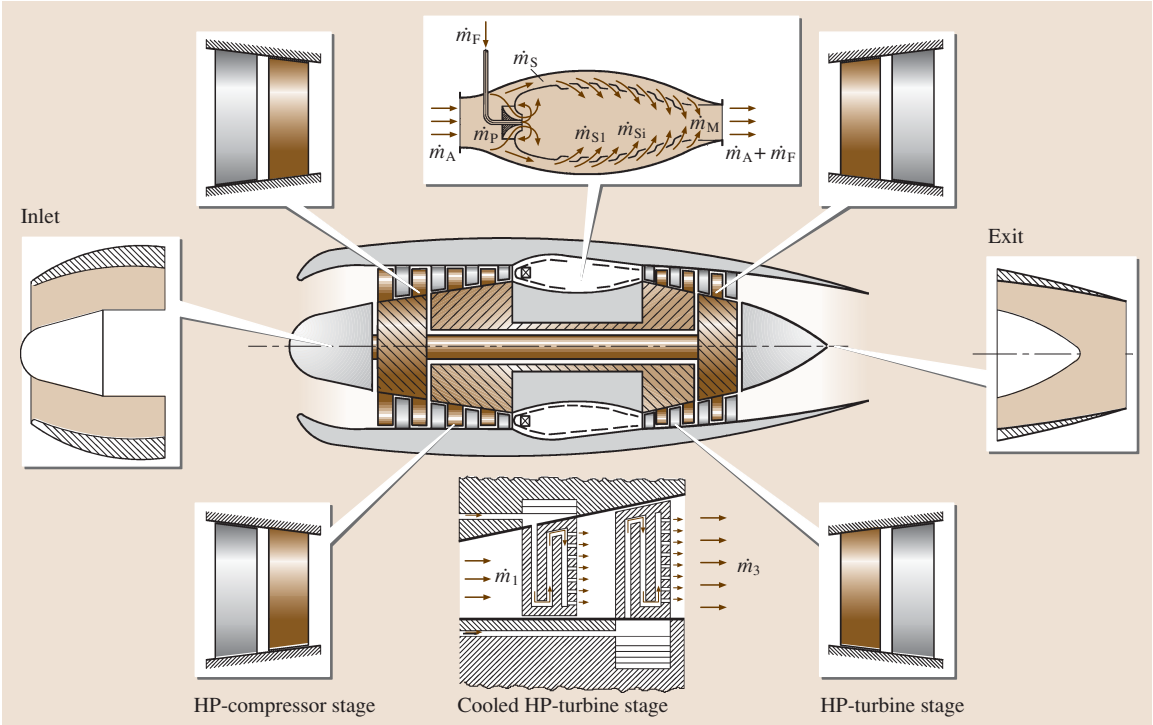

Fig. 12.28 Schematic of a twin-spool core engine, component decomposition

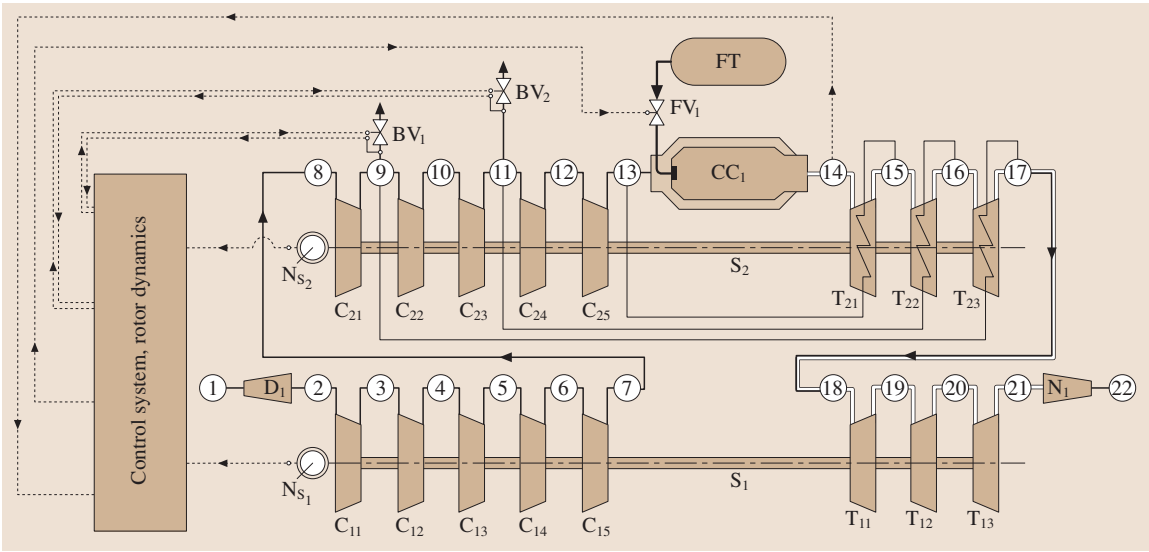

Fig. 12.29 Modular configuration of the engine exhibited in Fig. 12.28

through the exit nozzle. Two bypass valves, BV_1 and BV_2, are connected with the compressor stator blades for surge prevention. The fuel valve, FV_1, is placed between the fuel tank, FT, and the combustion chamber, CC_1. The pipes, P_i, serve for cooling air transport from the compressor to cooled turbines. The compressor stage pressures, the turbine inlet temperature, and the rotor speed are the input signals to the control system, which controls the valve cross sections and the fuel mass flow.

Figure 12.32 shows a more complex example of a three-spool supersonic engine with its modular decomposition. Figure 12.33 exhibits a systematic modular configuration of Fig. 12.32 that is represented by a large system of differential and algebraic equations.

12.2.4 Levels of Gas Turbine Engine Simulations, Cross Coupling

The accuracy of gas turbine dynamic simulation is determined by the level of component modeling. It increases by increasing the level of simulation complexity. Four levels of simulation are introduced:

- The *zeroth simulation level* is applied to simple cases utilizing a fixed system configuration with steady-state component characteristics that are described by algebraic equations, simplified differential equations, and lookup tables and maps. Furthermore, there is no dynamic coupling between the components. Since this simulation level does not account for engine dynamics, it will not be discussed further.
- The *first simulation level* uses the component global performance map only for turbines and compressors. The maps are generated using the row-by-row adiabatic calculation method detailed in [12.6]. The other components such as recuperators, coolers, combustion chambers, pipes, nozzles, and diffusers are simulated according to methods discussed in [12.6]. Primary air, secondary combustion gas, and metal temperature of the combustion chamber are calculated. All modules are coupled with plena, ensuring a dynamic information transfer to all modules involved. Modules are described by algebraic and differential equations.
- The *second simulation level* utilizes adiabatic row-by-row or stage-by-stage calculation for the compressor and turbine modules. For combustion chamber, primary air, secondary combustion gas, and metal temperature are calculated. Dynamic calculations are performed throughout the simulation, where the modules are coupled by plena. Each module is described by differential and algebraic equations.
- The *third simulation level* uses diabatic row-by-row calculation for compressor and turbine modules. This level delivers very detailed diabatic information about the compressor and turbine component dynamic behavior. It utilizes cooled turbine and

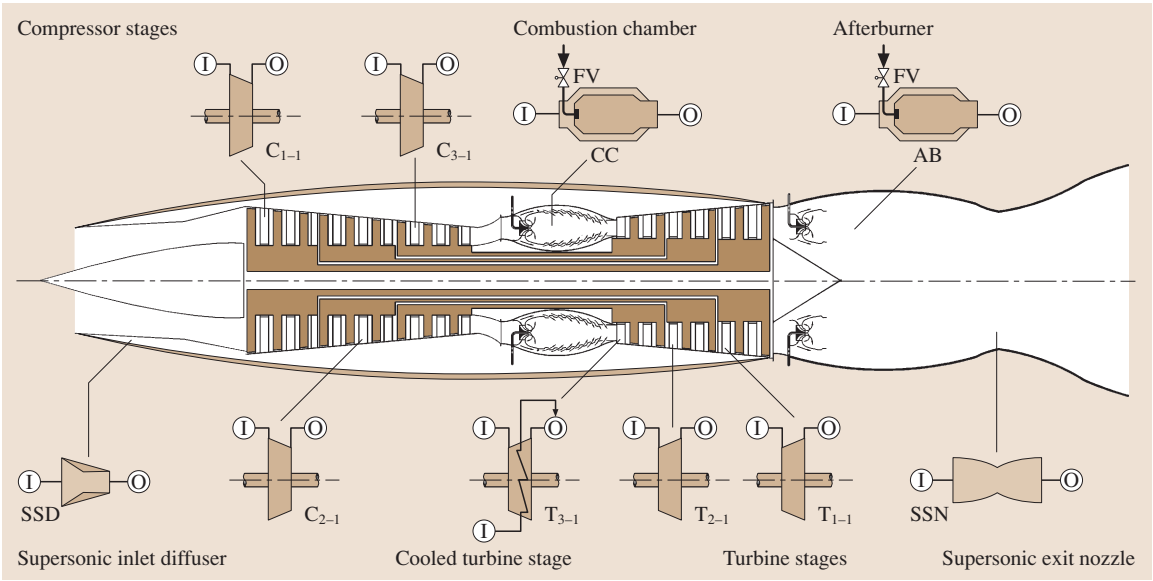

Fig. 12.32 Schematic of a three-spool high-performance core engine, component decomposition

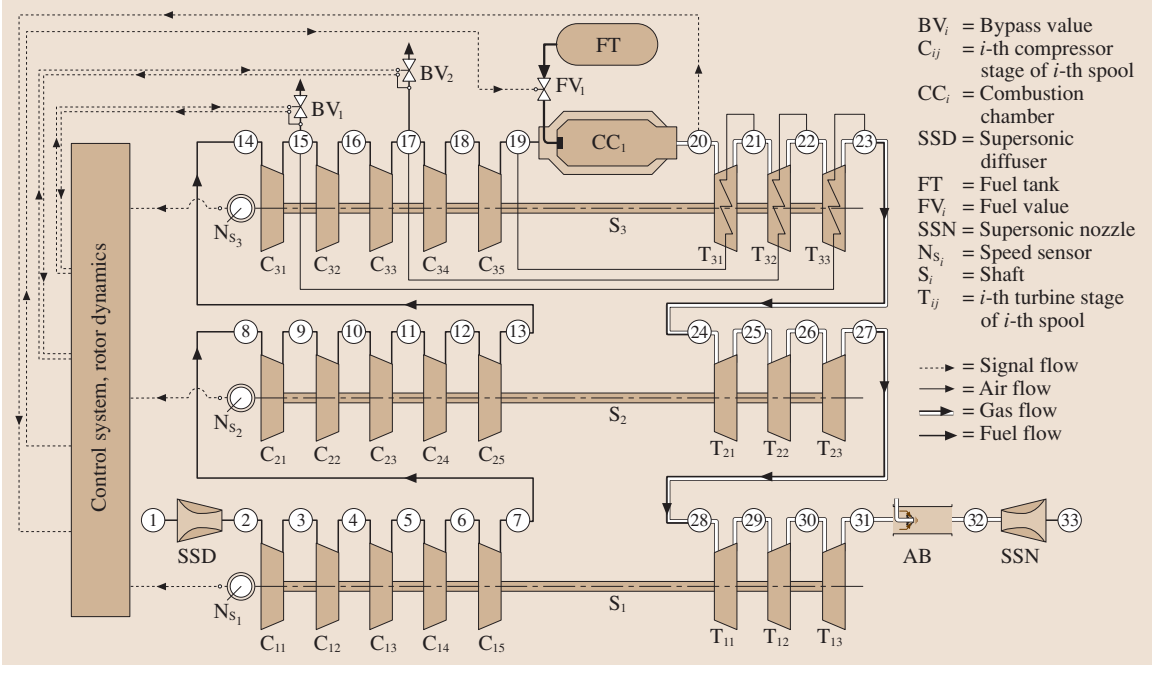

Fig. 12.33 Modular configuration of the three-spool engine shown in Fig. 12.31. The three compressors and turbines are connected aerodynamically. The plena addressing, the spool number, and the component number uniquely identify the set of differential equations that describe the module

compressor stages and simultaneously calculates the blade temperatures. For the combustion chamber, primary air, secondary combustion gas, and metal temperature are calculated. Dynamic calculations are performed throughout the simulation, whereas the modules are coupled by plena. Each module is described by differential and algebraic equations. The details of information delivered by this level and degree of complexity is demonstrated by the following example. The first two stages of a four-stage turbine component of a high-performance gas turbine engine must be cooled. For the first four turbine rows we use the diabatic expansion process that requires three differential equations for describing the primary flow, three differential equations for describing the cooling flow, and one differential equation for describing the blade temperature. This leads from two cooled turbine stages to 28 differential equations.

The generic structure allows to cross-couple levels 1 to 3. For example, we wish to simulate a gas turbine engine with a global compressor performance map, but need to obtain detailed information about turbine blade temperature, which is necessary to calculate the relative expansion between the blades and the casing, then we may use the diabatic calculation method. In this case, we cross-couple the first- and third-level simulation.

12.2.5 Nonlinear Dynamic Simulation Case Studies

Three case studies dealing with three completely different gas turbine systems are presented. Table 12.1 shows the matrix of the cases where the engine types and transient-type simulations are listed. These studies demonstrate the capability of the generic structured method discussed in [12.6] to simulate complex systems dynamically and with high accuracy. The case studies presented in this chapter are related to real-world engine simulation and are intended to provide the reader with an insight into nonlinear engine dynamic simulation. The selected cases ranging from zero-spool, single-shaft power generation to three-spool four-shaft thrust and power generation gas turbine engines provide detailed information about the engine behavior during design and off-design dynamic operation. For each engine configuration the simulation provides aerothermodynamic details of each individual component and its interaction with the other system components. Since the presentation of the complete simulation results of the three cases listed in Table 12.1 would exceed the scope of this chapter, only a few selected plots will be displayed and discussed for each case.

Case Study 1: Compressed Air Energy Storage Gas Turbine

The subject of this case study is a zero-spool, single-shaft compressed air energy storage (CAES) gas turbine [12.1], which is utilized to cover peak electric energy efficiently demand during the day. Continuous increases of fuel costs have motivated the power generation industry to invest in technologies that result in fuel saving. Successful introduction of combined cycle gas turbines (CCGT) has drastically improved the thermal efficiency of steam power plants, which is equivalent to a significant fuel saving. Further saving is achieved by using the excess electrical energy available during the period of low electric energy demand (6–8 h during the night) to compress air into a large storage system. During periods of peak demand, the compressed air is injected into the combustion chambers and mixed with the fuel. After the ignition process is completed, the high-pressure high-temperature gas expands in the turbine, generating electric energy for about 2–4 h. In contrast to a CCGT, the period of operation of a CAES

Table 12.1 Simulation case studies

Tests	Gas turbine type	Transient type
Case 1	CAES: Compressed air energy storage power generation gas turbine engine, zero-spool, single shaft, two turbines, two combustion chambers.	Generator and turbine shut down.
Case 2	Single-spool, single-shaft, power generation gas turbine engine, BBCGT9.	Adverse load changes.
Case 3	Three-pool, four-shaft, thrust and power generation core engine.	Operation with fuel schedule.

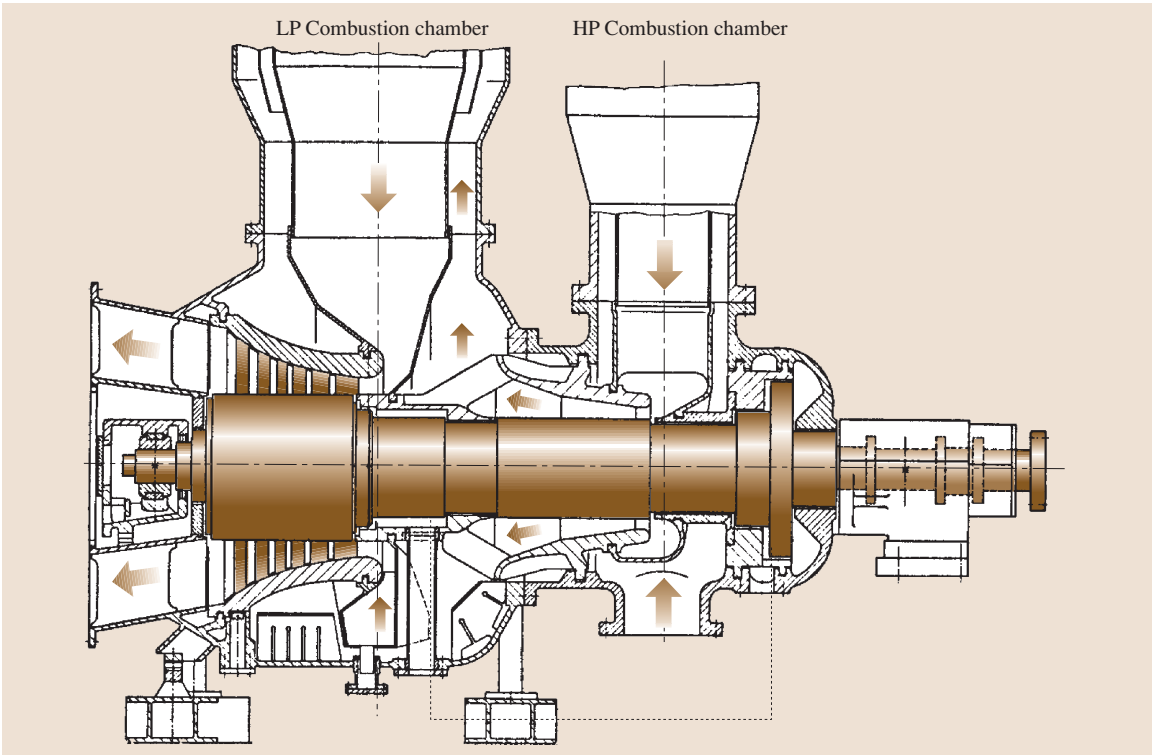

Fig. 12.34 BBC-CAES-Huntorf gas turbine engine after [12.1]

plant is restricted to a few hours per day, resulting in a daily startup followed by a shutdown procedure. This relatively high frequency of startups and shutdowns may cause structural damages resulting in reduced lifetime if the startup and shutdown procedures are not performed properly. The condition for a safe startup procedure is outlined in this study, which helps the engine and control system designer to integrate this into their design procedure. The CAES gas turbine system (Fig. 12.34) with the simulation schematic shown in Fig. 12.35 features a large-volume plenum (8) for storing the compressed air, a high-pressure combustion chamber (HPCC), a high-pressure turbine (HPT), a low-pressure combustion chamber (LPCC), a low-pressure turbine (LPT2), a cold-air preheater with a low- and high-pressure side (LPP and HPP side) and a generator (G). During steady-state turbine operation, cold air from the air-storage facility, plenum 8, passes through the shutdown valve (V_1) to the inlet plenum (1), where it is divided into combustion and cooling-air flows. The addition of fuel in the HPCC causes the combustion air to be heated to the combustion chamber's exit temperature. Immediately upstream of the HPT, the combustor mass flow is mixed with a portion of the cooling-air flow, which has already been preheated in the HPP. As a result, the gas temperature of the turbine mass flow lies below the combustion chamber's exit temperature. After expansion in the HPT, the combustion chamber (LPCC) mass flow is mixed in the LPT inlet plenum (4) with the rest of the preheated cooling-air flow and the sealing-air flow. After expansion in the LPT, the gas gives off some of its heat in the LPP before leaving the gas turbine system.

Figure 12.35 shows how the various components are interconnected. Plenum 8, the air storage facility, is connected via two identical pipes (P6) to two shutdown valves (V_1). During steady-state operation, the blow-off valve (V_2) remains closed, being opened in the event of a disturbance likely to cause rapid shutdown. In such an event, the valve blows off some of the gas, thereby limiting the maximum rotor speed. For the sake of clarity, the preheater (P) has been separated into its air and gas sides, designated by HPP and LPP, respectively.

Simulation of Emergency Shutdown. Starting from a steady operating point, a generator trip with rapid

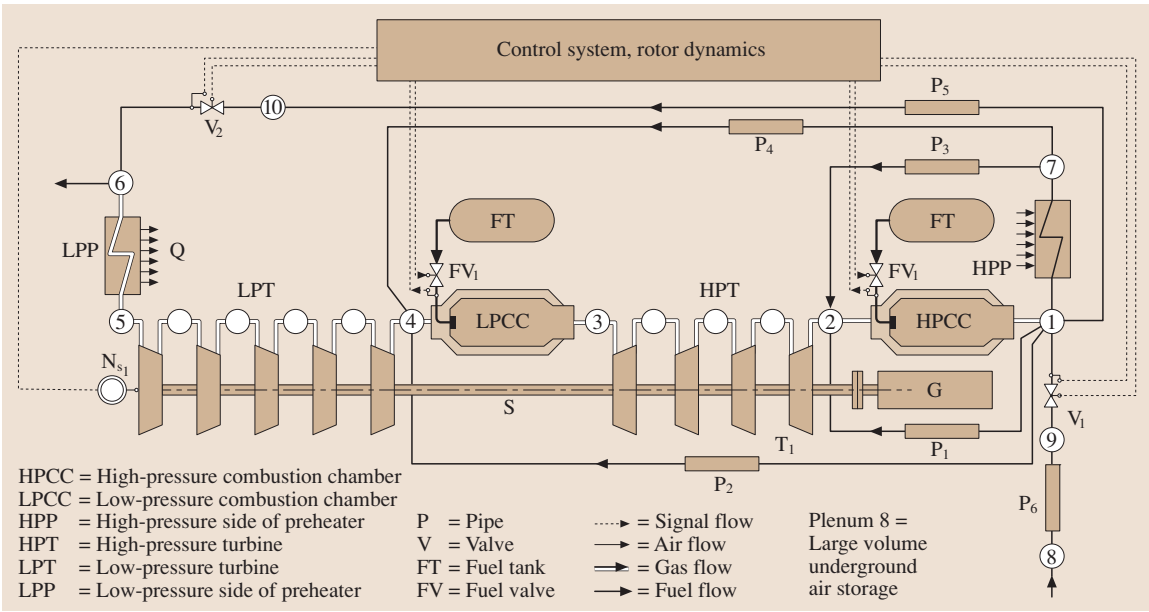

Fig. 12.35 Simulation schematic of the CAES shown in Fig. 12.34

shutdown was simulated, assuming a failure of the control system. This circumstance necessitates an intervention by the hydraulic emergency system. This incident simulates an extreme transient process within some of the components, as explained briefly. After the generator trip, the rotor is strongly accelerated because of the full turbine power acting on it (Fig. 12.36a).

The hydraulic emergency system intervenes only when the speed corresponding to the hydraulic emergency overspeed trip is reached. This intervention involves closing the fuel valves, FV_1 and FV_2, and air valves V_1, after which the system no longer receives any energy from outside (Fig. 12.36b). It also involves opening the bypass/blow-off valve V_2, which allows the high-pressure air contained in both large-volume combustion chambers as well as in the HP side of preheater to discharge.

The closing process of the inlet and shutdown valves and the opening of the bypass valves are shown in Fig. 12.36b. This process results in a steady drop in plena pressures and temperatures. As Fig. 12.37 shows, the pressure drop in the high-pressure section is initially

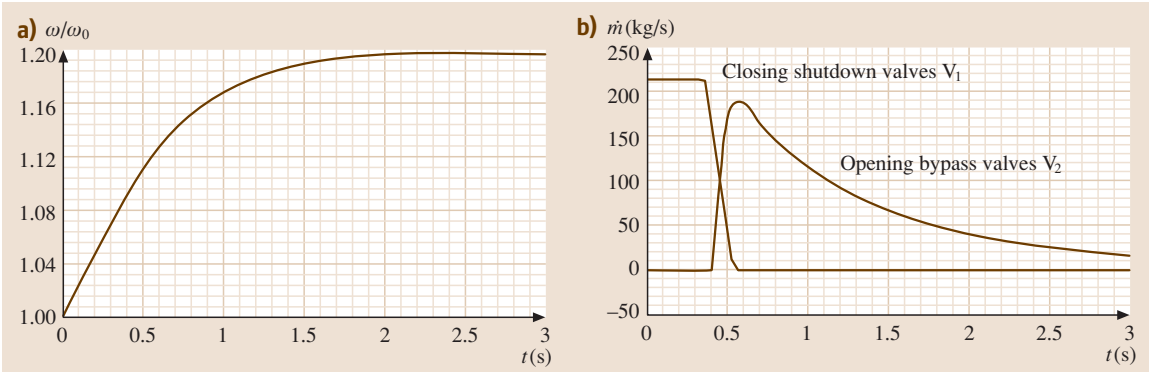

Fig. 12.36 **(a)** Relative angular velocity **(b)** and mass flows as functions of time. The inlet shutdown valves V_1 remain open until the trip speed at $t = 0.35$ s has been reached. The same procedure is true for opening the blow-off valves V_2. Closing the shutdown valves follow the ramp shown in **(b)**

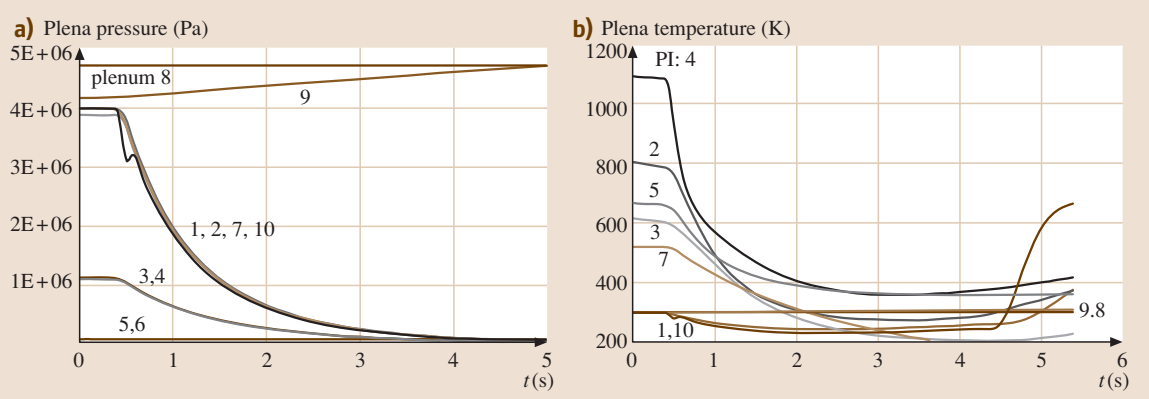

Fig. 12.37 (a) Plena pressure and (b) temperature as functions of time. The shutdown process causes rapid depressurization in the high-pressure plena 1, 2, 7, and 10

steeper than in the low-pressure section. This means that the enthalpy difference of the high-pressure turbine is reduced more rapidly than that of the low-pressure turbine. Immediately after the blow-off valve is opened, an abrupt pressure drop takes place in plenum 10, which is connected to plenum 1 via pipe P_5. Thereafter, dynamic pressure equalization takes place between the two plena. This drop in pressure and temperature causes a corresponding drop in the shaft power and the mass flow throughout the engine. Figure 12.38 shows the resulting drop in turbine inlet and exit temperature. The continuous decrease in turbine mass flow causes a strong dissipation of shaft power, resulting in the excessive increase of turbine exit temperature. In order to avoid thermal damages to the blades, a small stream of cold air is injected into the turbine flow path, which causes a reduction in temperature gradient. This is shown in Fig. 12.38 for the exit temperature at $t = 3.4$ s.

Dynamic behavior of the rotor speed is generally determined by the turbine power acting on the rotor. How the rotor behaves in response to a generator trip depends, in particular, on how long the full turbine power is available, a process monitored by the control and safety monitoring system. When the control system functions normally, a trip is signaled without delay to the shutdown valve. Failure of the control system causes the hydraulic emergency system to intervene. The intervention begins only when the speed corresponding to the hydraulic emergency overspeed trip is reached. During this process, and also the subsequent valve dead time, the rotor receives the full turbine power. The closing phase is characterized by a steady reduction in energy input from outside, which finally becomes zero. The total energy of the gases still contained in the system is converted by the two turbines into mechanical energy, causing the rotor speed to increase steadily (Fig. 12.36). When the instantaneous turbine power is just capable of balancing the friction and ventilation losses, the rotor speed reaches its maximum, after which it begins to decrease. Reducing the turbine mass flow (Fig. 12.39a) below the minimum value discussed in [12.6] causes the shaft power to dissipate completely as heat, resulting in negative values, as shown in Fig. 12.39b. From this point on, the rotational speed starts to decrease. Figure 12.39a depicts the mass flows through the HP and LT turbines that generate the total shaft power (Fig. 12.39b).

Case Study 2: Power Generation Gas Turbine Engine

The subject of this case study is the dynamic simulation of a BBC-GT9 gas turbine which is a single-spool single-shaft power generation gas turbine engine. It is utilized as a stand-alone power generator or in conjunction with combined cycle power generation. The engine shown in Fig. 12.40 consists mainly of three compressor stage groups, a combustion chamber, a turbine, a control system, and a generator.

The simulation schematic of this engine is presented in Fig. 12.41. The rotor speed and turbine inlet temperature are the input parameters for the controller, its output parameters are the fuel mass flow (fuel valve opening), and the mass flows of the bypass valves (bypass valve opening). The dynamic behavior of BBC-GT9 was experimentally determined for transient tests with extreme changes in its load. Its transient data was accurately documented by *Schobeiri* [12.9]. Starting from a given

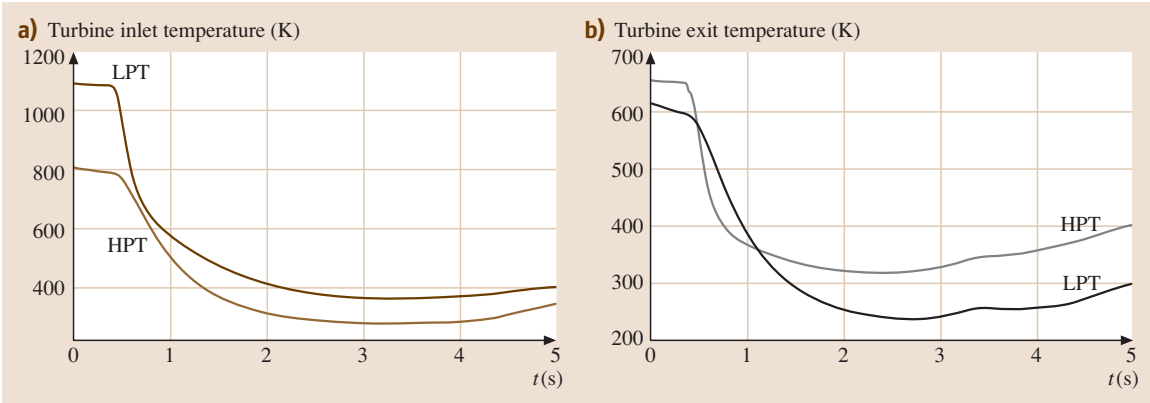

Fig. 12.38 (a) Turbine inlet and (b) exit temperature as functions of time. Note the changes of the exit temperature at $t = 3.4\,\mathrm{s}$

network load schedule, the dynamic behavior of the gas turbine is predicted and the results are presented.

The engine under consideration consists mainly of three compressor stage groups, a combustion chamber, a turbine, a control system, and a generator. The simulation schematic of this engine is similar to that of Fig. 12.42. For dynamic simulation, the first, second, and third stage groups are simulated using the row-by-row technique [12.6]. A similar row-by-row calculation procedure is applied to the turbine component. The rotor speed and the turbine inlet temperature are the input parameters for the controller; its output parameters are the fuel mass flow (fuel valve opening) and the mass flows of the bypass valves (bypass valve opening).

Simulation of an Adverse Dynamic Operation. Starting from steady state, in accordance with the load schedule indicated in Fig. 12.42a (curve 1), after 1 s, a generator loss of load is simulated that lasts for 6 s. The rotor at first reacts with a corresponding increase in rotational speed (Fig. 12.42b), which results in a rapid closing of the fuel valve (Fig. 12.42b). The rotational speed is then brought to an idling point and held approximately constant. The process of control intervention lasts until a constant idling speed is attained. After that, there is an addition of load in sudden increases, such that the gas turbine is supplying approximately 25% of its rated load (Fig. 12.42). The rotor first reacts to this addition of load with a sharp decrease in rotational speed, as exhibited in Fig. 12.42, causing a quick opening of the fuel valve (Fig. 12.42). After completion of the transient process, the steady off-design state is reached.

Plena Pressure and Temperature Transients. The above adverse dynamic operation triggers temporal changes of the flow quantities within individual com-

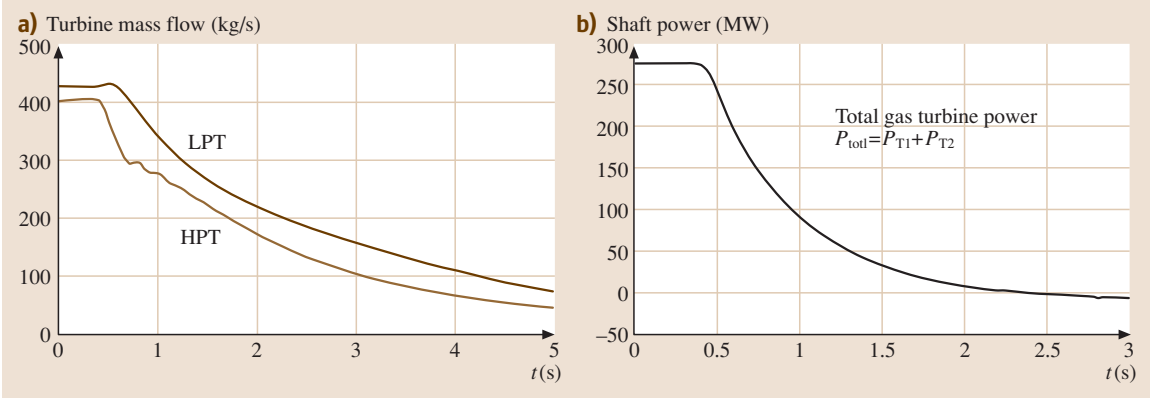

Fig. 12.39 (a) Turbine mass flow and (b) shaft power as functions of time

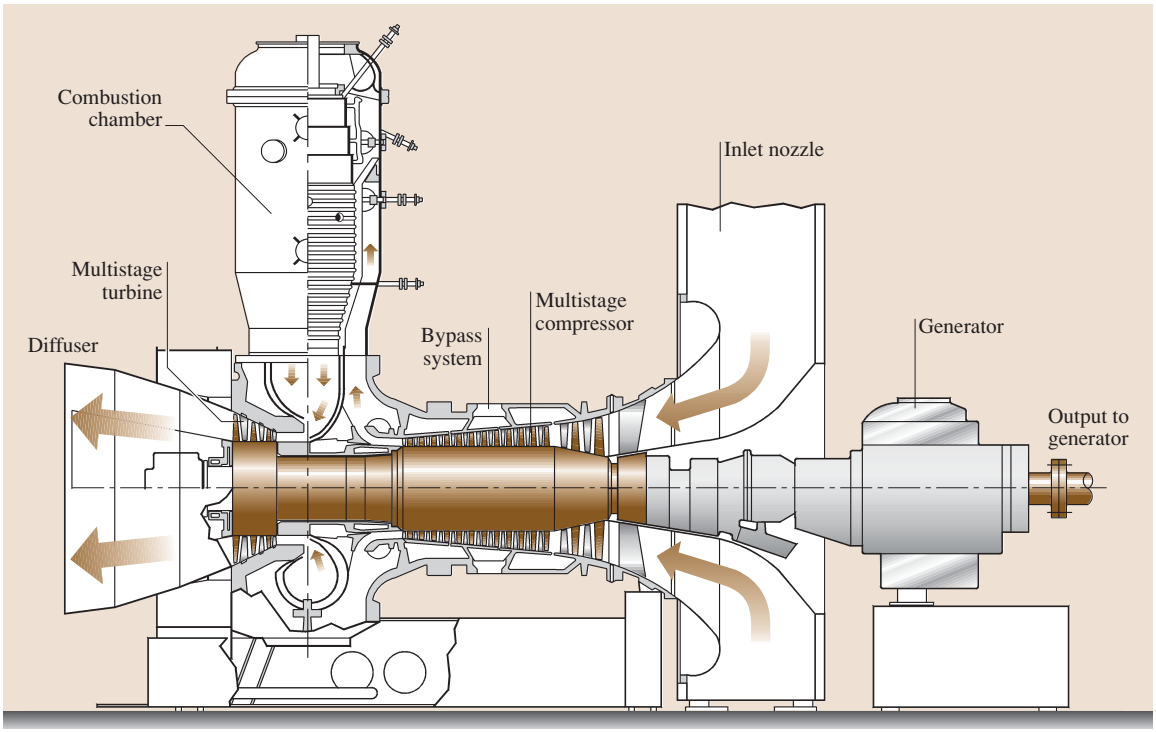

Fig. 12.40 A single-spool power generation gas turbine BBC-GT9

ponents. Figure 12.43 shows how the plena pressure and temperature change with time. Decrease of turbine power and increase of the shaft speed (Fig. 12.42) has caused the HP compressor exit pressure in plenum 5 to decrease. The temperature at the combustion chamber exit, plenum 6, and turbine exit, plenum 7, follow the course of fuel injection shown in Fig. 12.47b. The plena temperature upstream of the combustion chamber are not affected.

Compressor and Combustion Chamber Mass Flow Transients. Figure 12.44 exhibits the mass flow transients through low pressure (LP), intermediate pressure (IP), and high pressure (HP) compressors. While the IP- and HP-stage groups have the same mass flow, the LP part has a greater mass flow. The difference of 1 kg/s is due to the cooling mass flow extraction. As briefly mentioned, the increase in shaft speed and the simultaneous decrease in compressor power consumption leading to

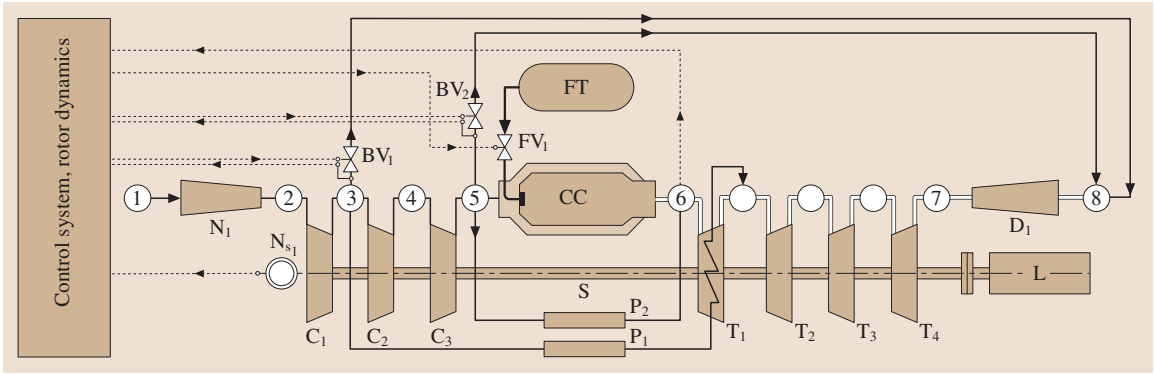

Fig. 12.41 Simulation schematic of BBC-GT9 shown in Fig. 12.40

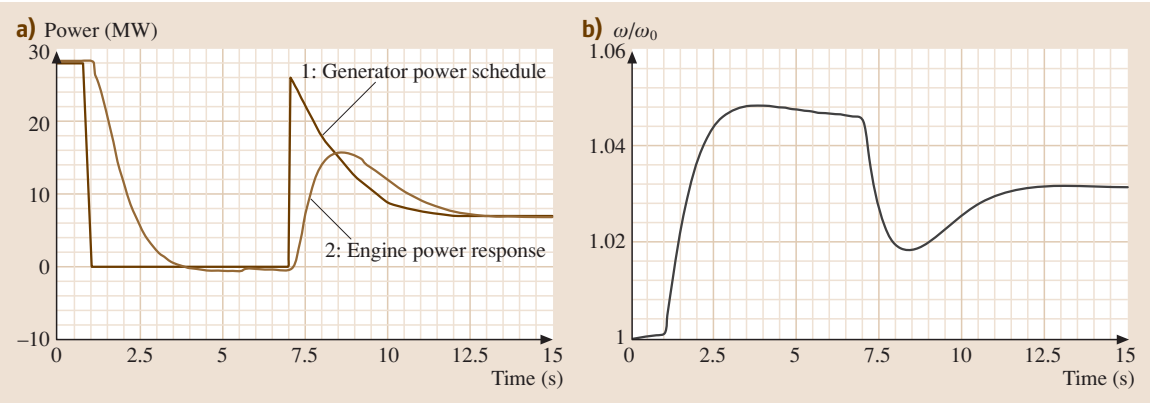

Fig. 12.42 **(a)** Generator load schedule (*curve* 1). Sequence of events: steady operation from 0 to 1 s, sudden loss of load, idle operation, sudden addition of load, continuous decrease of load to 25%. *Curve* 2: engine power response. **(b)** Relative shaft speed as a function of time

the compressor pressure drop has caused an increase in the compressor mass flow during the process of loss of load that lasts up to $t = 6$ s. The sudden load addition reduces the compressor mass flow.

The combustion chamber mass flow shows a similar course with a substantial difference: a substantial portion of the compressor mass flow is extracted for combustion chamber exit temperature mixing cooling.

Combustion Chamber Gas and Metal Temperature Transients. The combustion chamber component used in this simulation has three segments that separate the primary combustion zone from the secondary cooling air zone. Its module is shown in Fig. 12.45. Figure 12.46 exhibits the combustion chamber gas and metal temperatures as functions of time. Compressed air enters the combustion chamber at station 1 (Fig. 12.46). Fuel is added and the segment cooling occurs according to the procedure described in [12.6]. The secondary mass flow portions $\dot{m}_{Si}$ serve as cooling jets and are mixed with the combustion gas, thus reducing the gas temperature. Before exiting, the combustion gas is mixed with the mixing air stream $\dot{m}_M$, further reducing the temperature. Figure 12.46b shows the mean segment temperatures. In accordance with the measurements on this gas turbine, the flame length extends from station 1 to 3, which makes segment number 2 the hottest one. We assumed that all secondary cooling channels are open.

Turbine and Fuel Mass Flow Transients. Figure 12.47a exhibits the turbine mass flow transient, which is dictated by the compressor dynamic operation. The difference between the turbine and the compressor mass flow is the injected fuel mass flow. The particular course

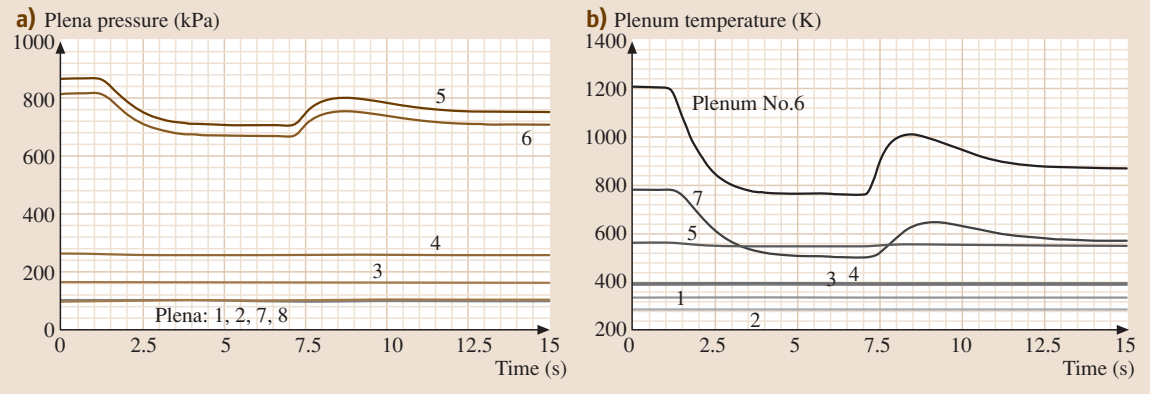

Fig. 12.43 **(a)** Plena pressure and **(b)** temperature as functions of time. Individual plena are labeled

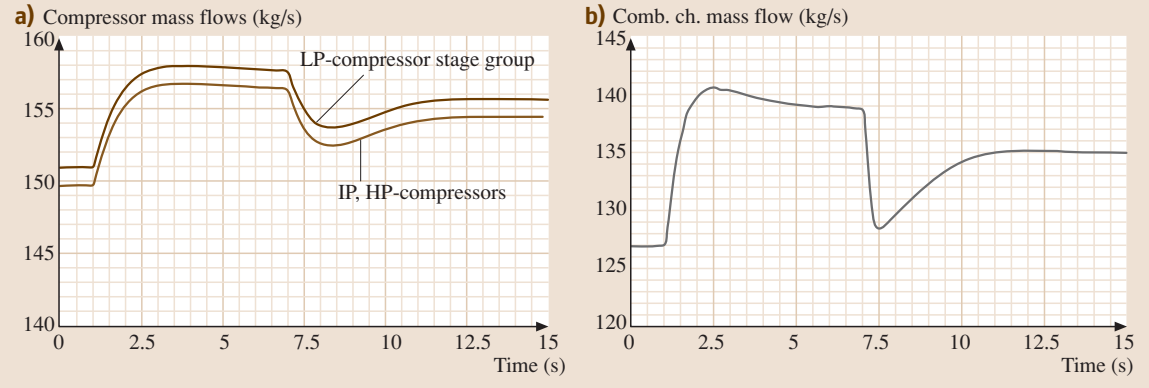

Fig. 12.44 (a) Compressor and (b) combustion chamber mass flows as functions of time

of fuel mass flow shown in Fig. 12.47b is due to the intervention of the control system. An increase in rotational speed causes the controller to close the fuel valve. Subsequent addition of generator load results in a steep drop of rotational speed, which causes an opening of the fuel valve.

Case Study 3: Simulation of a Multispool Gas Turbine Engine

The subject of this study is the nonlinear dynamic simulation of a gas turbine engine with a higher degree of complexity than the previous cases. For this purpose a three-spool thrust-generating gas turbine engine is designed that incorporates advanced components. The three-spool four-shaft high-performance gas turbine engine consists of a low-pressure spool that incorporates the LP compressor and turbine connected via shaft S_1. The intermediate pressure spool integrates the IP compressor and turbine connected via shaft S_2. The high-pressure spool carries the HP compressor and HP turbine on shaft S_3. To increase the level of engine complexity, a fourth shaft, S_4, with the power generating turbine T_4, was attached to the exit of the three-spool gas generating unit as shown in Fig. 12.48. The transient operation is controlled by a given fuel schedule. The component nomenclature for this configuration is the same as for the previous cases. The simulation schematics shown in Fig. 12.48 represents the modular configuration of the gas turbine.

Fuel Schedule and Rotor Response. The dynamic behavior of the above engine is simulated for an adverse acceleration–deceleration procedure (Fig. 12.49).

The transient operation is controlled by an open-loop fuel schedule shown in Fig. 12.49a. The three spools and the fourth shaft run independently at different rotational speed (Fig. 12.49b). The fuel schedule generated completely arbitrarily simulates an acceleration–deceleration procedure with emphasis on deceleration. We start with the steady-state operation and reduce the fuel mass flow to $\dot{m}_F = 2.8\,\mathrm{kg/s}$ for about 2 s. During this short period of time, the engine operates in a dynamic state which is followed by a cyclic acceleration–deceleration event with the ramps given in Fig. 12.49. The dynamic operation triggers a sequence of transient events within individual components that are discussed in the following sections.

Rotor Speed Behavior. The transient behavior of the three spools as well as the power shaft is determined by the net power acting on the corresponding rotor. For each individual spool, the cyclic acceleration–deceleration event has caused a dynamic mismatch between the required compressor power consump-

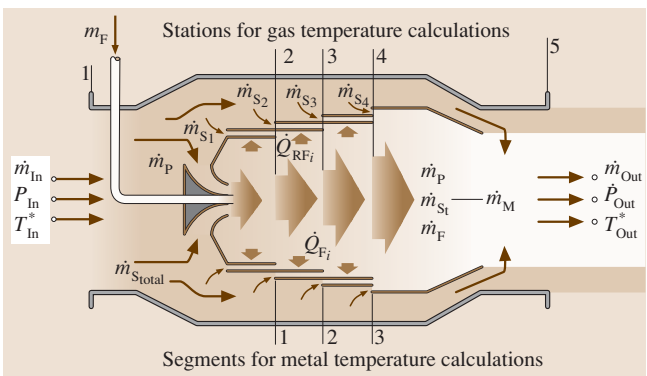

Fig. 12.45 Combustion chamber module, stations and segments, $\dot{m}_P$ – primary $\dot{m}_{S_{tot}}$ – total secondary air, $\dot{m}_{Si}$ – individual secondary air

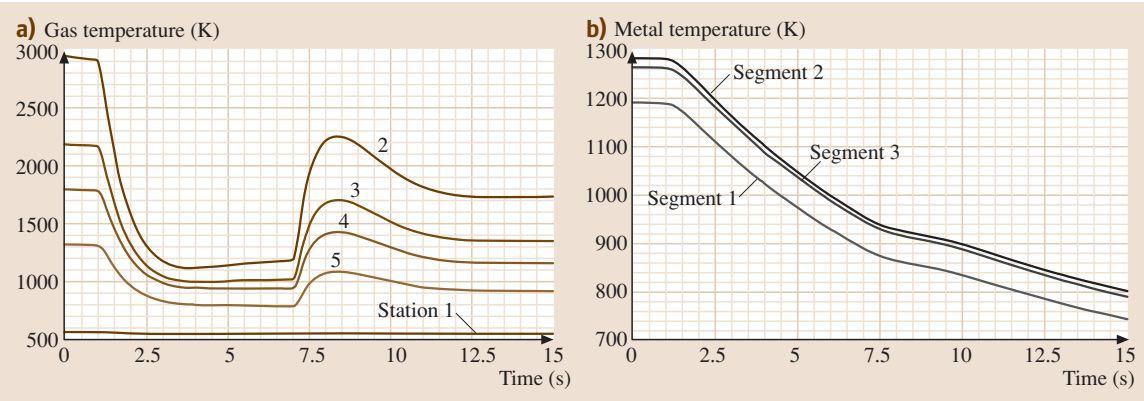

Fig. 12.46 (a) Combustion chamber gas and (b) metal temperature at different positions as functions of time

tion and the turbine power generation, as shown in Fig. 12.50. While the LP and IP spools 2 and 3 decelerate under the influence of negative net power, the HP spool 3 reacts faster to the acceleration. Since the fuel schedule places special weight upon deceleration, the rotational speeds of all three spools have a decelerating tendency as shown in Fig. 12.50.

Pressure and Temperature Transients within Plena. The change in fuel mass flow triggers a chain of transient events within the plena, as shown in Fig. 12.51. Plena pressure 5 and 6, which corresponds to the exit pressure of the HP compressor and the combustion chamber, are strongly affected by the cyclic fuel change, whereas the other plena that correspond to the inlet and exit plena of the remaining components experience moderate changes. The plena temperature distributions downstream of the combustion chamber shown in Fig. 12.51b reflect the course of the fuel schedule.

Combustion Chamber Gas and Metal Temperature Transients. Figure 12.52 exhibits the combustion chamber gas and metal temperatures as functions of time. The combustion chamber component used in this simulation has three segments that separate the primary combustion zone from the secondary cooling air zone. Its module is shown in Fig. 12.47. Compressed air enters the combustion chamber at station 1 (Fig. 12.52a). Fuel is added and the segment's cooling occurs according to the procedure described in [12.6]. The secondary mass flow portions serve as cooling jets and are mixed with the combustion gas, thus reducing the gas temperature. Before exiting, the combustion gas is mixed with the mixing airstream, further reducing the temperature. Figure 12.52a shows the mean segment temperatures.

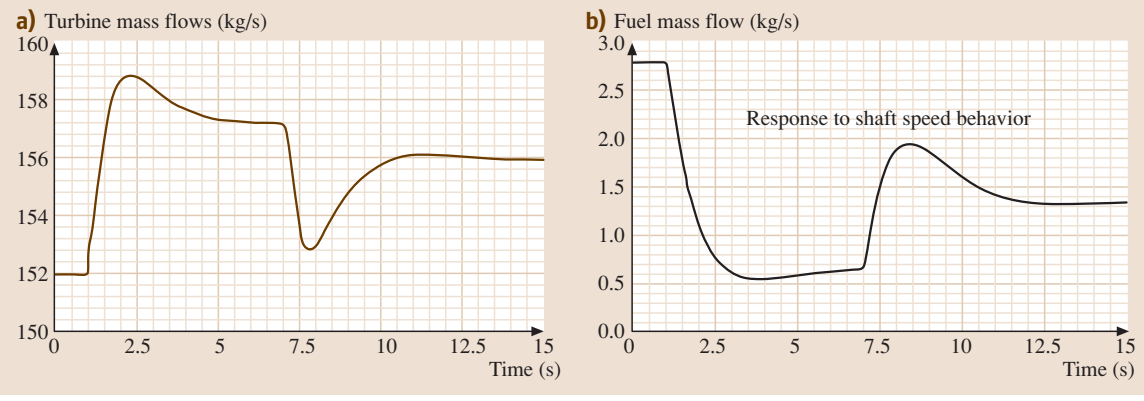

Fig. 12.47 (a) Turbine and (b) fuel mass flow as functions of time. The fuel mass flow is controlled by the shaft rotational speed

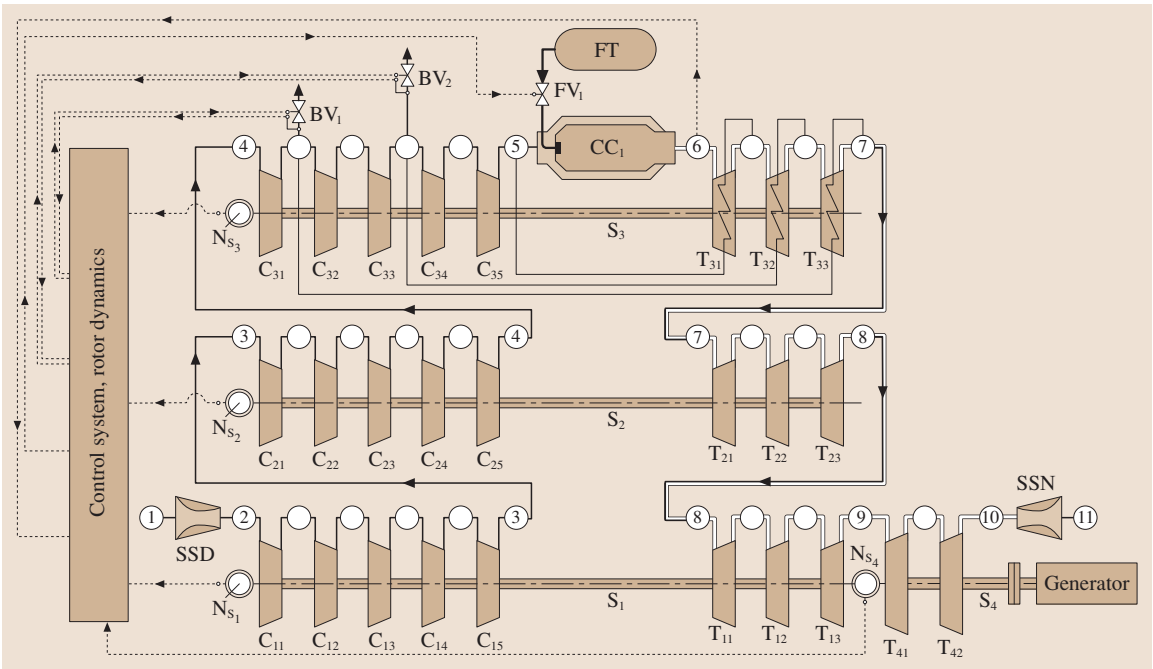

Fig. 12.48 Simulation schematic of three-spool four-shaft high-performance gas turbine engine. Spool 1 incorporates the LP compressor and LP turbine connected via shaft S_1; spool 2 incorporates the IP compressor and IP turbine connected via shaft S_2; spool 3 incorporates the HP compressor and HP turbine connected via shaft S_3

The flame length extends from station 1 to 3, which makes segment number 2 the hottest one. As seen, the gas temperature at station 2 follows the sharp changes in the fuel schedule. By convecting downstream, these sharp changes are smoothed out. The wall temperatures shown in Fig. 12.52b exhibit similar tendencies.

Compressor and Turbine Mass Flow Transients. Figure 12.53a exhibits the compressor mass flow transients, which are dictated by the compressor dynamic operation. The difference in compressor mass flow is due to the mass flow extraction for cooling purposes. Turbine mass flows are illustrated in Fig. 12.53b. Except for a minor time lag, they show identical distributions. The

difference in turbine and compressor mass flow is due to the addition of fuel.

12.2.6 New Generation Gas Turbines, Detailed Efficiency Calculation

One of the interesting aspects of a dynamic simulation is the capability to calculate the gas turbine thermal efficiency dynamically during steady-state and dynamic operation. Such calculations are performed to compare the thermal efficiencies of four gas turbines with different design methodologies. The calculations are performed with the nonlinear dynamic code GETRAN©. The first gas turbine dynamically simulated for efficiency calculation is a conventional single-shaft, single-combustion chamber power generation gas turbine. The second one is the ABB GT 24/26. The third is an ultrahigh-efficiency gas turbine (UHEGT) with a precombustor, a reheat turbine stage, and an integrated stator internal combustion, as

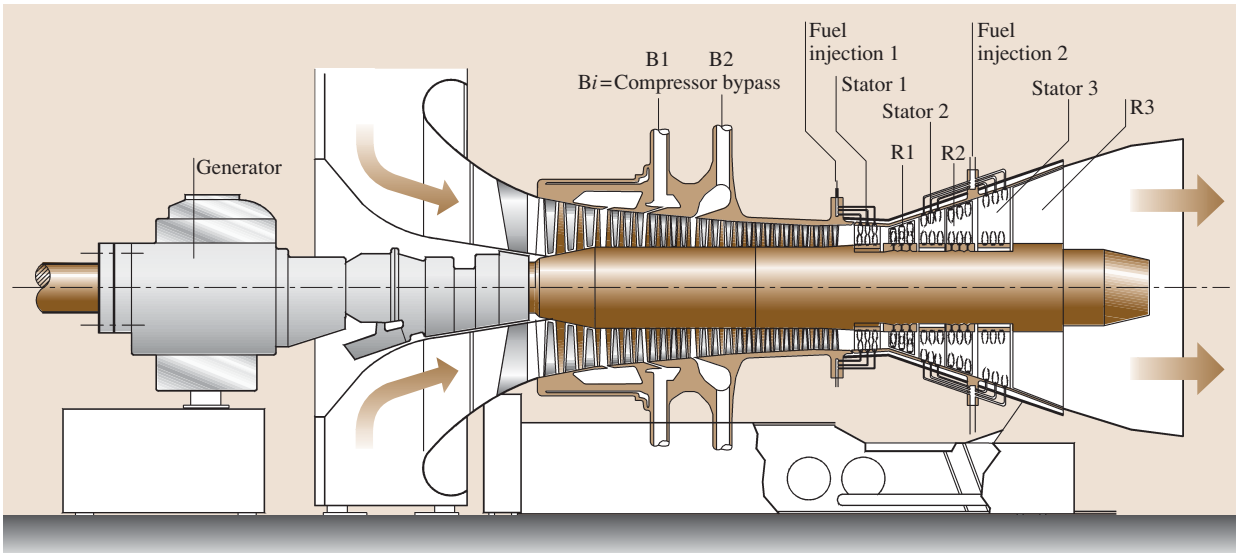

Fig. 12.55 An ultrahigh-efficiency gas turbine engine with a multistage compressor, and a three-stage turbine with an integrated stator internal combustion. B1, B2: compressor bypass blow-off, Fl1, Fl2: fuel lines to stator. The combustion process takes place inside the stator flow path (after *Schobeiri* [12.7])

illustrated in Fig. 12.54. For the fourth gas turbine, the combustion process is placed entirely within the stator rows, thus eliminating the combustion chambers all together, Fig. 12.55. The dynamic efficiency calculation results are presented in Fig. 12.56. To accurately determine the thermal efficiency and specific work of the gas turbines, calculations are performed with GETRAN© and the results are presented in Fig. 12.56. To compare the degree of efficiency improvement, the thermal efficiency and specific work of a baseline GT, GT-24, and the three UHEGT gas turbines are included in the figures.

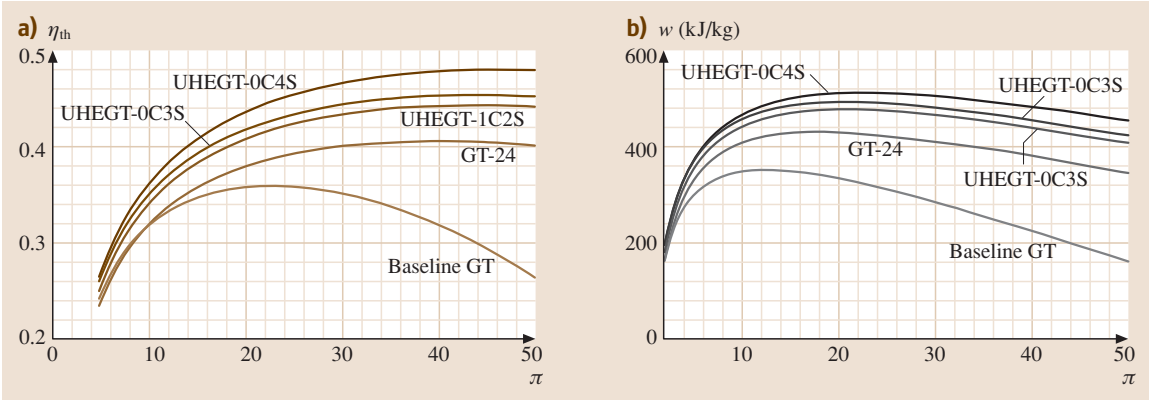

Fig. 12.56 (a) Thermal efficiency and (b) specific work as functions of compressor pressure ratio for the reference baseline gas turbine engine, the ABB-GT-24 with two combustion chambers, the UHEGT-1C2S with one conventional combustion chamber and two UHEGT-stator combustion, the UHEGT-03S with three-stator combustion, and the UHEGT-0C4S with four-stator combustion. Turbine inlet temperature = 1200 °C, calculation with GETRAN (after [12.9])

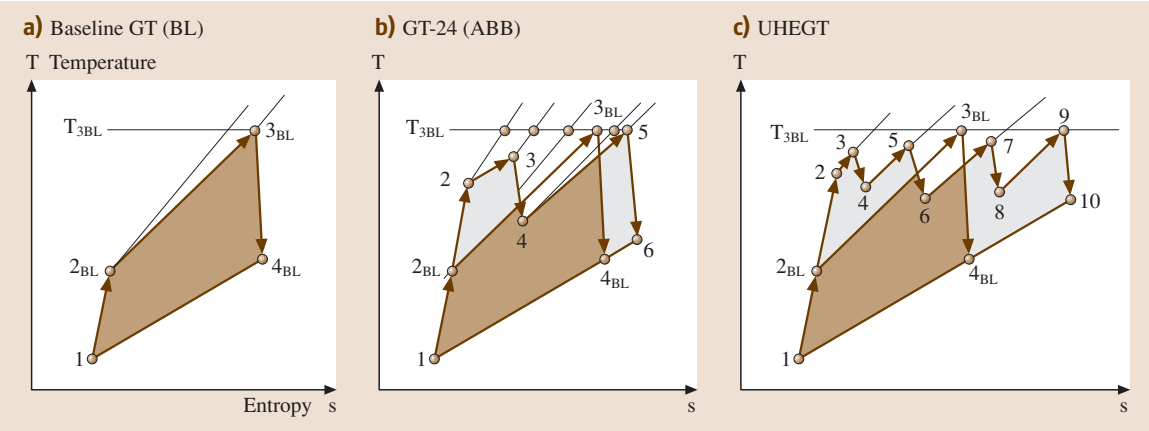

Fig. 12.57a–c Process comparison for (a) the baseline GT, (b) the GT-24, (c) the ultra high efficiency gas turbine technology (UHEGT) which has four stages with four integrated stator internal combustion

For a UHEGT with three-stator combustion, denoted by the curve UHEGT-0C3S, a thermal efficiency above 45% is calculated. This exhibits an increase of at least 5% above the gas turbine engine GT-24, which is close to 40.5%, as shown in Fig. 12.56a. Increasing the number of stators for internal combustion to four (curve labeled "UHEGT-0C4S") raises the efficiency above 48%. This is an enormous increase compared with any existing gas turbine engine. In the course of this calculation, the UHEGT technology is applied to a gas turbine engine with a precombustion chamber, such as the first one in GT-24 (Fig. 12.54). Using this combustion chamber with two-stator combustion, the curve labeled "UHEGT-1C2S" shows an efficiency of 44%. This is particularly interesting for upgrading the existing gas turbines with UHEGT technology. Figure 12.56b shows a comparison of the specific work for the gas turbines discussed above. Compared to the GT-24, UHEGT technology has about 20% higher specific work, making these engines very suitable for aircraft, stand-alone, as well as for combined cycle power generation applications. The evolution of the gas turbine efficiency improvement is summarized in the corresponding T–s-diagrams presented in Fig. 12.57a–c. In addition to the efficiency improvement brought about by utilizing a reheat turbine and two combustion chambers already discussed in conjunction with Fig. 12.26a,b further improvement is achieved by using stator internal combustion. As shown in Fig. 12.54c, with the UHEGT facilitates *quasi-Carnotising the Brayton cycle*. It is interesting to note that this efficiency increase can be established at a compressor pressure ratio of $\Pi_{\text{UHEGT}} \approx 35–40$, which can be achieved easily by existing compressor design technology with high polytropic efficiency. In performing the GETRAN© calculation, compressor and turbine efficiencies are calculated on a row-by-row basis. This automatically accounts for an increase of secondary flow losses based on aspect ratio decrease. Thus, in a compressor case, efficiency decrease with pressure ratio increase is inherently accounted for.

13. Transport Systems

Gritt Ahrens, Torsten Dellmann, Stefan Gies, Markus Hecht, Hamid Hefazi, Rolf Henke, Stefan Pischinger, Roger Schaufele, Oliver Tegel

Transportation is derived from two Latin words *trans* and *porta* meaning *in between* and *carrying*, respectively. Transportation is seen as one of the basic human needs and has a significant impact on a country's economy; productivity usually correlates well with the amount of transportation of goods and people. Transportation takes place on the ground, sea, and in the air and can be subdivided into the areas automotive, railway, naval, and aerospace. The respective engineering disciplines have gained increasing importance in the past as they face severe challenges for the future arising from: (i) increased transportation demand and customer needs, (ii) shortage of energy and rising fuel prices, and (iii) more stringent legislative requirements regarding for example pollutant and noise emissions and safety issues.

Section 13.2 provides an overview of aspects of automotive engineering. It starts with a historical view of how cars have evolved over time until today. Section 13.2.2 covers automotive technology, first describing the different car types and the fundamental requirements for car development. The technological areas and corresponding components relevant to cars are then briefly explained according to their major functions, the requirements they have to fulfill, and the challenges for further development in the future.

The car development process, with emphasis on the early phase where the car concept is defined and verified, is described in Sect. 13.2.3. Finally, some methods used in car development and cross-functional aspects to be covered in order to manage the car development process and meet the goals of a car development project are depicted.

At the end of the Chapter, a list of references is provided which will enable the interested reader to obtain detailed information about the technological aspects of modern cars and their development.

For general reading on automotive engineering, refer also to [13.1–5].

13.1 Overview

The forecasted increase in the world's population and its industrialization are the main drivers for the predicted rise in transportation demand, posing environmental concerns but also possible energy supply risks for the future.

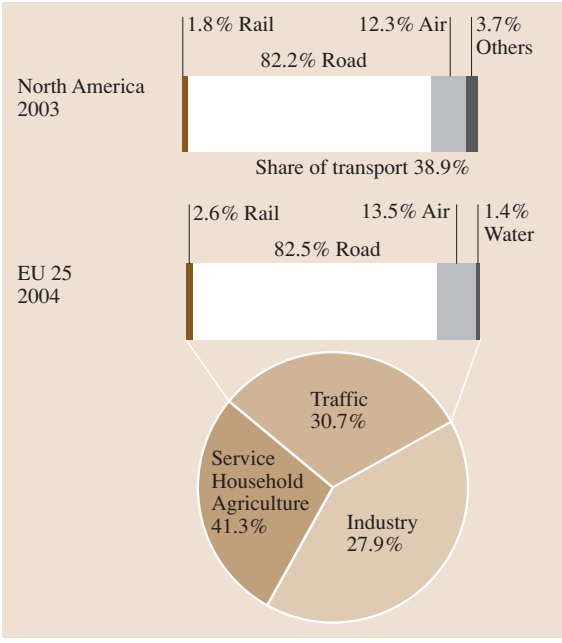

Fig. 13.1 Share of energy use in transport and distribution by modes of transport (from [13.6, 7])

Referring to Fig. 13.1, traffic's share in total demand for primary energy in the year 2004 amounted to 30.7% in Europe and to 38.9% in 2003 in North America (USA and Canada). Road transportation consumes the highest portion: 82.5% in Europe, and 82.3% in North America.

In Fig. 13.2 the predicted development in passenger travel and freight transportation in Europe up to the year 2020 is shown. For passenger travel, one can see a steady increase in road and air transport, while rail and public transportation remain more or less constant.

An increase in freight transportation is also foreseen, whereas the highest total share, in ton kilometers, is and will continue to be covered by road transportation, accounting for most of the increase up to the year 2020. However, it has to be noted that air transportation is forecasted to double in the same period.

In Fig. 13.3 the resulting predicted rise in energy demand of the transportation sector is shown for Organisation for Economic Co-operation and Development (OECD) and non-OECD countries.

For OECD countries an increase of 48% and for non-OECD countries a rise of 66% is envisioned up to

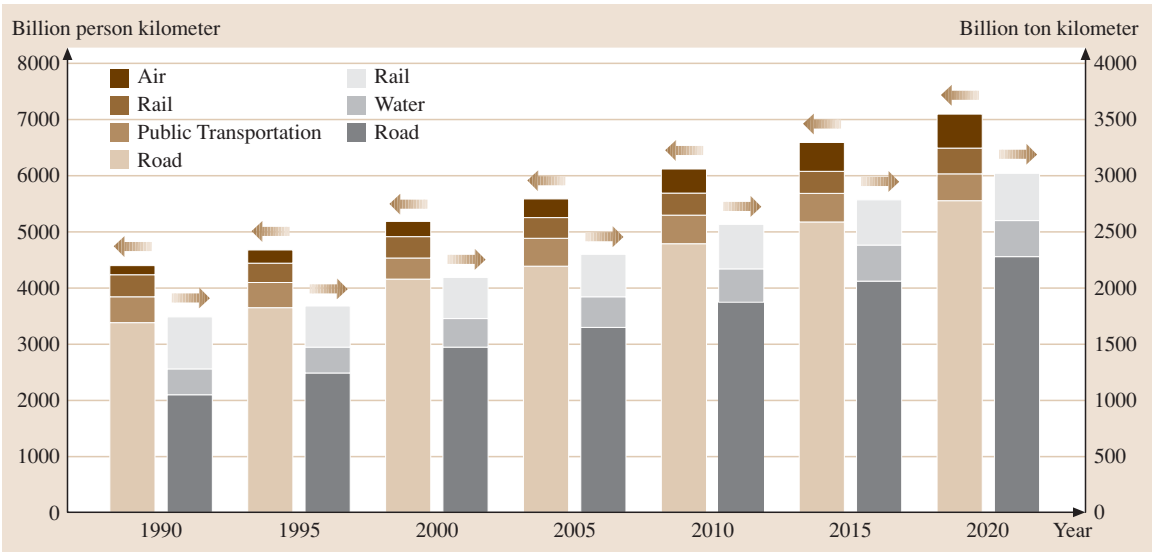

Fig. 13.2 Share of different modes of passenger and freight transportation in Europe (EU-25) (Source: European Commission)

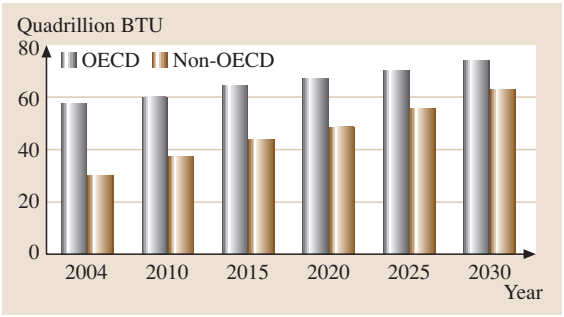

Fig. 13.3 OECD and non-OECD transportation, delivered energy consumption 2004–2030 (from [13.8])

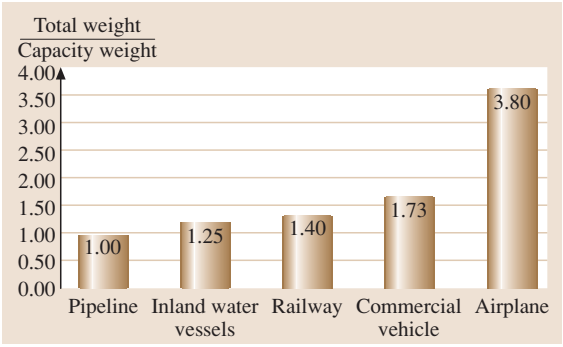

Fig. 13.5 Fraction of total weight to capacity weight for different transportation systems

the year 2030, leading to the necessity to improve efficiency of transportation as well as to search for new sources of energy.

An accurate comparison of the different transport modes (road transportation, aviation, and rail) regarding efficiency is difficult, because calculations are based on assumption for, e.g., travel distances, transport speeds, or average occupation.

In comparison with road transportation, rail transportation is more efficient. In [13.9], an electrical energy demand of 37 W h/seat-km is stated for an InterCity Express (ICE) (electro) with maximum speed higher than 200 km/h. Assuming an average passenger per seat ratio of 47.6%, an energy consumption of 78 W h/passenger-km results, which is equal to the gasoline energy content of 0.9 l/100 km. This energy does not include the efficiency of the energy production. Regarding aviation, in [13.10] the average kerosene consumption per 100 passenger-km of the Lufthansa fleet for intercontinental, continental, and regional flights are given as 4.06 l/100 passenger-km, 4.39 l/100 passenger-km, 8.85 l/100 passenger-km.

In Figs. 13.4 and 13.5 further criteria regarding transportation space and mass requirements are compared. Commercial vehicles and railways have higher transportation velocities compared with inland vessels and pipelines and can thus handle larger transportation streams. In contrast, the pipeline has the smallest profile area due to its construction and therefore achieves the largest transportation stream relative to its cross-sectional area.

The most favorable payload ratio is achieved with the pipeline, followed by inland vessels, railroads, commercial vehicles, and finally by airplanes.

Economical aspects such as energy and cost efficiency, investment needs, transportation speed, and space requirements will jointly play a decisive role for

Means of transportation	Cross-sectional profile	Transportation speed v (mph)	Transportation flow $\dot{v}$ (m^3/h)	Profile area A_p (m^2)	Relative transportation flow $\nu = \dot{v}/A_p$
Railway		32 (without shunting operation)	20 000	37	
Highway		32	14 500	115	
Canal		7.5	6250	470	
Pipeline		4.5	2850	0.4	
Fig. 13.4 Comparison of freight transportation systems (from Institut für Kraftfahrzeuge (ika), Aachen)

which transportation mode will become dominant in which area.

In addition, legislative requirements pose increasing constraints on all areas of transportation. One such area is the restriction of pollutant emissions of vehicles such as nitrogen oxides, unburned hydrocarbons, carbon monoxide, and particulates, resulting from the combustion of hydrocarbon bases fuels with air. In Fig. 13.6 particulate (PM) and nitrogen oxides (NO_x) emissions limits of diesel-powered passenger vehicles are shown for the USA and Japan as well as for the European Union (EU). These graphs illustrate a common trend among the industrialized nations to reduce the limits of pollutants emitted by vehicles.

The current focus on reducing the climate-relevant CO_2 emissions, which are not regarded as toxic emissions, will most likely lead to legal limitations in the future as well.

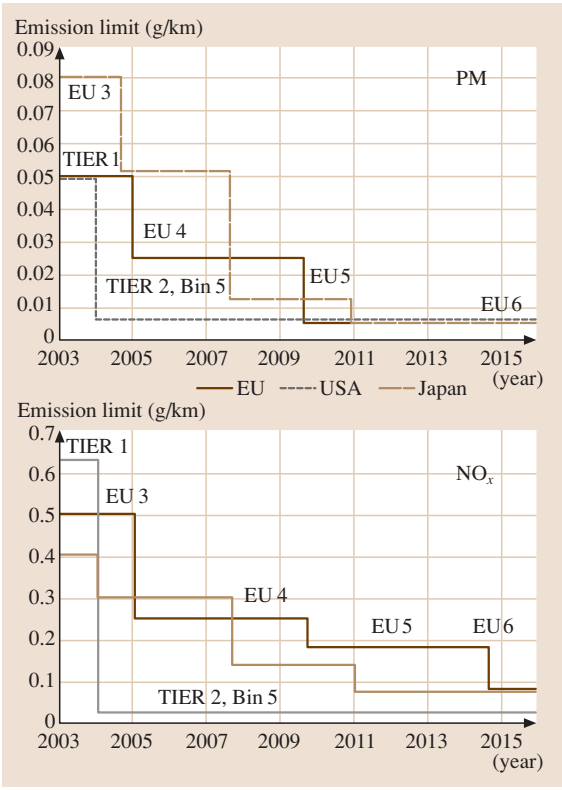

Fig. 13.6 Emission limits of diesel passenger cars (TIER 1 and TIER 2, bin 5: 50 000 miles; EU 5: draft proposal by European Commission in July 2005; Japan beyond model year 2011: proposed limits)

Besides emission of chemical components, noise is also generated and emitted by the various transport modes. Noise levels of 130–140 dB(A) are registered as pain; lower noise levels are also considered as harmful today, causing annoyance and aggression, high stress levels, hearing loss, and other harmful effects depending on the noise level and duration of exposure. Major sources of transport-related noise emissions are road, rail traffic, and aircraft traffic.

As early as 1937, noise limits for motor vehicles were specified in the German road traffic act (StVZO). The § 49 StVZO states: *Motor vehicles . . . must be created in such a manner that the noise produced does not exceed a value unavoidable by the current state of technology*. Over time, the limits have been tightened. A new EU regulation is in progress.

In 1971, the International Civil Aviation Organization (ICAO), an agency of the United Nations that codifies the principles and techniques of international air navigation, established regulations for limiting the noise radiation for civil aircrafts, distinguishing between different aircraft classes. As for road transportation, regulations for air traffic have also been tightened in several steps.

Finally, safety issues should be mentioned as a major driver for transportation technology, being imposed by legislation as well as being driven by customer requirements. In general, one has to differentiate between measures enabling a safe use of the transport mode involved and the possibility of harming a third party using the same, a different or no transport mode. For aeroplanes, for example, safe use is the main focus,

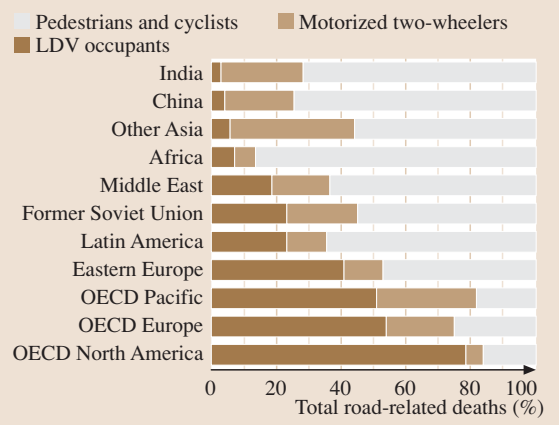

Fig. 13.7 Share of total road-related deaths by category of road users (source: 2007-09-14_WBCSD.org_mobility-full.pdf/LDV Light Duty Vehicle)

accomplished by stringent service routines and scrutinized development processes. On the one hand this is because any severe failure in air would almost certainly cause a large number of casualties and on the other hand design alterations of the aircraft cannot prevent harm to third parties. These have to be safeguarded within the operation, e.g., air-traffic control is responsible for ensuring that two aircraft do not collide. In contrary, road vehicles operate in partially very dense traffic and, although various regulations concerning servicing apply, they are mostly dependent on the awareness of the driver. In Fig. 13.7 the distribution of road-related deaths is shown. In North America light duty vehicles (LDV) contribute approximately 80% of road-related deaths, which in turn means that improving the vehicle's passive safety systems could be beneficial. In contrast to this, 70% of road-related deaths in India are accounted for by pedestrians and bicyclists. Combining this information with the survival probability in such accidents as shown in Fig. 13.8 the significant impact of reducing the allowable vehicle speed becomes obvious.

However such a measure would also have a severe impact on the transportation flow. As the severity of injuries inflicted on the pedestrian or bicyclist is not only a function of the collision speed but primarily of the actual impact harshness of the body on the vehicle, a passenger car should be designed in such a way that it can absorb a substantial amount of an impact, thus inflicting less harm on the other party.

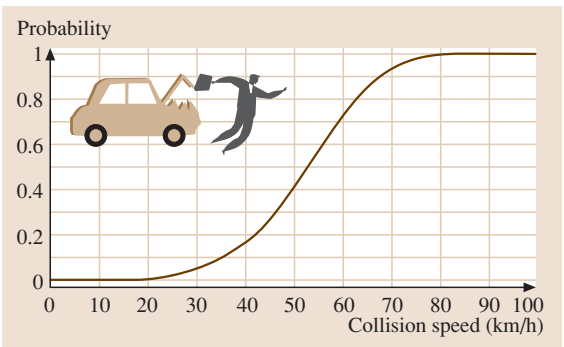

Fig. 13.8 Probability of fatal injury for a pedestrian after collision with a vehicle (after [13.11])

13.1.1 Road Transport – Vehicle Technology and Development

The automotive industry is one of the most important global key industries. In order to participate on the

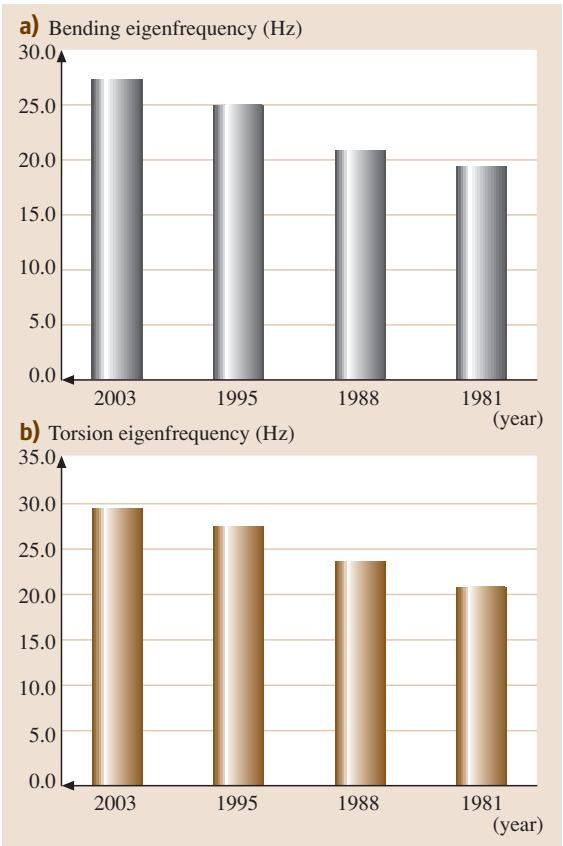

Fig. 13.10a,b Dynamic stiffness of an intermediate-class car model (source: Automobiltechnische Zeitschrift (ATZ)). **(a)** Bending eigenfrequency, **(b)** torsion eigenfrequency

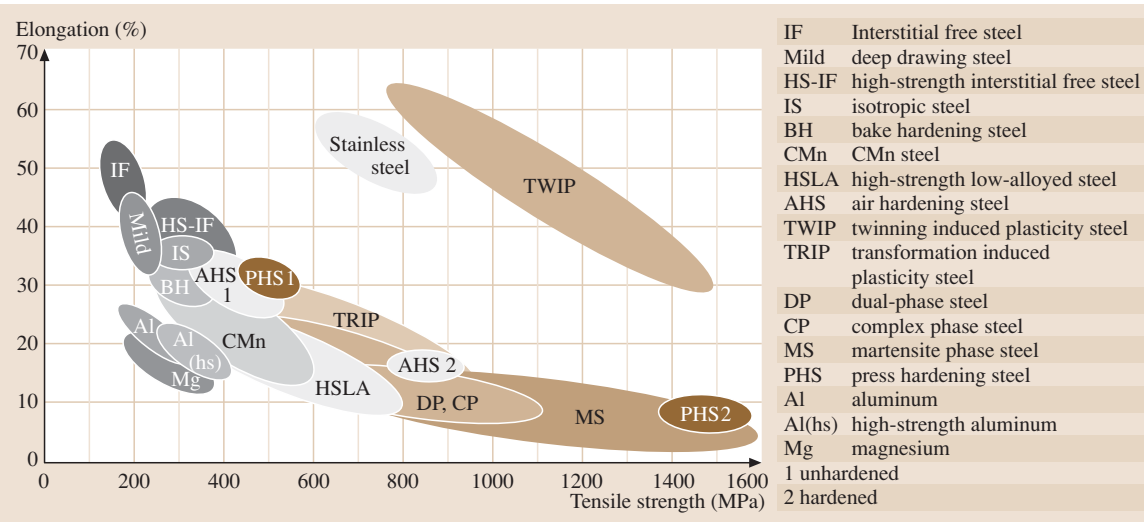

Fig. 13.11 Strength and formability characteristics of various steel grades (source: Forschungsgesellschaft Kraftfahrwesen mbH Aachen (fka))

steady growing automotive market, original equipment manufacturers (OEMs) and suppliers need to generate innovations. Below, the technological developments and the future challenges in the areas of body, chassis, advanced driver assistance systems, and internal combustion engines (Fig. 13.9) are described.

Development Trends in the Field of Automobile Bodies

The body is not only the central load-carrying part of a motor vehicle, it also determines its capacity for passenger and/or freight transport, dominates the outer appearance of the vehicle, and has an important influence on safety and driving comfort.

The requirements of passive safety (noise–vibration–harshness, NVH), driving comfort, and dynamics determine the design of the body structure. In Fig. 13.10, the increasing dynamic stiffness of cars is shown.

Another aspect of vehicle safety of growing relevance is pedestrian protection (Sect. 13.1). The introduction of corresponding regulations in Europe and in Japan has already brought about major changes to the design of the front of many car models. With those regulations becoming more stringent, additional pedestrian safety measures will be launched in the coming years. Moreover, crash compatibility in vehicle-to-vehicle collisions will be an important safety issue for the future, and will probably have a considerable influence on body design as well.

While safety measures tend to result in a mass increase, there is a strong desire to reduce vehicle weights in order to improve handling characteristics, driving performance, and last but not least fuel consumption and CO_2 emissions. However, during the last three decades, the empty weight of passenger cars has increased steadily in spite of intensive efforts regarding lightweight design of body structures. A major challenge in vehicle engineering will be to reduce vehicle weight in spite of additional functions and requirements and cost pressure.

For high-volume cars, the steel unibody is the standard design concept. Substantial improvements in the

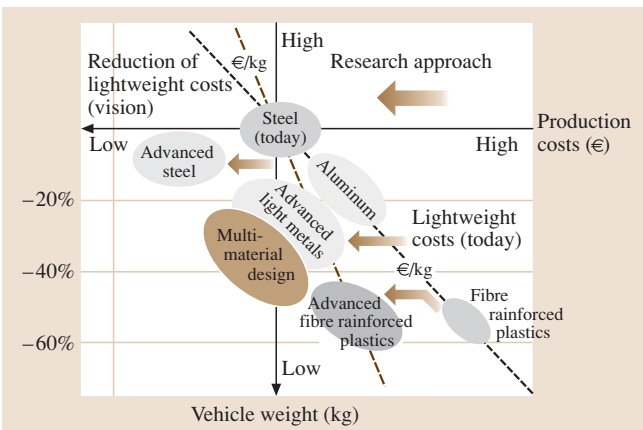

Fig. 13.12 Vehicle weight versus production costs (source: Volkswagen)

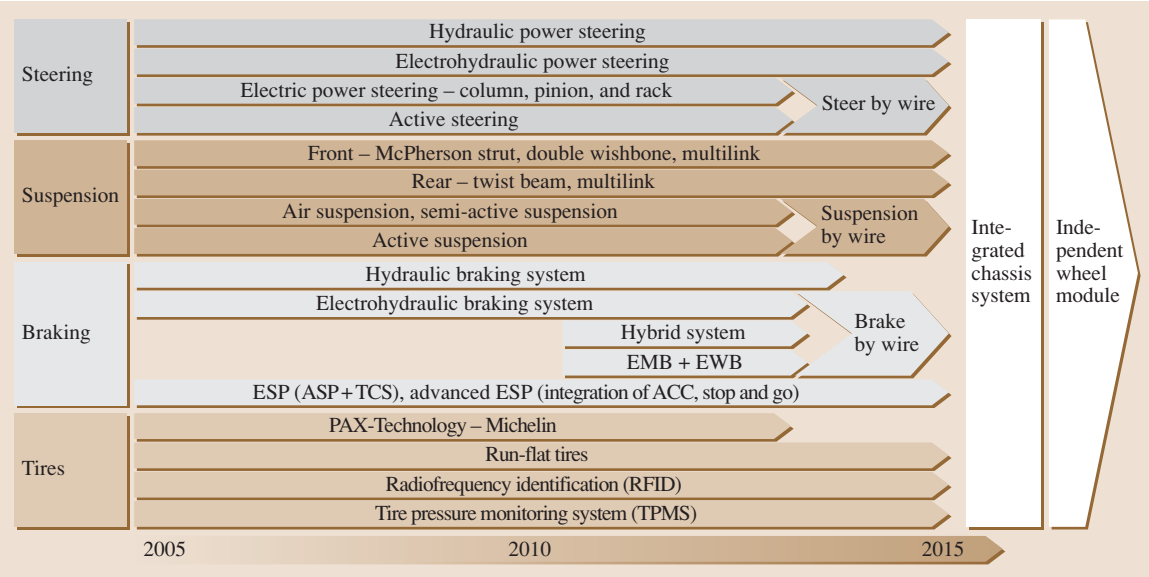

Fig. 13.13 Evolution of chassis components (source: Frost & Sullivan Consulting, 2007)

crash behavior of steel unibodies as well as weight savings have already been realized by the application of new high- and ultrahigh-strength steel grades (Fig. 13.11).

Rolled profiles and hydroformed tubes offering superior strength and stiffness properties in comparison with conventional spot-welded steel-sheet structures. In addition, a trend towards multimaterial design is noticeable. In principle, this means that for each body component or module the most suitable material will be selected, which will result in an intelligent mix of materials such as aluminum, magnesium, plastics, and of course steel. The main purpose is to realize a beneficial combination of low weight and relatively low production costs, as illustrated in Fig. 13.12.

Development Trends in the Field of Chassis

For decades, the trade-off between safety (road holding) and comfort (soft suspension and noise insulation) was the greatest challenge for every chassis engineer. Adaptive components and active chassis systems aim at solving this issue. Over the next 10 years, the portion of electronic systems in the chassis will increase five times in terms of cost compared with today (Fig. 13.13). The more intelligent and controlled systems that are introduced, the more the need for an integrated control strategy increases. The next step is the link to passive systems.

The electronic stability program (ESP), for instance, can be connected with active steering or electric power steering for a combined steering and braking input, or with adaptive air suspension or variable damping systems for roll angle adjustment. Also, ESP sensors can detect the risk of an accident and pretension passive systems.

Regarding suspension types, the McPherson strut and the double-wishbone suspension are the commonly used front suspension types, while the twist beam and multilink types are the choice for rear suspensions. The McPherson strut already has a marked share of 85%; the multilink rear suspension is expected to grow over 55% in the long term.

The developments in brake and steering systems and also damping systems are moving towards the so-called *dry* chassis, which means that hydraulic actuation is replaced by electric motors. This offers more opportunities for control and easier system integration.

Development Trends in the Field of Advanced Driver-Assistance Systems

Due to the increasing traffic volume and growing complexity of driving tasks, technical systems have been developed in order to support the driver and relieve him/her of some of these tasks. These systems are called advanced driver-assistance systems (ADAS). The roadmap of upcoming ADAS is shown in Fig. 13.14. These comfort systems are the basis for safety systems,

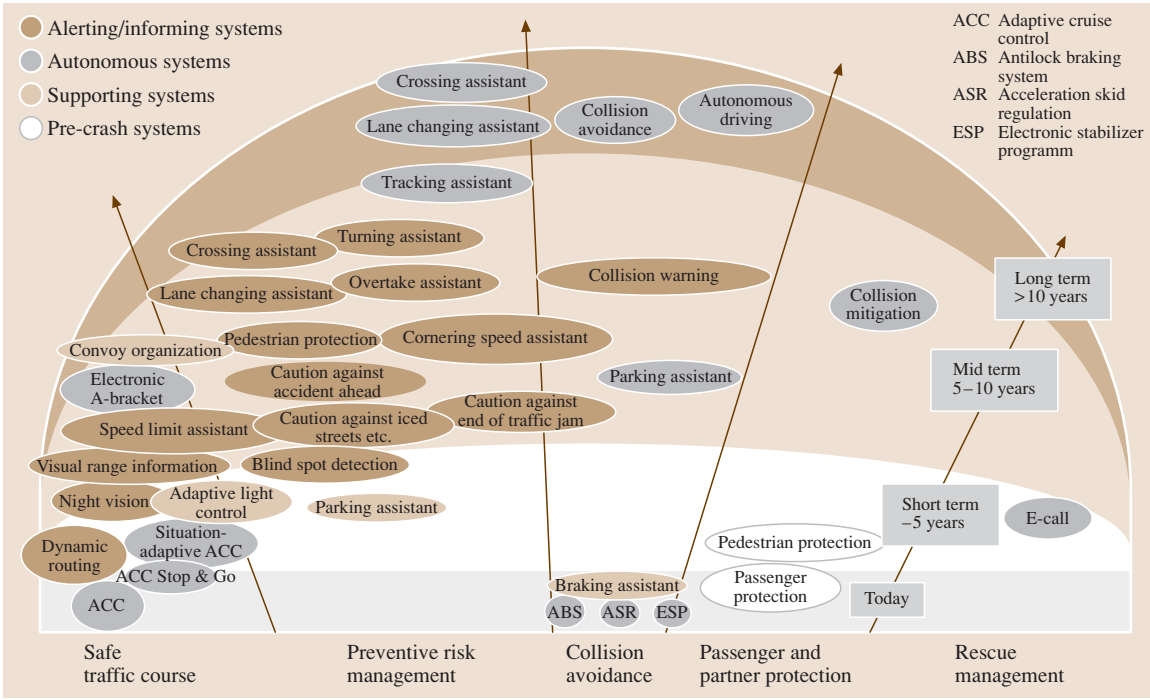

Fig. 13.14 Roadmap ADAS/active safety

because they can avoid accidents or at least reduce the collision speed.

Today the focus of ADAS is increasingly on safety. The European Commission has set the goal of reducing the number of road-traffic fatalities in 2010 by half in comparison with the number in 2001. It is obvious that such a goal can only be achieved with the support of ADAS and active safety systems.

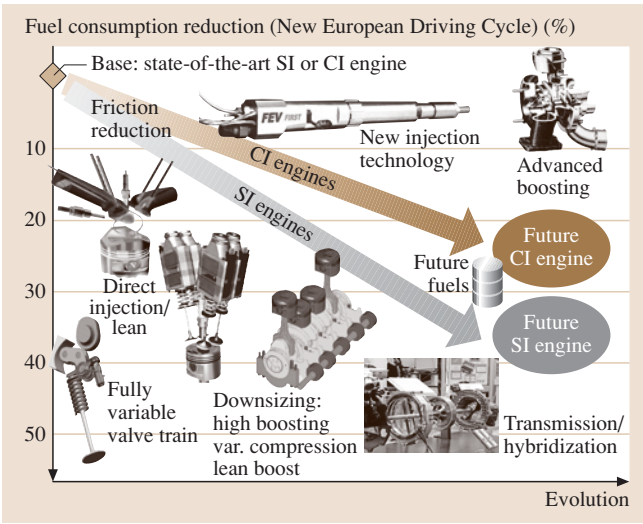

Fig. 13.15 Potential of fuel consumption reduction with power-train technology (source: VKA)

Development Trends in the Field of Internal Combustion Engines

In Fig. 13.15 an overview of current development trends for internal combustion engines (ICE) is given, showing the potential for fuel consumption and corresponding CO_2 reduction of 20–40% for compression-ignited (CI) diesel and especially spark-ignited (SI) gasoline engines.

The main technological trends for future SI engines are direct injection combined with advanced boosting strategies, an increase in variability, e.g., variable valve train, variable compression ratio, and an increasing degree of hybridization. Advanced injection systems (increased injection pressures and higher degrees of variability) and boosting technology are the focus of research and development (R&D) for modern diesel engines. Additional improvements are possible by using future fuels, e.g., tailored fuels produced from biomass, for both combustion concepts.

13.1.2 Aerospace – Technology and Development

Aerospace and Society

As addressed in the general introduction, the wealth of any modern society is based on fast and reliable transport of information, passengers, and freight in an environmentally acceptable way. Aerospace is a mandatory part of the overall transportation system: satellites provide weather information, navigation signals, and transmit messages worldwide; transport aircraft provide fast and safe transportation of passengers and/or freight across borders; and military aerospace is part of any strategy for many years to come. In commercial terms, the future of aeronautics is bright: the increase of passenger traffic has been stable at some 5% per year for three decades, and is forecast to continue this trend for the next decades; for cargo growth is higher, at 6% per year. From Fig. 13.2 it can be derived that passenger transport by aeronautics exceeds that by rail and public transport from 2015 onwards.

In addition, aeronautics has always touched the human imagination: from the story of Daedalus through Leonardo da Vinci to Antoine de Saint-Exupéry. It is an ancient wish of mankind to be able to fly, and space has inspired human thoughts for a long time as well, from ancient cultures, which already knew much about the stars, up to today, where we think about an ever-expanding or finally collapsing universe.

In some fields of activity, aeronautics and space systems merge. After launch space payload carriers not built in space have to cross the atmosphere, coping with gravity and air friction, similar to aeronautic vehicles. More specifically, common interests are in space tourism, hypersonic transport, and rail guns as satellite launchers.

The launch of space vehicles is somehow spectacular, but limited to a few places in the world. Therefore, the public takes quite some interest in such a launch, because it is linked to that dream of mankind mentioned before. On the other hand, and even though aeronautic vehicles are also part of that dream, and are mandatory for modern life, their operation is more heavily criticized. Whereas, for example, railway noise is accepted even in the heart of cities at midnight, aircraft noise seems to be annoying even if hardly noticeable. The public is used to all other kind of traffic, and has accepted their drawbacks, but noise and emissions from aeronautics are more in the focus of today's discussion than their share of the overall transport system. This may be due to the fact that the basis of one's desire to fly is the ease and weightlessness of a bird soaring in the sky. Thus, man reacts more sensitively to aircraft noise and pollution than to pollution of any other means of transport. In reality, much progress has been made over recent decades. Noise has been drastically reduced with the target of keeping the major part of the noise carpet within the airport area (Fig. 13.16), and the amount of exhaust emissions has even been decoupled from the number of aircraft (Fig. 13.17).

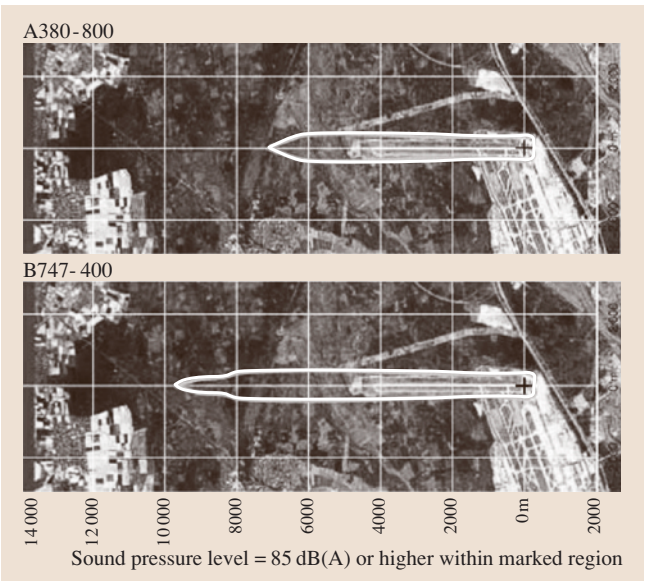

Fig. 13.16 Noise carpet at Frankfurt airport (source: DLH)

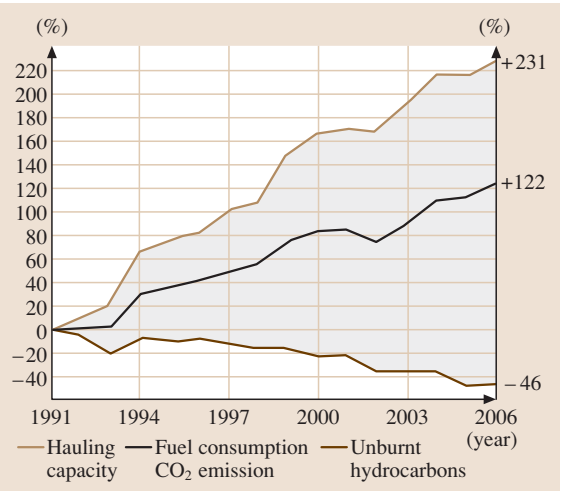

Fig. 13.17 Decoupling of fuel consumption and hauling capacity (source: DLH)

As in other fields, there are many ways to look at aerospace engineering. Firstly, there is the work of specialists in many fields, but one can also consider a system approach combining disciplines into increasingly complex components up to the level of the final vehicles; finally there is a *system-of-systems* approach, when talking about the air transport system (ATS). In astronautics, this system-of-systems approach includes the vehicle, payload, transfer, and ground support. In any case, the total life has to be addressed, from the first flight or launch via planned operation up to the disposal of the vehicle. The importance of the last topic is increasing, in aeronautics due to the issue of global resource management and in astronautics due to issue of space debris.

Aerospace Disciplines and the Design Process

Aerospace in general is an integrated or so-called integration subject, with aeronautics and astronautics as particular fields of activities. Vehicle design is based on inputs from the fundamental engineering disciplines, namely aerodynamics, structures, and systems. As subgroups, flight mechanics, static, kinematics, and others are found but can be allocated to the first three disciplines. In addition, combinations of the original disciplines have emerged, such as aeroelastics and aeroacoustics. Within each of these disciplines, progress has been made in the past, such as new flow control means, new materials, and new electronic systems.

Building upon the foundations laid by work in the individual disciplines, components are created. This is already an interdisciplinary task, as for an aircraft flap aerodynamic performance is needed as well as the structure, including the kinematics and actuators on the systems side. Today, in aeronautics the largest components are the complete aircraft structure and the engine, which are developed and manufactured separately. As for components, their development and final composition into a complete vehicle is a multidisciplinary and interdisciplinary task.

As for most other product developments, aircraft or spacecraft design follows a process which has been set up throughout recent decades. Initially, there is a market analysis, looking for what is missing in the present set of products. In aeronautics, this may be defined by the so-called *transport task*, i. e., the requirement to move a given payload in a given time across a given distance. In astronautics, apart from the vehicle, the payload itself can be the product to be developed, such as a satellite.

From these general requirements set by the market demands, the so-called top-level aircraft requirements (TLAR) can be derived as a basis for the future project office (FPO) work. They will work out a general arrangement (GA) of the vehicle to be designed, working with tools mainly based on statistics and/or simple calculation methods.

This GA will then be given to various departments, such as flight physics or structures. Together with the aircraft programme management, they will start component development, accompanied by tests in wind tunnels, test rigs, or simulators. At this stage, new technologies already available in the respective disciplines can be included in the design process. Increasingly, digital mock-ups (DMU) are used in the first part of the development phase instead of hardware.

With the GA and first performance estimates available, launching customers have to be found. They will influence the final design by their own needs. Depending on the product size and cost, with a certain number of products sold, the actual development starts with the programme *go-ahead*, almost in parallel with the production of the first parts. At the end, specific tests will be carried out on prototypes, which may require some final, hopefully minor, changes in the design. The last

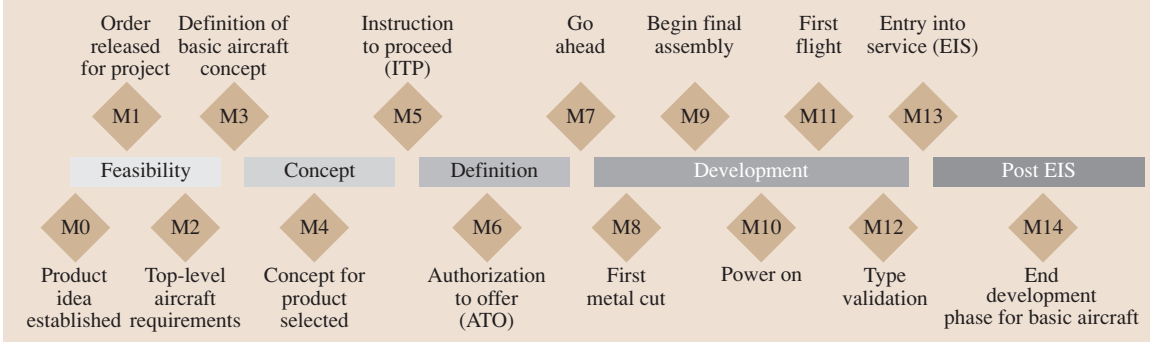

Fig. 13.18 Development process

step is the certification process, which ends with entry into service (EIS).

The whole development process as outlined above is almost the same for any aircraft manufacturer, and can be seen as a series of milestones as shown in Fig. 13.18.

At present, the market analysis may last for 2 years, the predevelopment for some 3 years, the development and manufacture for about 5 years, and the certification for another year. Just before the committed start of a programme, technology development may take place, with technology feasibility or prematurity as a first step, and technology application studies as the final step. Overall, the time between the first thought about a new aircraft and the EIS is approximately 10–15 years.

For example, first thoughts on the Airbus A380 were published in 1989; at that time it was called the megaliner, ultra-high-capacity aircraft (UHCA). Later it became the very large commercial transport (VLCT, as a common Airbus–Boeing feasibility study.

The committed programme start occurred in 2000, and finally the A380 was introduced into airline service in 2007, corresponding to a total of 18years. Of course, all manufacturers try to speed up this process. For the given and already highly optimized standard aircraft configuration, i. e., fuselage, wing, engines, and tailplane as for today's aircraft, further optimization is possible mainly by improving the design chain, including supplier management. However, for a completely new design, such as a blended wing body (BWB) (Fig. 13.19) or an oblique flying wing (OFW), the exhaustive time scale as described above is likely to remain.

Apart from monodisciplinary technologies such as a new material, a new actuator or a specific aerodynamic vortex generator, integrated technologies make their way into the product, too; for example, the fly-by-wire technology was a *must* for the European supersonic transport aircraft Concorde in the 1960s. Without it, it would not have been possible for the pilots to fly this aircraft in all the different flight regimes, in each of which the aircraft control behavior is different. Afterwards in a first attempt, this technology was introduced into the Airbus A310, until it finally became mature in the Airbus A320, which made its maiden flight in 1987. Flow control technology or artificial instability are other examples of technology development, and manufacturing technologies such as friction steer welding or laser beam welding, advanced bonding or surface coating have been developed in the past and are part of the production process today.

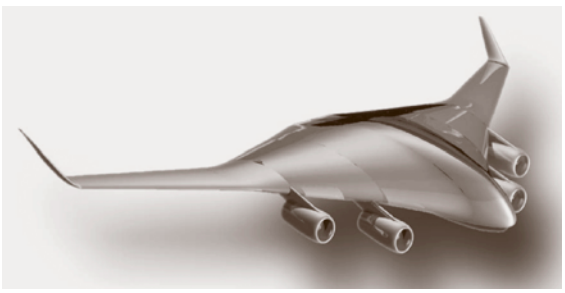

Fig. 13.19 Blended wing body (source: DLR)

Following the complete vehicle assembly, the vehicle will be operated in a larger system. Aircraft navigate with the help of air-traffic control, they are linked to other traffic in the air, and on the ground, especially in the vicinity of airports, they need to be loaded and unloaded and are part of a so-called intermodality concept that links personal and public transport on the ground with air or sea transport.

Challenges in Aeronautical Engineering

Looking at aeronautics' history, it can be structured into three blocks. From its beginning until the end of World War II, physical understanding was the dominating driver. This began with daring pilots in *fantastic flying machines*, permanently hunting for records in range, speed, and altitude. As the next phase, coinciding with the introduction of jet engines, commercial aeronautics emerged. Many different configurations have been studied, such as vertical take-off and landing (VTOL) aircraft such as the Dornier Do 31, supersonic transport in the shape of Concorde, and flying wings such as the Northrop YB-49. This led to the third phase, which is based on today's configuration of a commercial transport aircraft, all looking very much the same regardless of the manufacturing company. This configuration has reached a high level of maturity, so after all the expensive configuration studies, finally civil transport aircraft design and manufacture pays off.

However, with the success of commercial transport, three other issues have emerged. Firstly, airports are increasingly operating at their capacity limits, so it is questionable whether there is any chance to increase air traffic, even if there is a demand for it. Secondly, linked to this, environmental aspects play a leading role. Even though the contribution of aeronautics to global emissions may be small, i. e., at about 2% today, it is debated very intensely. Thirdly, and still linked to growth, safety issues are of increasing importance. Today's reliability rate of 10^{-9} failures per flight hour for critical components will not be sufficient if the number of aircraft

doubles within a decade. In order to reduce the number of accidents in parallel with an increasing number of vehicles, functional hazard analysis must yield greater reliability. This holds true for single components such as an actuator, up to subsystems such as an aileron, and also the complete aircraft system and structure.

Almost at the same time, the European Commission published its *Vision 2020* on aeronautics and the National Aeronautics and Space Adminstration (NASA) published its *Aeronautics Blueprint* on these issues. Both came to similar conclusions: with aeronautics being a vital element for the wealth of society on one side, and the environmental issues linked to it on the other side, in the future there will be additional TLAR, in order to balance transport needs, society needs in terms of safety and security, and environment protection. These additional TLAR may ask for totally different vehicle configurations as well as for new ways of operating these vehicles. In addition, all of these issues ask for a system approach; for example, in contrast to road and rail transport, security will play an increasingly important role in aeronautics. There are an increasing number of studies on the seamless air transport which ask for new ground procedures and probably even new vehicle designs. To define and finally solve all the new TLAR will be a demanding task for any discipline as well as for the overall vehicle and system composition, in aeronautics as well as in astronautics. Therefore, a fourth phase can be expected, aiming for *sustainable growth*.

13.1.3 Rail Transport – Rail Technology and Development

The main difference between railways and other means of transportation is the automatic guidance of the vehicles, leaving only one degree of freedom for a vehicle. This automatic guidance keeps the vehicle on course, defined by the infrastructure. A train can be handled just by controlling the velocity.

However there is no possibility to sidestep other vehicles spontaneously, as the vehicles are guided along the tracks on an accurately defined path. Rail vehicles can only pass each other in specially equipped places. To prevent the system from deadlocks a schedule is absolutely necessary. Together with the timetable there is a need for train protection which prevents two trains heading in opposite directions on one track.

Efficiency, Resistance, and Traction Forces

An advantage of the aforementioned railway schedule is the fact that trains can run almost nonstop from one station to another, as long as the schedule works properly. Thus long and heavy trains can be operated in an energy-saving manner, as they have to be accelerated only once. This small number of accelerations and decelerations becomes even more important regarding a train's ability of acceleration. Because traction forces have to be generated by friction between the wheels and the rail, acceleration forces are limited. The frictional coefficient between rolling steel bodies is always correlated with the relative velocity (slippage) between the bodies (Fig. 13.20).

The maximum coefficient of friction on dry rails is about $f_x \approx 0.45$; if rails are wet or polluted it can decrease to values of $f_x \approx 0.1$. This means for deceleration, where all axles are braked, a maximum deceleration of $b \approx 1\,\mathrm{m/s^2}$ can be guaranteed (13.1). Besides traction power, the maximum acceleration depends on the number of powered axles and the actual friction conditions. For passenger trains this problem is increasingly being solved by using multiple train units in which the traction is distributed over the whole length of the train. Freight trains are still equipped with conventional locomotives, where only four or six powered axles have to pull the entire train

$$F_\mathrm{B} = mb = f_x mg$$
$$\Rightarrow b = f_x g = 0.1 \times 9.81\,\mathrm{m/s^2} = 0.981\,\mathrm{m/s^2}\,. \tag{13.1}$$

Once a train is in motion the low frictional force of the wheel–rail contact offers a big advantage due to the low rolling resistance of steel on steel. Compared with road vehicles, for which rubber is rolling on tarmac, resistance is marginal. Especially for heavy loads this generates an advantage for railways. So when the

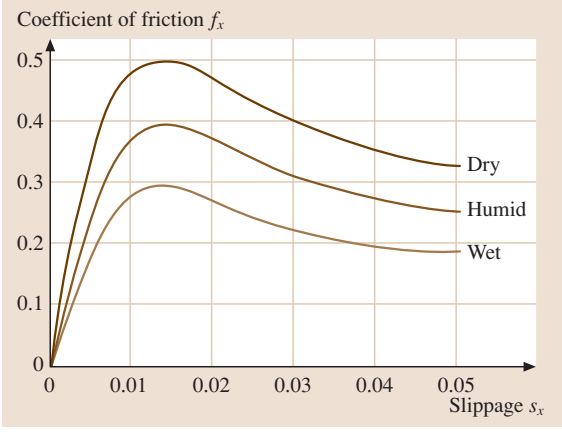

Fig. 13.20 Coefficient of friction

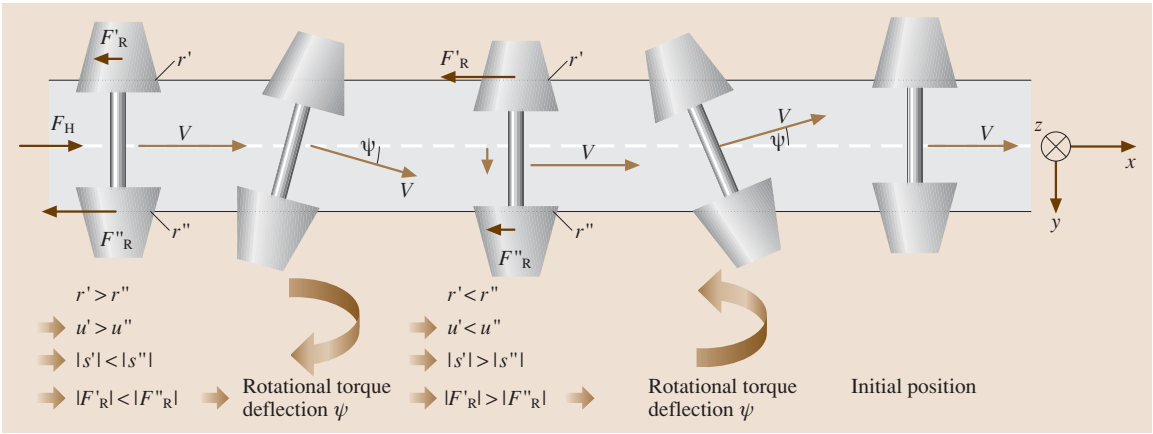

Fig. 13.21 Sinusoidal movement of a (powered) wheel-set (circumferential velocity u > translational velocity v)

train reaches its cruising speed only a small amount of traction is needed to keep the train moving (Table 13.1).

Guidance

Automatic guidance is also an effect of wheel–rail interaction. Conventional wheel sets are guided by an effect called *sinusoidal movement*, which is caused by the wheel profile. In a simplified approach wheel profiles can be regarded as conic, so that deflection of the wheel set (pair of wheels torsion resistant fixed on a shaft) causes different circumferential speeds of both wheels. Together with the slippage–adhesion correlation this leads to different traction forces on both wheels and for this reason to a turning torque acting upon the wheel set.

As shown in Fig. 13.21 the resulting torque on the wheel set always acts in a direction turning a deflected wheel set back towards the centreline of the track. After passing the centreline the orientation of the torque will change and turn the wheel set back into a position offset and aligned to the tracks centreline. At this time the action will start again with opposite sign. Due to the wave-like motion of the wheel set along the track's centreline this is called the sinusoidal movement of the wheel set.

Table 13.1 Rolling resistances of different vehicles $F_R = f_R mg$

Wheel type	f_R	Example of contact pairs
Heavy rail	0.002	e.g., intercity train
Light rail	0.008	e.g., tramway
Tire	0.01	Tire on tarmac
Tire	0.2	Tire on unfortified road
Tire	0.007	Race cycle on tarmac

As well as the desired effect of guidance, the sinusoidal movement causes lateral forces which disturb the riding comfort of the vehicle on the one hand and on the other hand can lead to derailment of the wheel set when a certain velocity is exceeded. To achieve higher speeds and to increase riding comfort damping of the sinusoidal movement is necessary. As sinusoidal movement always coincides with slippage and tangential forces, energy dissipation in terms of noise and wear will occur.

The vast majority of rail vehicles are equipped with wheel sets providing the guidance. However, a few vehicles have single wheels that are independently joined to the axle (Fig. 13.22). Here guidance is achieved by geometrically induced forces. The wheel profile is shaped in such a way that the inclination of the profile increases towards the wheel flange. When a wheel's flange comes close to the rail this will generate a higher lateral share of the normal force between the wheel and rail, which will have a greater magnitude than the lateral force of

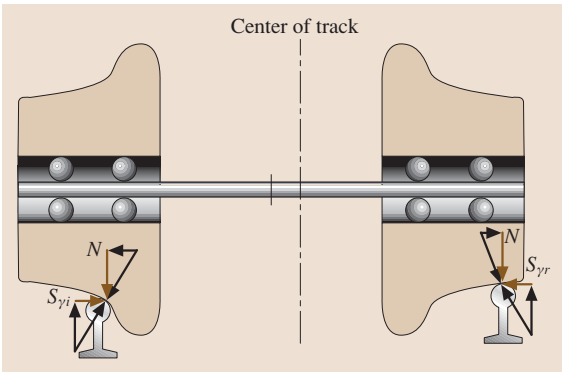

Fig. 13.22 Guidance by single wheels

the opposing wheel, where the flange is far from the rail and thus the inclination of the profile is smaller. Therefore the pair of wheels is pushed back towards the center of the track.

As the single wheels need no axles between the wheels, they are primarily used in low-floor trams to allow an entirely low-floor design without any steps between the wheels. For heavy rail applications only the Spanish manufacturer Talgo provides guidance by single wheels profiting from the fact that single wheels result in smoother guidance on straight tracks due to the lack of sinusoidal movement.

Braking Systems

Because train vehicles are automatically guided the system's safest state is at standstill. Therefore railways are designed to lead to standstill in the case of severe failure. To achieve this failsafe behavior, braking systems play the major part and must themselves exhibit failsafe behavior. In the past after almost every serious accident braking systems were improved to prevent the sort of failure that led to the accident. This in turn led to the current state, where regulations for railway brakes are tight, and render almost any other technical solution other than pneumatic brake systems unworthy.

A main characteristic of the pneumatic railway brake is the main air pipe (MAP), i. e., a pressure line running through the complete train (Fig. 13.23). The pressure within the main air pipe controls the driver's brake valve in such a way that, for detached brakes, the pressure has a maximum value of 5 bar. To apply the brakes the pipe's pressure is decreased and the distributor valve transmits the pressure of the reservoir through to the brake cylinder. Because of this engineering methodology the train brake is failsafe: a loss of energy within the MAP causes the brakes to apply.

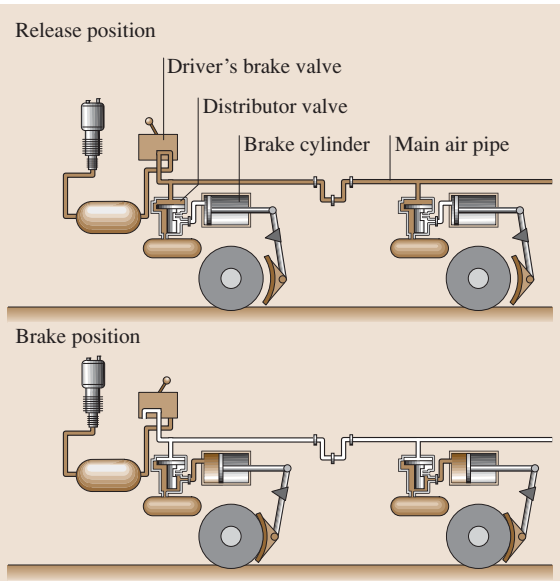

Fig. 13.23 Pneumatic braking system

To convert the cylinder's pressure into a braking torque there are basically two different devices: for ordinary vehicles there is the tread brake, where a brake pad is directly pressed onto the surface of the rail. This on the one hand causes wear and ripples on the running surface of the wheel, which lead to higher noise emissions of the running car. On the other hand damage to the wheel can be caused by thermal energy that has to be absorbed by the brake. For passenger cars braking torque is usually generated by a disc brake, where two brake pads are applied to a disc mounted on the wheel set. The chance of a mechanical damage to the wheel as a direct cause of applying the brake is eliminated. However, damage can still be caused by brakes locking up and forcing the wheel to slide on the rail, resulting in the wheel being planed. So wheel-slide protection (WSP) is needed to avoid wheel flats.

Apart from its failsafe behavior the pneumatic brake has various disadvantages, especially as the response time of pneumatic systems is quite slow. Not only is their controllability for purposes such as WSP poor, but also braking performance suffers from the time it takes the pneumatic signal to reach the last car (in the case of freight trains a delay of approximately 30 s can be expected until the last car has reached full braking performance). To improve the performance of the classical pneumatic brake, passenger trains are usually equipped with additional braking devices such as electropneumatic brakes, in which brake signals are transmitted electronically to achieve better response times. Furthermore powered cars are equipped with regenerative brakes and retarder brakes to increase the efficiency and decrease the wear and thermal stress of the brakes.

Train Protection/Management

As mentioned above a schedule is necessary to protect the system from deadlocks and to ensure that there is no more than one train per track section. To ensure safe operation also in the case of trains not running on time, there is always a system of train protection. Interlocks ensure that no train enters a section that is already occupied by a train. Entry to each section is guarded by a signal that allows or denies access to the block. As a crash is hard to avoid once two trains are on the same

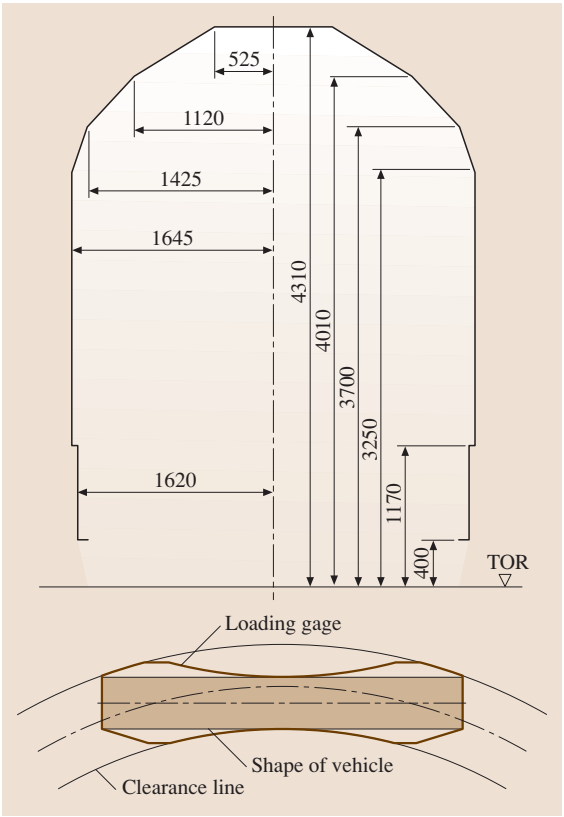

Fig. 13.24 Clearance line for international traffic; shape of vehicle within a clearance line (in mm)

track, railway signals have an even more serious meaning than traffic lights in road traffic. To avoid human mistakes signals are equipped with automatic train protection devices that can stop a train automatically if the driver does not react properly to a signal. These systems are likely to differ from country to country and thus restrain international rail traffic.

Because of their long stopping distances, trains cannot stop within their range of visibility. Thus there are approach signals several hundred meters ahead showing the engine driver what event to expect. As the train has to come to a standstill within the distance of approach and main signal, this distance has to be the stopping distance of the train and is one parameter that defines the maximum speed. Besides the distance of the approach signal the minimum curve radius determines the maximum speed of a railway line. Due to passenger comfort and to prevent cargo from slipping the maximum allowed lateral acceleration on board a train is limited to $1.0\,\mathrm{m/s^2}$.

Structure of Vehicles

The appearance of rail vehicles is primarily dominated by the car body. The size of the car body is determined to a large extent by the infrastructure: the maximum height and width are clearly defined by the clearance outline, and the space beside the track that is guaranteed to be free from obstacles (platforms, bridges, signal posts, etc.). As vehicles also have to pass curves with specified clearance lines, the vehicle's length is also defined by these parameters (Fig. 13.24). A rail vehicle has to be designed in such a way that the vehicle does not touch the clearance line even on narrow curves. So for European standard-gage tracks a typical size of a passenger car has been established with a length of 26.4 m, a width of 3 m, and a height of 4 m. Those cars are usually carried by two bogies with two axles each.

Furthermore the vehicle's mass is limited by the permitted axle load. In Europe, this load is usually limited to 22.5 t per axle, so that a conventional four-axle car has a maximum weight of 90 t. For passenger cars and freight cars with a small payload there are also different arrangements of axles in order to economize tare weight by minimizing the number of axles. Besides the four-axle car the most common type is the articulated train with Jacobs bogies, where two car bodies share one bogie (Fig. 13.25). The disadvantage of this arrangement is that they may only be separated in the workshop, as the link to the bogie replaces the coupling between the cars.

Coupling

The most obvious use of couplings is to create a detachable connection between cars. Furthermore couplings have the function of transmitting longitudinal forces within the train and to prevent the train from being exposed to forces exceeding its specifications. If tensile forces become too high the coupler will break (e.g., if the pulled train is too heavy); if compressive forces are exceeded, for example during a crash, the coupling can

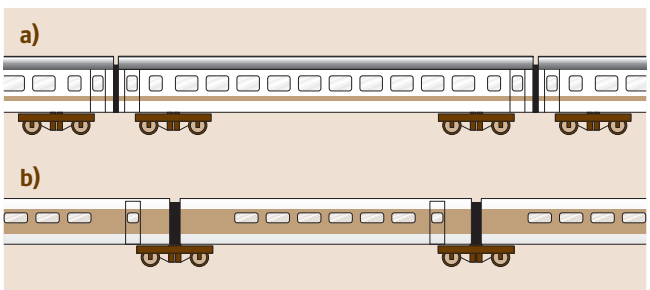

Fig. 13.25 (a) Conventional passenger car. (b) Passenger car with Jacobs bogie

absorb some of the energy. Another important function of a coupling is data transmission. Conventional couplings just transmit the pneumatic signal and energy of the brake's main air pipe. For passenger cars there is also an electric coupling that links the cars' energy supply and various types of signal cables.

In Europe the manually operated screw coupling is standard, offering the possibility to combine all cars without limitation. The advantage of standardization compensates for the disadvantage that the coupling cannot be automated. Automatic couplings in Europe are only fitted to multiple-unit trains in passenger service which have to be coupled solely with other units of similar type. In the USA and in the states of the former USSR automatic couplings are also used for conventional passenger and freight trains.

Shunting of freight trains is – because of the screw-coupling among others – very complicated and requires special shunting yards of huge dimensions. Due to shunting the average speed of a freight car in Germany is below 8 km/h despite the maximum speed of freight trains being 100 km/h loaded and 120 km/h empty.

Within this introduction the significance of today's transportation has been outlined, whereas increasing demand for commercial and recreational freight and passenger travel will enhance the importance of transportation as a highly interdisciplinary field. Transportation and its dependencies offers researchers multiple opportunities to optimize various aspects, i. e., cost, time, safety, and reliability. In this chapter however, the engineering involved in automotive, railway and aerospace will be described in more detail.

13.2 Automotive Engineering

The development of cars differs from the development of other technical products. In this chapter it will be explained why this is the case from a general point of view. Furthermore it will be stated how the topic of *automotive engineering* is imparted.

In principle, a car is a technical product such as a toaster, a refrigerator or a computer. All of these products are things used in everyday life.

13.2.1 Overview

Today every technical device is subject to innovation, development, and production, which are the basics of engineering in general. However, there are differences between cars and their development compared with other technical products, which will now be described.

First of all, a car is a *highly complex* product which has developed tremendously since the times it simply had to transport its load from one point to another. Today, the passenger and their satisfaction are the focus. The passenger is not only kept safe, dry, and warm but also entertained, informed, and even comforted in their seat. The function of transport seems to have become secondary. Still its realization has gained complexity too (Sect. 13.2.2).

Buying a car is normally a *highly individual* process. Thousands of models of hundreds of brands are available. After having decided for a certain brand and a specific model again there are thousands of possibilities to configure one's individual car (at least for premium European car brands).

Furthermore, a car is a *mass product*. Every year, millions of cars are produced and sold in countries all over the world. Characteristics of mass products are: (a) a high number of produced units per year, and (b) there is no direct customer for the development (i.e., there is only a customer for an individual car) but the company itself.

Moreover, cars are *durable products*. About 20 years go by from the first idea to the recycling of cars, and some of the cars remaining at this point even start a second career as classics after this long period of time. In order to achieve this level of durability the development team has to have *a look for the future*: which features will be demanded 3–5 years later? How much is the customer willing/able to pay for the specific feature? Are the development departments of other OEMs working on similar features and what will the specifics of those be? Will there be regulations that might prohibit the use of this feature?

Due to its complexity, required quality, and resulting high development and production costs the car is quite an *expensive* product.

Because of the sum of these characteristics – that the car is an expensive, highly complex, and highly individualized mass product – a lot of *jobs* depend on the automotive industry, not only in many industrial countries. In Germany, for example, one-seventh of all jobs are directly or indirectly dependent on the car industry [13.12]. As a consequence, the automotive industry has a huge influence on society.

To achieve the countless functions and features, design the car and its variants, and set trends in styling a huge *variety of expertise* is needed. In order to bundle this expertise a *well-organized development process* is needed, which again consists of *adapted methods*. Subsections 13.2.3 and 13.2.4 provide details of the characteristics of car development and the methods applied.

As cars are such complex products, a lot of components are *developed externally*, meaning that specialized companies supply their expertise to the OEM to develop components – usually complex, special components such as brake systems (ESP) – and integrate them in association with the OEM into the car context.

Because a car is a product in everyday use, there are thousands of *regulations* to keep the use of it safe and convenient as well as protect the *environment*. The consideration of these regulations again increases the challenge of the generation of functions and features that meet all existing requirements (function, low cost, etc.).

The complexity of a car and its development naturally also affect the costs of development and production. The demanded *high investments* for an entire new car can be up to five billion Euros. Only the aerospace or military industry can boast similar numbers, but have entirely different customers.

Automobiles – A View Back and Ahead

This section provides a general idea of how the car has changed since its invention, what has influenced the development of the car, and on the other hand how the development of cars has influenced our way of life and thereby society and the world. A brief look at the directions that car development might take in the future rounds off this journey.

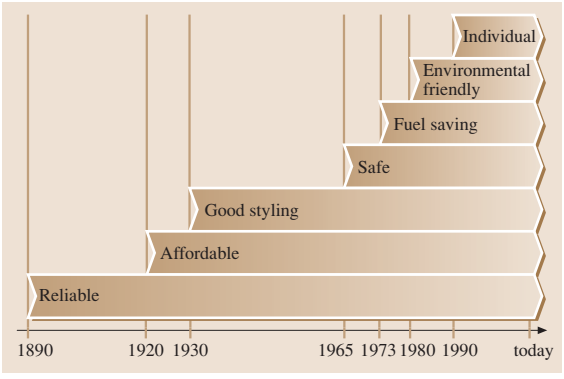

Fig. 13.26 Main aspects of car development and the points in time when they gained in importance

Trends That Have Influenced Car Development. The specifications for a car to be developed include several important points: technical reliability, an appealing styling that makes the customer buy the car, safety for the passengers and other traffic participants, fuel-saving, good economics, and environmental compatibility. Above that, a car also should be individual but nevertheless affordable. An overview of car development over the last 120 years will be given based on these main points.

The first cars built by Daimler and Benz in 1886 were nothing more than coaches with a slow-running Otto engine. These motor carriages had no roof and were not much faster than traditional horse-powered carriages (Fig. 13.27).

One of the first goals of car companies, of which there were increasing numbers in the 1890s, was to achieve greater technical reliability and more comfort for car users. Because no-one had experience in developing cars and no development methods were known, the old-fashioned approach of *trial and error* was used to develop cars (Fig. 13.26).

The Early Car Races as a Field for Testing Inventions. The car companies needed the opportunity to test the inventions they were making and, of course, a forum where they could show off how good their cars were. To do this, car races became popular and helped to accelerate the development of innovations. Car races, for example, accelerated the development of bodies with lower center of gravity, which was good for their driving performance. Hard rally-like races showed how to build a frame that was robust but also lightweight. New techniques such as the electrical ignition system and the

Fig. 13.27 Benz and Daimler carriage (courtesy of DaimlerChrysler archive)

Fig. 13.28 1912 Ford Model-T roadster (copyright 1995–1999 The Henry Ford Organization, Photo: P.833.38916)

shock absorber also demonstrated their reliability in car races.

However, improving the chassis and body was only one way to win races; increasing the engine power was another. In the late 1890s and early 1900s the *classic* approaches for increasing the power of an engine were found: increasing the engine displacement, increasing the compression (which led to the development of higher-quality fuel types), improving the carburetor, including more valves into the cylinder head, locating camshafts above the cylinder head [overhead camshaft (OHC) engines], and so on. Increasing the motor power led to the development of better braking systems for all four wheels which was no natural thing first and optimized suspensions.

Cars for Everyone: the Ford Model-T as an Example. At this stage, cars were still not affordable for most people. Hence, one of the next main goals in car development was to find a way to build cars cheaper so that everyone could buy a car. A pioneer in this field was Henry Ford. He developed a simple car that was cheap to produce and cheap to run – the Ford Model-T (the so called Tin Lizzy, Fig. 13.28).

To achieve this goal, Ford used ideas which are still current: he lowered the producing costs with the introduction of new production methods (e.g., the assembly line), he simplified every component of the car (reaching two goals: greater reliability and lower production costs), and he restricted the variety of options available to choose from.

Good Styling Wakes Desirability. After World War I (WWI), developing more reliable cars was not enough. Increasingly, the customer wanted to have an individual car to stand out from other motorists. This development was accelerated by cars such as the Tin Lizzy; if everyone had the same car, the demand for more individuality and outlining became increasingly important.

Although there was still only one type of carriage – the frame body – emphasis was placed on a number of different body styles: phaetons (Fig. 13.29), tourers, town cars (Fig. 13.30), several styles of convertibles, convertible sedans, Pullman bodies with an extended number of seats, limousines with short and long wheelbase, roadsters, coupés, sedans, etc. The only limit for this kind of technology was the solvency of the customer.

Of course, only very rich people had the means to choose whatever they want from this range, and order a car at an OEM-independent coach builder such as Gläser in Dresden, Castagna or Farina (later Pininfarina) in Italy, Park Ward in England or Saoutchik in France (Fig. 13.31).

In the years following World War II (WWII) cars were optimized in three development dimensions: reliability, affordability, and eye-catching styling. WWII

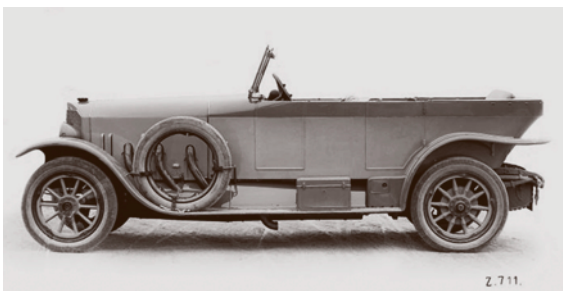

Fig. 13.29 Mercedes 28-95 PS Phaeton (courtesy of DaimlerChrysler)

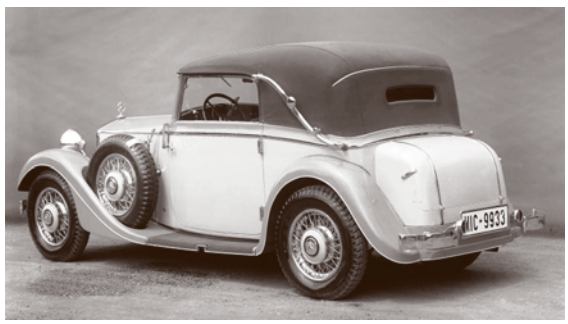

Fig. 13.30 1933 Mercedes-Benz 290 Cabriolet C (courtesy of DaimlerChrysler)

stopped car development throughout the world from about 1941 onwards; car companies changed into defense companies producing tanks, military trucks, jeeps, and even airplanes.

A New Start. After WWII many of the old European OEMs were not able to rise again. Some of them had lost their coach supplier (such as Adler) and were not able to produce. Others had lost their complete production plants as war reparations to the Soviet Union (Auto Union and BMW). Some OEMs had to reestablish themselves (such as DKW and BMW) in Western Germany. All of the cars produced at this time were mainly the same as those produced before WWII.

Car development was thrown back years; the first goal mentioned in this paragraph, technical reliability, became once again the most important. In those days, it was not important to have a good-looking car, but one which was able to fulfill its function to transport people and goods (Fig. 13.32).

As times improved, good design and affordability again became important development goals. A new body style was introduced by Kaiser-Frazer in 1946, the so-called pontoon-type body (Fig. 13.33).

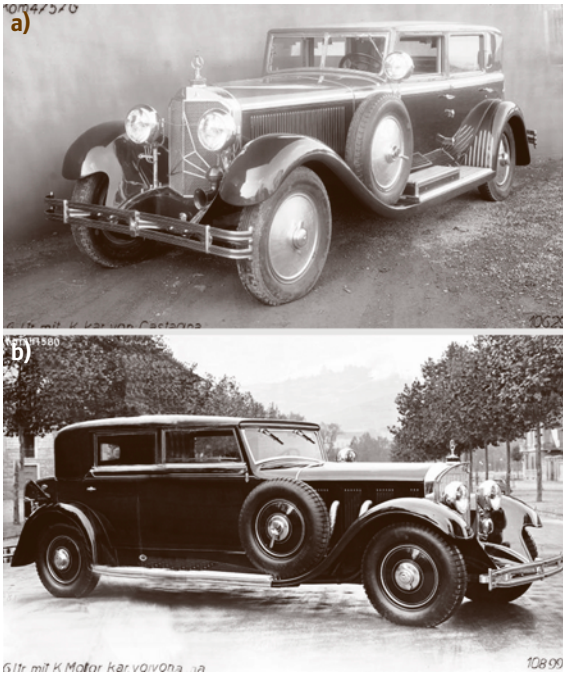

Fig. 13.31a,b Mercedes-Benz Type 630 Modell K, body by Castagna **(a)** and Mercedes-Benz Type 630 Modell K, body by Farina, **(b)** both 1926 (courtesy of DaimlerChrysler)

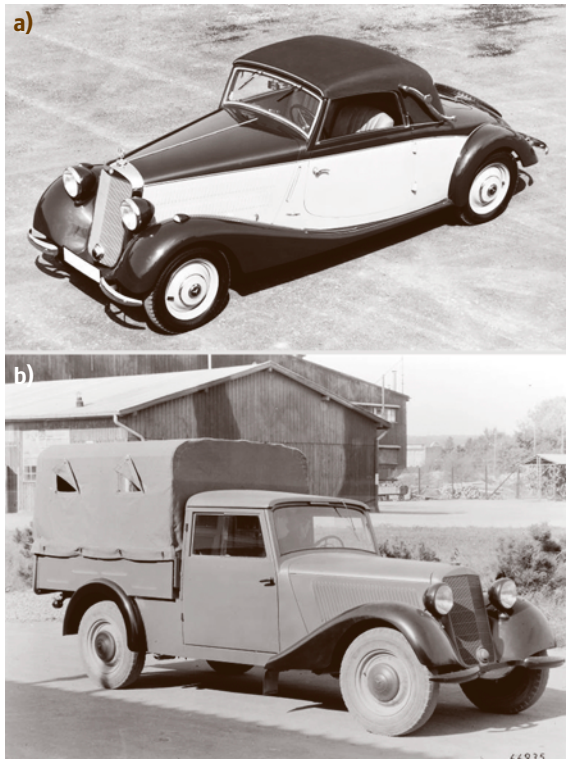

Fig. 13.32a,b Two Mercedes-Benz 170 V; **(a)** 1936 Convertible A, **(b)** 1946 light truck (courtesy of Daimler-Chrysler)

The pontoon-type body was built upon unit body cars, provided more space than the old-fashioned body types, and was much lighter than older designs. On the other hand, this body type strongly restricted the degrees of freedom with respect to individuality of body shaping because of the lack of a separate frame.

Though the idea of the pontoon style and unit body soon showed their superiority, it took almost 10 years

Fig. 13.33 1947 Kaiser-Frazer

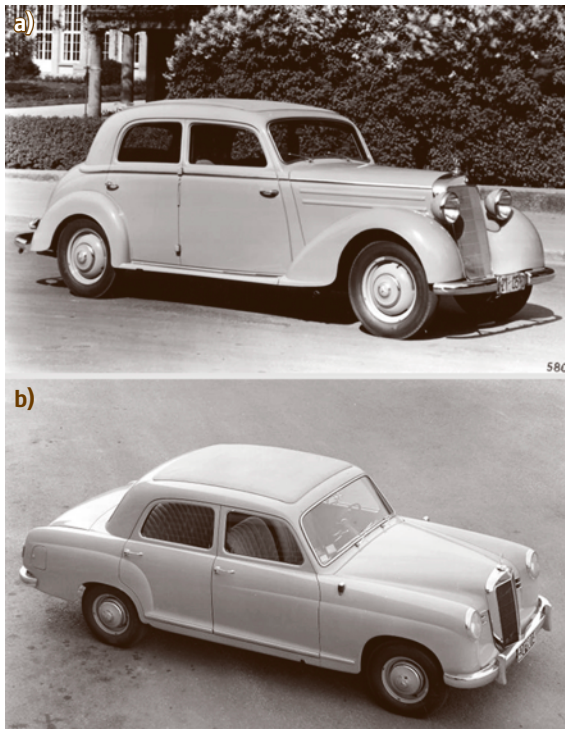

Fig. 13.34 (a) Mercedes-Benz 170 S-V, (b) Mercedes-Benz 180 *Pontoon* (both 1953) (courtesy of DaimlerChrysler)

until the last companies switched their vehicle range. Mercedes-Benz, for example, even as late as 1955 sold a modern and an old-fashioned car in the same class (Fig. 13.34).

Styling Dominates Technical Issues. In the subsequent years the number of car body styles decreased, but styling *exploded*. Some companies, mainly those in the USA and their subsidiaries (such as Ford Germany and Opel) brought out *new* cars every year. The only new thing about these cars was the styling; technical issues were mainly the same – except that almost every car had large tail fins on the rear. The high point of this development was the 1959 Cadillac Convertible (Fig. 13.35).

The Need for Safety Changes Car Development. In the mid 1960s, after the release of a book about car safety (*Unsafe at any speed* by *Ralph Nader*, Pocket Books, New York 1966), the US government took measures to make cars safer: cars had to pass standardized crash tests, which were tightened every 2–3 years. Every car company selling cars in the USA had to pass these tests in order to obtain the approval of the US Department of

Fig. 13.35 1959 Cadillac Convertible (source: http://www.classic-cadillac.com, Classic Cadillac Community, Timmendorfer Strand)

Transportation. Almost immediately all car companies optimized their current car types to pass the government security tests. Research was set up to develop safer cars.

Research was expensive and so was changing current cars to pass new tests. This almost marked the end for many car companies that could not afford this kind of development or had car types in their programs that were not adaptable to the new rules. One class of cars was especially affected by this: the convertibles. The largest market for cars, the US market, stopped buying convertibles because they were considered unsafe (especially in the case of a rollover). As a result almost every OEM that served this market took convertibles out of their program. The casualty of this develop-

Fig. 13.36 1976 MG Midget with US security bumpers (source: http://en.wikipedia.org/wiki/Image:1976.mg.midget.arp.jpg)

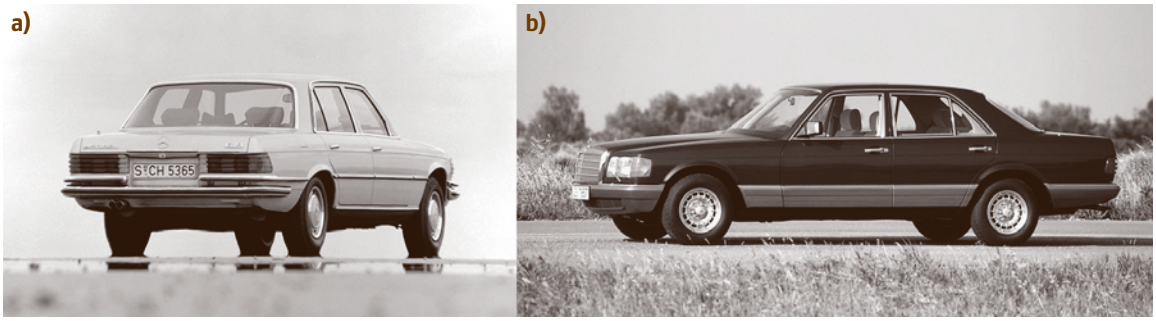

Fig. 13.37 (a) 1978 Mercedes-Benz S-Class, (b) 1979 Mercedes-Benz S-Class (courtesy of DaimlerChrysler)

ment was mainly the British car industry: almost every British OEM had convertibles in their program, including the MGB, the MG Midget (Fig. 13.36), the Jaguar E-Type, the Austin–Healey Sprite, and the Triumph TR-series. All these cars ceased to exist because of these security regulations or were unaesthetically adapted due to the addition of security bumpers and plastic adaptations.

Reliable, Affordable, Good Looking, Safe – and Fuel Saving? In 1973 there was an oil crisis. The oil-exporting nations reduced the amount of oil produced to a minimum and as a consequence the prices of oil and fuel rose tremendously. People could not afford to run their cars in the way they were used to. Now everyone tried to save oil and fuel. In Germany, for example, four car-free Sundays were installed in the autumn of 1973. This naturally also affected the car industry. Several measures were taken by the automobile industry to develop cars that were more economical.

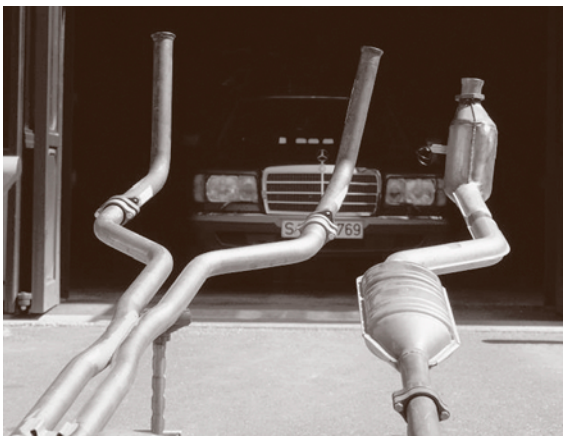

Fig. 13.38 Exhaust system without (*left*) and with (*right*) catalytic converter (courtesy of DaimlerChrysler)

However, now there was a conflict of targets in car development: cars had to be safe, but safety meant that cars became heavier, which resulted in higher fuel consumption. Hence, new ways of developing and producing cars had to be found to solve this conflict. It was not sufficient to concentrate on one development target; for the first time in car history the car had to be looked upon as a unit.

One of the first measures to achieve both security and light weight was to use new materials such as high-strength low-alloy (HSLA) steel and new plastics. The dramatic changes in this area can be seen when compar-

Fig. 13.39 Mazda MX-5 Miata (copyright: Mazda)

ing the 1978 Mercedes-Benz S-Class and its successor (Fig. 13.37).

Plastics replaced chromium-plated metal, engines made out of aluminum replaced those made out of grey cast iron, and aerodynamics was improved. The carburetor was increasingly replaced by the fuel injection, because an injection system controlled by microcomputer was able to reduce fuel consumption in a way that an *analog* carburetor could never achieve. However, there was another reason why the carburetor fell out of favor.

Do Cars Damage the Environment? A phenomenon unknown until that time was experienced from the early 1980s: the dying of forests caused by acid rain, which itself was the consequence of industrial waste gases as well as car exhausts. Measures had to be taken to reduce air pollution.

This trend influenced car development: the catalytic converter for cars with gasoline engines, which had been in use since the mid 1970s in the US, was now used in Europe as well (Fig. 13.38).

The diesel engine was developed for direct injection and common rail technology and, in combination with exhaust-gas turbocharging, a former lame duck named diesel found its way into sports cars, luxury cars, and even convertibles.

Mass Individualization as a New Trend. In the late 1980s the common car changed due to a change in society in the industrial nations: the demand for more individual products. Throughout the 1980s there were several studies for new, small fun cars, but the first one to make it into serial production was the Mazda MX-5 (Miata) in 1989 (Fig. 13.39).

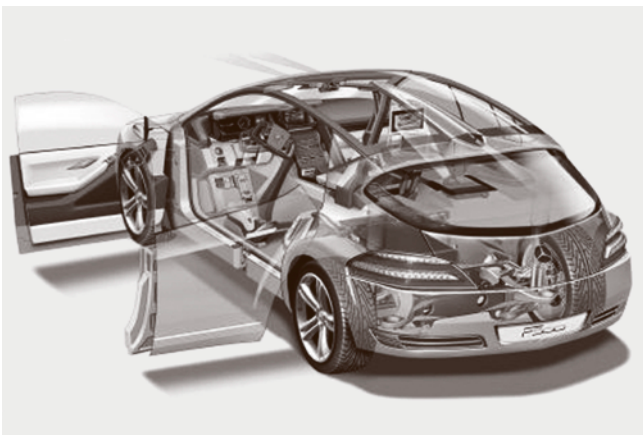

Fig. 13.40 Mercedes-Benz F 500 Mind – a look into automobile future (courtesy of Mercedes Car Group)

Because of the success of this car, other OEMs also created cars for this market: the Porsche Boxster, the Fiat Barchetta, the Mercedes SLK, and BMW Z3 are some examples of this new style.

Another trend which emerged in the 1980s was vans. As they became wealthier, societies in the industrialized nations had more leisure time that was now used for hobbies. For a lot of those hobbies bulky accessories were needed and these hobbies were carried out anywhere but at home – as a consequence cars had to provide more space. The first such vans introduced were the Chrysler Voyager and the Renault Espace in 1984. A classic among these vans is the Volkswagen Microbus.

This mass individualization led to an exploding OEM product range and a trend called crossover, meaning that several car types are crossed. The sports utility vehicle (SUV), for example, is a crossing between a station wagon and an all-terrain vehicle.

What Are the Trends for the Future? Technology is heading towards saving even more fuel. Today new petroleum reservoirs are still being discovered, but it is predictable that one day there will be not enough reserves to run millions of cars let alone other uses.

Steps towards saving fuel include, for example, more widespread use of the diesel engine because it needs less fuel than a gasoline-driven car. Hybrid cars are also an alternative to conventional cars (Sect. 13.2.2). Other technologies under investigation include engines driven by fuel cells, hydrogen, and vegetable oil.

Electronic features for enhancing driving safety, accident avoidance systems, and infotainment systems will probably play an even more important role than today in fulfilling customer demands.

The variety of options and the frequency of replacement of model line versions might be reduced since there is no real return on invest any more.

13.2.2 Automotive Technology

Automotive technology consists of separate areas, which in general have their organizational counterparts in the departmental structure of the automotive company in terms of functional departments and model lines. In this section, an overview of car types and the general targets for car development (and thereby automotive technologies) is given. Then, the technological

areas are briefly described with the demands which have to be taken into account by each and the major functions to be realized.

Car Types

Car types can be classified into one-box, two-box, and three-box concepts.

Cars designed as one-box concepts are perceived as one single volume (one box) and are to be found mainly in the area of vans but also in small cars such as the MCC Smart and Mercedes A-class. Their major advantage is very good space economy, while these cars are comparatively high and thus have disadvantages in terms of aerodynamics and vehicle dynamics due to the high center of mass.

Two-box concepts divide the car into two different volumes, the front volume usually used for the engine bay, and the second volume for passenger compartment and/or loading space. Two-box concepts are used for SUVs, station wagons, and cars in the compact class such as the Volkswagen (VW) Golf.

Finally, the three-box concept is the classic division of the car body into three volumes, separating the engine bay from the passenger compartment and the trunk. This concept is used for limousines, classic coupés, convertibles, and roadsters.

Targets for Car Development

Customer Demands. Customer demands are the most crucial targets for car development. Methods for the translation of customer demands to technical requirements are described in the literature, namely the *house of quality* [13.13].

When clustering the demands that customers and society place on cars one can identify various target conflicts. What is needed is cars that are:

- Safe
- Emotional
- Comfortable
- High quality
- Highly reliable
- Low emission
- Low noise
- Highly recyclable
- Have decent driving performance and load capacity
- Low cost, both in acquisition and utilization

A rough overview of the major design requirements in different market segments is shown in Table 13.2.

Regulations. Regulations from legislation, car associations, and consumer groups are a major influence on car development and the final products themselves. In different countries, different regulations have to be taken into account to:

- Be able to introduce a car model (line) into this specific domestic market at all
- Be able to fulfill the consumer expectations, especially concerning car safety and fuel economy

The European Union has published far more than 50 regulations concerning active and passive car safety (prevention of accidents, reduction of consequences of accidents, car emissions, etc.).

Causes for the definition of regulations are manyfold: from the protection of the domestic markets and domestic car manufacturers to protection of people, the environment, and the traffic.

Table 13.3 shows as an example the relevant standards concerning safety published by the National Highway and Traffic Security Association (NHTSA), an operating unit of the Department of Transport (DoT) of the US government.

Technical Requirements – Specific Example: Climate Stress. Technical requirements for car development are derived from a number of external and internal influences on the car and its operation. Here, as an example area, climate parameters to be taken into account when designing a car, are described.

A car and its components are exposed to a multitude of external factors in terms of climate stress. The strength of these factors depends on the planned operating area of a car and has to be taken into account when designing a car:

- Temperature: the maximum and minimum operating temperature and the temperature levels where the car and its components are kept (e.g., during transport).
- Humidity: from extremely dry conditions (e.g., the Mojave Desert) to tropical conditions – the most stressful environment is a humid, hot climate.
- Water: rain, car wash (with different kinds of washing equipment).
- Sand and dust: a challenge for the layout of sealings (e.g., keeping the passenger compartment free of dust, and taking care that the air convection compo-

Table 13.2 Design requirements in different market segments [13.14]

Mini car	Small car	Family car	Luxury car	Performance sedan	Sports car/coupé	Rallye or track car
Versatile accommodation	Versatile accommodation	Versatile accommodation	Distinctive style	Fast appearance	Sleek styling	Priority to function
Small frontal area	Small frontal area	Low C_d and reasonable area	Low C_d	Low C_d	Low C_d	Ground effect and low C_d
Small engine	Small engine	Choice of engines with diesel option	Wide choice of engines, optional diesel, possibly with turbo	Large engine with fuel injection and/or turbo	Large engine with fuel injection and/or turbo	Maximum power output
Good performance	Good performance	Good performance	Smooth performance	Fun to drive	Fun to drive	Quick response, ultimate handling
Maximum fuel economy	Good fuel economy	Good fuel economy	Good fuel economy for class	Good fuel economy for class	Performance first	Performance first
Low cost	Low cost	Low cost	Value for money	Value for money	Cost secondary	Cost no object
Ride secondary	Adequate ride	Good ride	Good ride	Good handling	Good handling	Maximum road holding
Easy to service and repair	Easy to service and repair	Easy to service and repair				Fast repairs at p.t.o. service stops
Minimum mass	Minimum mass	Minimum mass	Controlled mass	Good power-to-mass ratio	Good power-to-mass ratio	Low mass
Maximum package for size	Maximum package for size	Maximum package for size	Maximum package for size	Reasonable luggage room	Reasonable luggage room	To carry long-range fuel tank and large-section spare tire
Some noise acceptable	Reasonable noise	Low noise	Very quiet interior	Quiet at high speed	Quiet at high speed	Noise not important

FWD	FWD	FWD or RWD	FWD or RWD	FWD or RWD	RWD	RWD

nents in the cooling system do not become covered with dust.

- Sun: especially for lower parts in the cockpit, high temperatures up to 80 °C and above lead to thermal stress and aging.
- Corrosion: especially for operation on salted winter roads and in coastal climates.
- Chemical fluids: engine oil and fuel can come into contact with certain areas of the car.
- Air pressure: extreme operating conditions in high-altitude areas have to be taken into account when designing seals and membranes.

Body

Targets for body design can be divided into two different classes: targets relevant from the point of view of the end customer and those relevant for internal optimized production [13.15].

Table 13.3 Prescriptions of the federal motor vehicle safety standards (FMVSS) (relevant extract) [13.16]

Standard No.	Title
101	Controls and displays
102	Transmission shift lever sequence, starter interlock, and transmission braking effect
103	Windshield defrosting and defogging systems
104	Windshield wiping and washing systems
105	Hydraulic and electric brake systems
106	Brake hoses
108	Lamps, reflective devices, and associated equipment
109	New pneumatic bias ply and certain specialty tires
110	Tire selection and rims
111	Rear view mirrors
113	Hood latch system
114	Theft protection
116	Motor vehicle brake fluids
117	Retreated pneumatic tires
118	Power-operated window, partition, and roof panel systems
119	New pneumatic tires for vehicles other than passenger cars
120	Tire selection and rims
121	Air brake systems
124	Accelerator control systems
125	Warning devices
129	New nonpneumatic tires for passenger cars
135	Light vehicle brake systems
138	Tire pressure monitoring systems
139	New pneumatic radial tires for light vehicles
201	Occupant protection in interior impact
202	Head restraints
203	Impact protection for the driver from the steering control system
204	Steering control rearward displacement
205	Glazing materials
206	Door locks and door retention components
207	Seating systems
208	Occupant crash protection
209	Seatbelt assemblies
210	Seatbelt assembly anchorages
212	Windshield mounting
213	Child restraint systems
214	Side impact protection
216	Roof crush resistance
219	Windshield zone intrusion
223	Rear impact guards
224	Rear impact protection
225	Child restraint anchorage systems
301	Fuel system integrity
302	Flammability of interior materials
303	Fuel system integrity of compressed natural gas vehicles
304	Compressed natural gas fuel container integrity
305	Electric-powered vehicles
401	Interior trunk release
403	Platform lift systems for motor vehicles
500	Low-speed vehicles

Targets relevant for customers are:

- Appealing design
- Maximum safety
- Minimal fuel consumption
- High comfort
- High level of functionality
- High quality and long life time
- Attractive/acceptable price
- Low maintenance cost
- Low noise emissions
- Usable every day

Targets relevant for production are:

- Easy assembly
- Utilization of existing production machinery
- Small number of different parts
- Easy to manufacture
- High, constant process quality

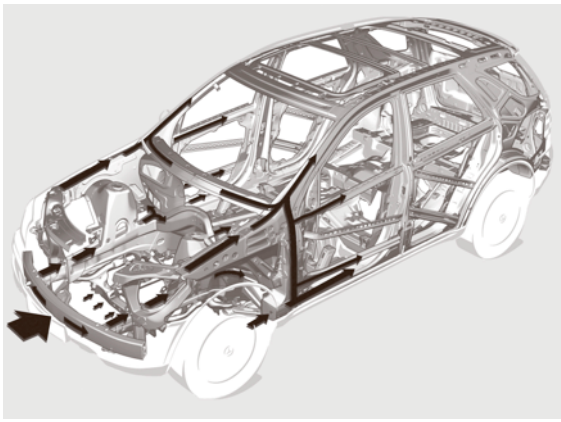

Fig. 13.41 Visualization of the load paths in the car body (courtesy of Mercedes Car Group)

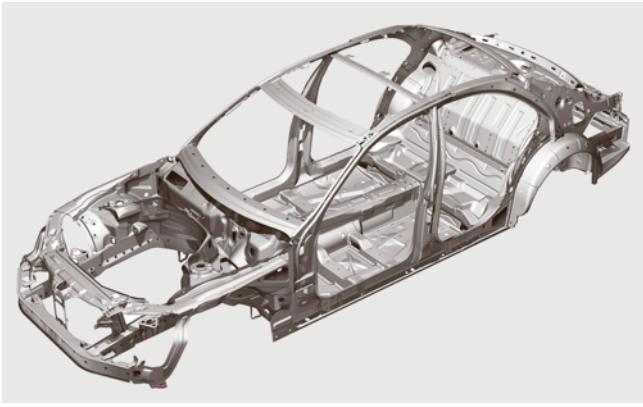

Fig. 13.42 Car body of a limousine (courtesy of Mercedes Car Group)

- Carryover of part and platform strategies
- Optimized utilization of material
- Low production cost

The basic layout of the body is influenced by the basic load cases of a car: bending case, torsion case, combined bending and torsion, lateral loading, and fore and aft loading [13.17]. These load cases lead to stresses in the vehicle body structure. Theses stresses must under the worst load conditions be kept at acceptable limits. The torsional and bending stiffness of the vehicle structure is a main influence on the NVH performance of the car, the tightness of sealings, and high-speed performance, especially of convertibles [13.18–20].

There are various basic concepts for the layout of body types. The ladder frame, historically the first and most flexible way to build car bodies, had its disadvantages especially in terms of weight. Thus, today in most cases the car body is an integral structure with sheet-steel parts spot-welded together (Figs. 13.42, 13.43), providing structural and other functions. Since integral structures – also due to their flexibility in terms of design and utilization of different materials (Fig. 13.40) – are very complex, traditional mechanical analysis cannot be used to predict their behavior in the layout phase, but rather finite element (FE) analysis must be used to determine the optimal shape and material usage. This is also true for crash simulations of the body (Fig. 13.41).

The exterior of the body is defined by three major influences: styling, aerodynamics, and packaging. Together with the body design itself, these are the tightest simultaneously running constraints in the early phase of car development.

Because weight reduction while optimizing stability and crash performance is a challenge which cannot be met by using conventional steel bodies, lightweight design, e.g., using aluminum or tailored blanks, is used to optimize weight, stiffness, and crash performance while trying to limit the production cost.

Since sheet-metal stamping of body shell parts for the car assembly process is partly outsourced, in the car body development process, modules are defined which are delivered by suppliers preassembled and then connected as a whole to other body parts. A typical example is the front bumper, where often, besides the body sheet metal parts, electrical components such as the front lights and the ventilation device as well as crash deformation elements made from plastic material are integrated into one module that is delivered just in time and just in sequence to the production line of the car manufacturer.

Car body properties are the significant parameters used to describe the behavior and performance of the car body. Tolerances in the design process as well as in the assembly process contribute a lot to the body quality and the perception of car quality by the customer. Too large or too inhomogeneous joints between two body sheet metals deliver a sense of low quality in engineering and styling.

Chassis

Overview. Targets for chassis design from the point of view of the end customer are related to the class of vehicles (buses, trucks, SUV, convertible, etc). The most fundamental differences among the requirements for different classes of vehicles are between passenger and

commercial vehicles [13.14]. For passenger vehicles, the major concerns are:

- Ride comfort
- Good handling characteristics (depending on the style of driving)
- Provision of these features over a wide range of different driving scenarios and scenarios

For commercial vehicles, the driving force is economical operation. Thus, design is usually based on a fully loaded vehicle being the most economic way to transport goods from point A to point B, and long time of operation. The major concerns here are:

- Low cost
- Reliability of operation

Between these two different classes of vehicles with completely different demands in terms of function and performance are the requirements for buses, building a compromise between these classes.

The function of the chassis is to isolate the passengers and/or load from shocks and vibration caused by the roughness of the driving surface. Two basic components are used to cover this function:

- Springs, providing flexibility
- Dampers, absorbing energy

Figures 13.44–13.46 show different car axles.

The basic components of the chassis are shown in Fig. 13.47 as a design principle.

The driving characteristics of a car are dependent on a number of chassis and car concepts and layouts. The concepts differ in terms of the position of the engine inside the car (front engine, mid engine, rear engine) and the type of wheel drive (front-wheel drive, rear-wheel drive, and four-wheel drive).

Most of the disadvantages of the car concepts described briefly in Table 13.4 are reduced nowadays through the application of electronic driving support systems.

For further reading on automotive chassis in general, refer to [13.21–30].

Brakes. Brakes are among the most important components in a car. They have to operate under any circumstance, and under every operating condition have to provide the functionalities to:

- Decelerate the car in a controlled and repeatable fashion and, when appropriate, cause the car to stop
- Permit the car to maintain a constant speed when traveling downhill

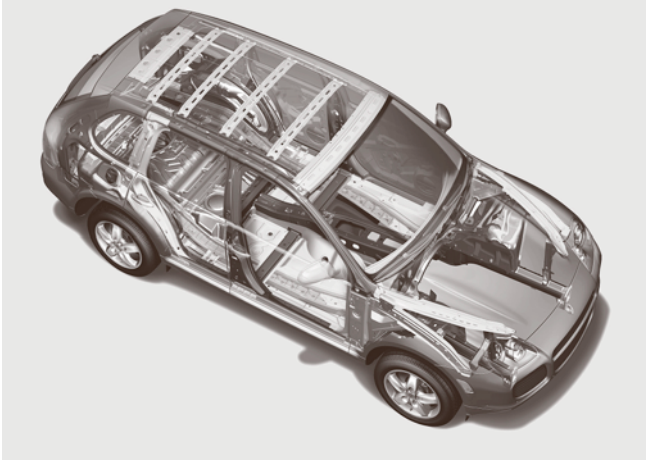

Fig. 13.43 Car body of a sports utility vehicle (courtesy of Dr. Ing. h.c. F. Porsche AG)

- Hold the car stationary when on the flat or a gradient [13.31]

These functionalities have to be provided:

- On slippery, wet, and dry roads
- On rough and smooth roads
- On split friction surfaces
- During straight-line braking or when braking on a curve
- With dry and wet brakes

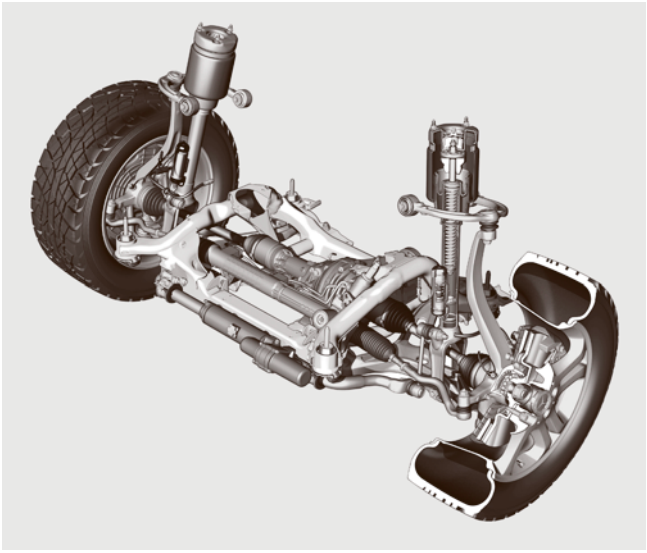

Fig. 13.44 Car axle of a sports utility vehicle (courtesy of Mercedes Car Group)

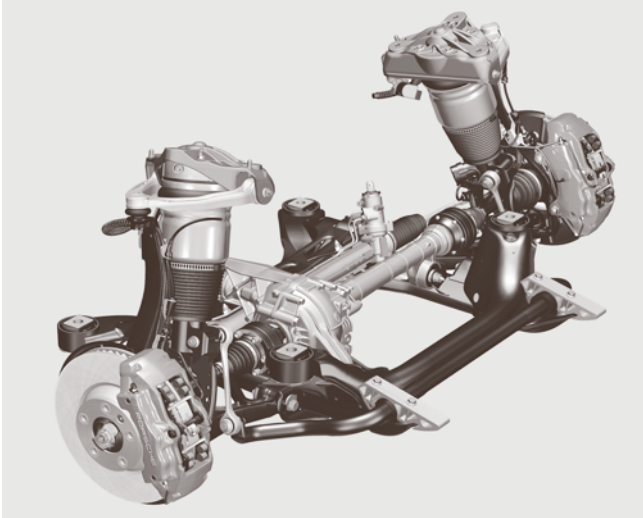

Fig. 13.45 Car axle of a sports utility vehicle (courtesy of Dr. Ing. h.c. F. Porsche AG)

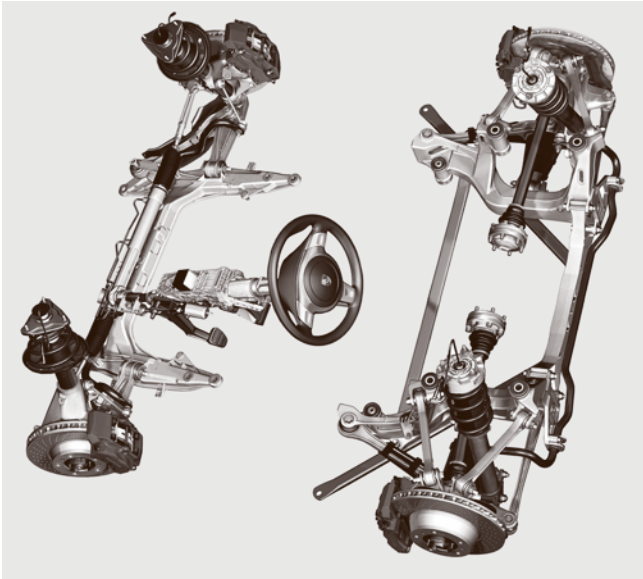

Fig. 13.46 Front and rear axle of a sports car (courtesy of Dr. Ing. h.c. F. Porsche AG)

- With new and worn linings
- With a fully loaded or unloaded car
- When the car is pulling a trailer or caravan
- During frequent or infrequent applications of short or lengthy duration under different temperature conditions and speed levels
- During high and low rates of deceleration

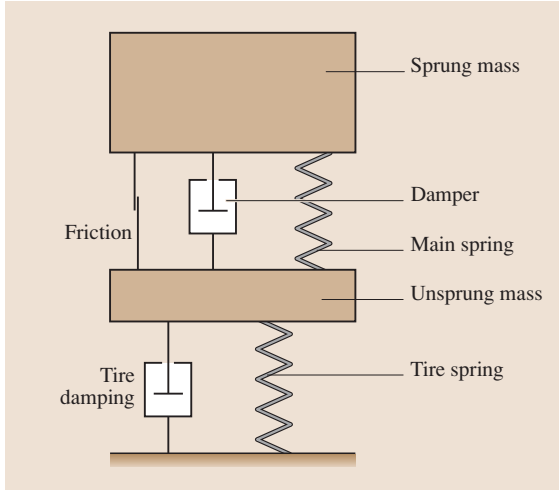

Fig. 13.47 Design principle of a suspension [13.14]

- When used by both experienced or inexperienced drivers

Each car is equipped with two independently operating brake systems, thereby providing redundant functionality at each point of time.

Comfort functions, safety functions, and even functions influencing other car dynamics have been implemented in braking system over time. Figures 13.48–13.50 show the major milestones in the development of car brakes.

Today's hydraulically operating brake systems consist of the brake pedal assembly, the brake booster amplifying the pedal force when the brake pedal is pressed down, the master cylinder initiating and controlling the process of braking by providing the necessary hydraulic fluid pressure, the regulating valves necessary to implement functionality such as antilock braking, and the control software enabling high-level control of car dynamics using brake functionality such as ESP.

Modern brake technology is often derived from insights found in race applications [13.32].

For reasons of comfort, brake noise is a major issue in the design of today's braking systems. Although intensive theoretical and experimental research has been undertaken over many years, the mechanism of brake screech is not yet fully understood, and this problem is one of the most common reasons for warranty claims on new vehicles [13.20, 33–35].

Power Train

The main requirements for the power train in a car are:

Table 13.4 Car concepts in term of placement of engine and type of wheel drive

Placement of engine	Type of wheel drive	Major benefits	Major disadvantages	Sample cars
Front engine	Front-wheel drive	Tame driving characteristics, less design effort	Tight packaging in engine bay, good traction only if light load is carried	VW New Beetle Mercedes A-class
Front engine	Rear-wheel drive	Good packaging restrictions	Weight distribution not optimal	Mercedes C-/E-/S-class
Mid engine	Rear-wheel drive	Good weight distribution, excellent driving dynamics	Not applicable in passenger cars (>2 seats) due to packaging constraints	Porsche Cayman
Rear engine	Rear-wheel drive	Good traction, excellent take-off characteristics	Cooling costly, directional stability difficult to cover by design	VW Beetle Porsche Carrera

- Accelerate the car from standstill up to an arbitrary speed
- Allow for quick regulation of torque and engine speed for good dynamic behavior
- Provide good efficiency in terms of space consumption inside the car as well as energy efficiency and low mass of the components used
- Ability to deal with shocks and extreme temperature conditions

The power train consists basically of the engine, transmission, and clutch.

Engines. In automobiles, 3-, 4-, 5-, 6-, 8-, 10-, and 12-cylinder engines are used as a straight engine, a V-engine, a VR-engine, a Boxer engine or a W-engine [13.15]. Current trends are for diversification of engine concepts also in terms of size and power output, from small engines aimed at drastic reduction of fuel consumption to large engines with high power output for ultimate and comfortable performance.

Combustion Engine. The combustion engine is the most commonly used engine in passenger cars. The working principle is to convert gasoline into motion, usually on the basis of the Otto cycle. The four strokes of the Otto cycle are:

- The intake stroke, during which air enters the combustion chamber
- The compression stroke, during which the air in the combustion chamber is compressed
- The combustion stroke, during which a spark of gasoline is added to the compressed air, ignited, and the air–gas mixture explodes

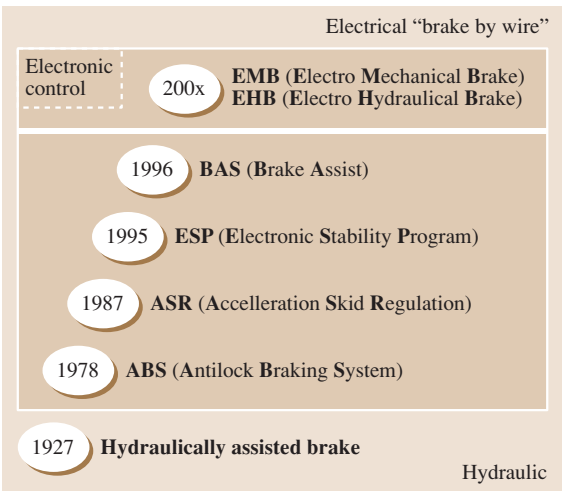

Fig. 13.48 Major milestones in the development of brake systems [13.36]

- The exhaust stroke, where the exhaust fumes leave the combustion chamber

Diesel Engine. Characterized by compression ignition of the air–diesel mixture, the diesel engine has become a favorite type of propulsion system in some European countries due to low fuel cost and tax reductions. The advantages of the diesel engine compared with the Otto engine are:

- Better efficiency, especially in the part-load range, resulting in
- Lower specific fuel consumption

- Lower emissions of carbon dioxide and carbon monoxide
- Diesel fuel is easier to manufacture
- High reliability and long service life

Disadvantages are:

- Higher output of nitrogen-oxides emissions and soot particles
- Higher weight
- Lower engine speed
- Less smooth engine running, and less impulsive reaction to driver signals

Future diesel engines will have to meet the following demands:

- Good environmental properties (e.g., use of particle filters)
- Further reduction of fuel consumption (e.g., increased injection pressure)
- Reduction of production cost (e.g., use less expensive material or simpler engine concepts)
- Longer lifetime
- Even greater reliability
- Greater comfort (reduction of vibration, smooth torque development over engine speed)
- Reduction of noise emission

Besides the combustion engine (p.t.o. or diesel), which is by far the most commonly used propulsion unit in today's cars, there are a lot of different engine types which are used very rarely or in research prototype cars, e.g.:

- The electrical motor, powered by battery, fuel cell or by a generator operated by a combustion engine (Figs. 13.51–13.53)
- The Stirling engine, which has very low emissions and is characterized by a smooth and continuous torque output even at low engine speed
- The gas turbine, which is characterized by low vibrations and low emissions

For further information on automotive engines in general, refer to [13.37–46].

Low-Emission Engine Concepts. The rising number of cars, especially in urban areas such as Los Angeles, CA, has led to the definition of regulations aiming at reduction of air pollution and fuel consumption. Zero-emission vehicles (ZEV), today only effectively realizable using electrical motors or fuel cells, and ultralow-emission vehicles (ULEV), are required to achieve these targets. Today, a certain percentage of all cars sold in the market of California have to meet the restrictions of ZEV/ULEV, otherwise the automotive manufacturer has to pay penalties.

One contribution to ULEV are cars with hybrid drives (Fig. 13.54). These drives consist of a minimum of two different energy conversion units and use two different energy storage methods for means of vehicle propulsion. The main potential benefits of the hybrid drive are:

- Reduction of fuel consumption
- Reduction of emissions
- Reduction of noise

There are three different concepts for hybrid drives: parallel, serial, and mixed.

Serial hybrids use electrical energy for wheel drive, and the energy stored in the battery is recharged from

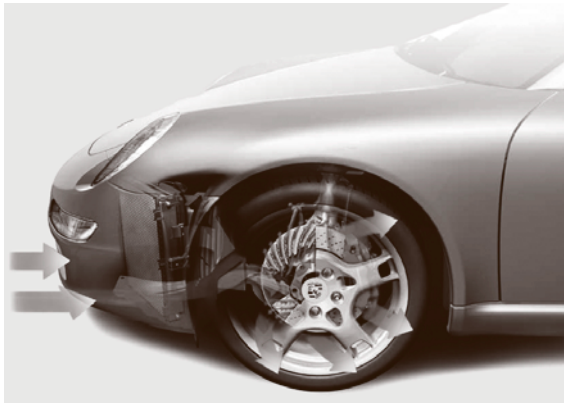

Fig. 13.49 Conduction of airstream for cooling of brakes (courtesy of Dr. Ing. h.c. F. Porsche AG)

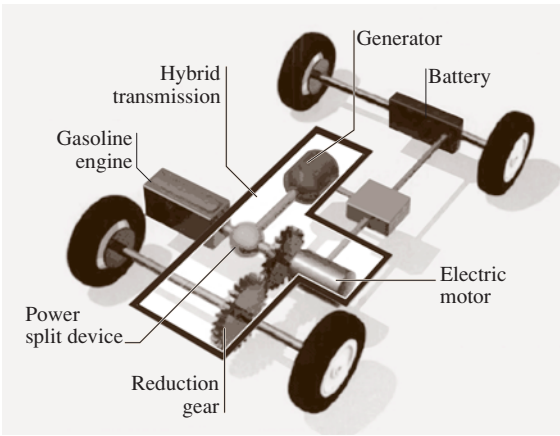

Fig. 13.54 Schematic view of a hybrid drive concept (courtesy of Toyota Motor Corp.)◀

time to time by a generator powered by a combustion engine. In parallel hybrids, the wheels are driven both by electrical motors or a combustion engine alternatively or even simultaneously. Mixed hybrids are a combination of parallel and serial power flow, and many versions are available.

The major components of hybrid drives are the combustion engine, the battery, the gearbox, and the electrical engines, which have to be harmonized for integration into the final concept.

For further information about low-emission concepts, refer to [13.47–53].

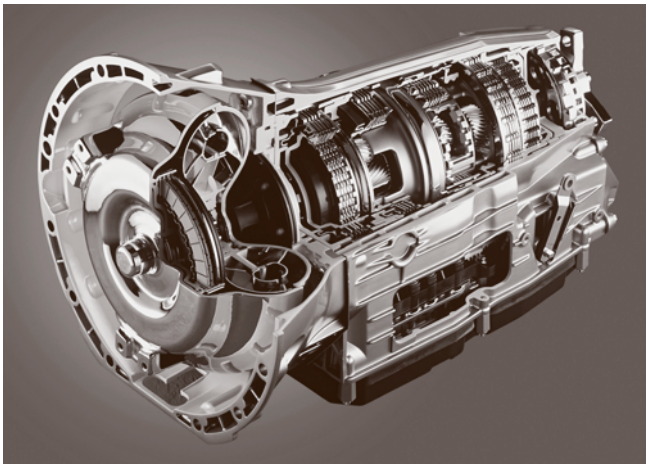

Fig. 13.55 Seven-gear automatic transmission (courtesy of Mercedes Car Group)

Transmissions. The function of the transmission is to adjust the engine speed and torque according to the needs of the current driving situation. Two basic concepts are implemented in today's cars: manual (Fig. 13.56) and automatic transmissions (Figs. 13.55, 13.57). Manual transmissions offer in most cases better efficiency compared with automatic transmissions, which in turn provide greater comfort and, depending on the experience of the driver, even optimize the utilization of the engine speed and torque in different driving situations.

Clutches. The clutch is placed between the engine and the transmission in cars with manual gearboxes, providing:

- Adaptation of engine speed during approach
- Separation of engine and transmission when shifting gears
- Safety for transmission and other components during overload conditions
- Damping vibrations

In cars with automatic transmission, the hydraulic unit of the automatic transmission provides these functionalities. For further information about transmissions and clutches, refer to [13.54–57].

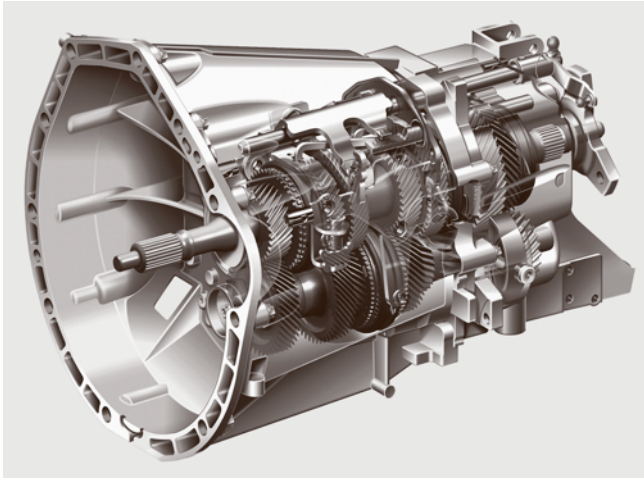

Fig. 13.56 Manual transmission (courtesy of Mercedes Car Group)◀

Interior

When designing the interior of a car, the man–machine interaction is the core issue. The interior has to be adapted to the driver and the passengers as far as possible. Ergonomics of the controls and information

instruments presented to the driver and the passengers is a major influence in order to be able to drive safely and without being stressed. Methods and tools used for ergonomic development are described in Sect. 13.2.4.

Besides the components and their placement inside the car, another important aspect of positive feeling inside the car is the interior climate [13.58]. Separately adjustable air conditioning for driver and passengers, not producing any noticeable draft, heated seats and steering wheels, as well as an air scarf for convertibles are elements which cover the needs for a pleasant interior climate in modern cars (Fig. 13.58).

Interior Materials. Individualization of luxury cars plays an important role in sales. To be able to configure a car in such a way that no-one else owns a similar one is often a very important feature for customers of these kinds of cars. Thus, providing a choice of different interior materials (aluminum, carbon, different types of wood, different types of leather, alcantara, etc. [13.59]) from which the customer can choose when configuring the car is a characteristic of luxury cars. In order to be able to provide this multitude of materials, the design of the interior components has to take account of the fact that different materials could be applied as the outer shell. Sharp edges and small radii should be avoided when planning to use leather on a surface, and the manufacturing process of placing tiny pieces of wood on the gear stick has to be taken into account when designing the standard design variant. When introducing a new, additional interior material, extensive tests (head impact, airbag functionality, etc.) have to be carried

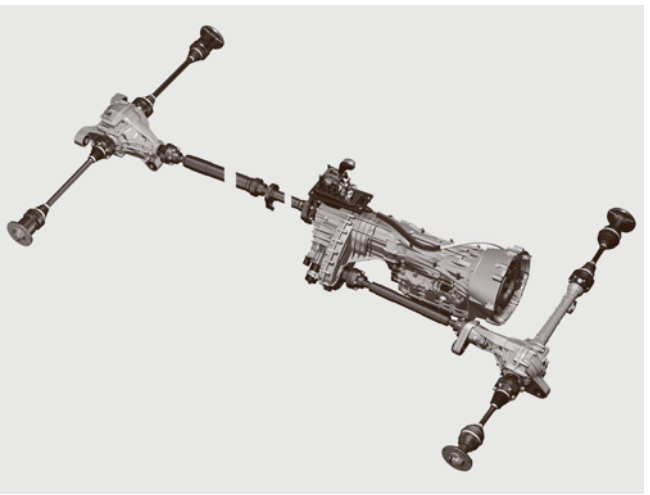

Fig. 13.57 Automatic transmission in the context of a four-wheel drive (courtesy of Dr. Ing. h.c. F. Porsche AG)

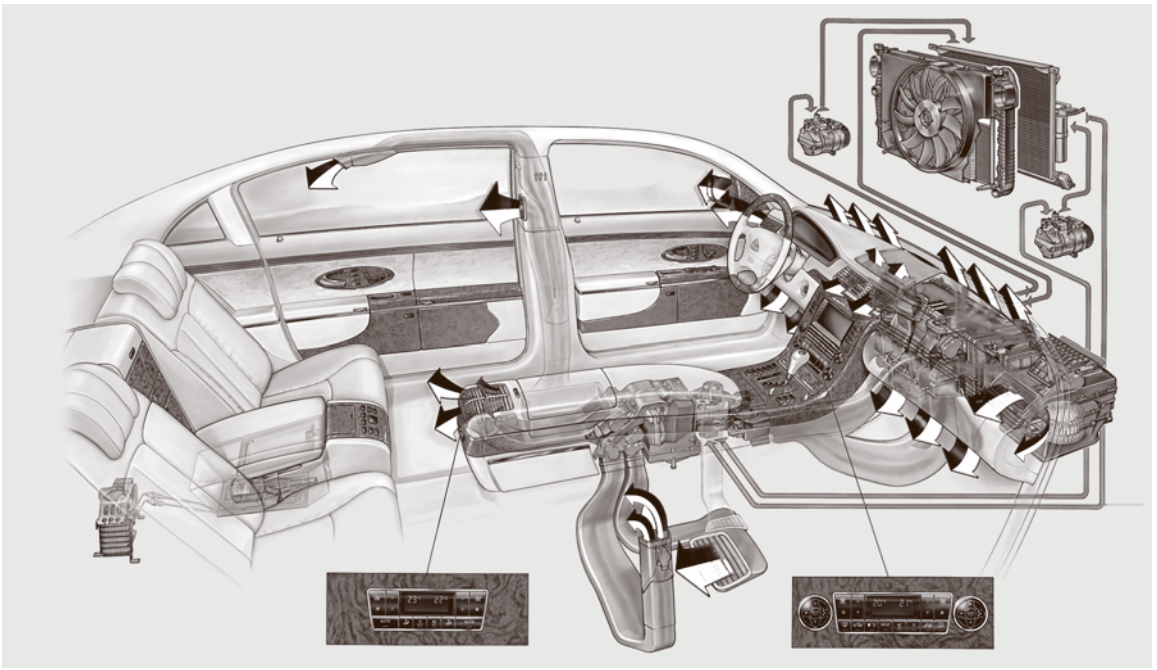

Fig. 13.58 Climate control in a luxury car (courtesy of Mercedes Car Group)

out and it has to be verified that this additional material can be handled and provided with the desired (i. e., expected) quantity throughout the supply chain.

Infotainment. Car radios are increasingly becoming integrated into infotainment components, consisting of a radio with a compact disc (CD)/digital versatile disc (DVD) changer, telephone, navigation system, onboard computer, and other information services. The benefit for the customer is that there is only one interface to deal with and that, due to the tight integration, different comfort functions can be realized more easily. An example is the integration of the traffic message channel (TMC) radio service with the navigation system, allowing for dynamic adaptation of the route in the navigation system due to TMC-based information of traffic delays.

Electric/Electronic Components

Many of the functions in modern cars cannot be realized without the intensive use of electronic components realizing, controlling, and integrating the functions into a system.

Greater demands for reliability, comfort, safety, provision of information, reduction of fuel consumption, and reduction of environmental pollution could not be satisfied by purely mechanical systems. Modern safety features such as airbags and dynamic stability programs could not operate without extensive use of electronics and microcomputers. Besides electronic hardware, software in cars is also becoming increasingly important.

Electronics can be roughly divided into:

- Sensors
- Actuators
- Controllers
- Information devices
- Network components (e.g., the controller area network, CAN)

Sensors feed information about the current status of the car and its behavior on the road into the electronic microprocessor-based infrastructure. Based on the algorithms implemented, this information is checked for necessary actions (e.g., *brake is locking – activate antilock-brake sequence*), actuators are triggered to start operation, and appropriate information for the driver and the passengers is passed forward to an information device, which may be cockpit instruments or the simple chime of a bell when seat belts are not fastened.

Figure 13.59 shows schematically the electronic elements in a car and their connections.

Sensors are intensively used in engine management, measuring, e.g., the intake manifold pressure, the mass airflow, the temperature at different locations in and around the engine, the engine speed, the crankshaft reference position, enabling correct triggering of the pulse for injection cycle, the throttle position, the knock sensor, allowing lower-quality fuel to be used as a fuel, and the lambda sensor for catalytic operation. For driving dynamics and safety purposes, sensors measure various parameters from chassis, including wheel speed – also relative wheel speed between different wheels – steering-wheel angle, and steering shaft torque, the chassis acceleration or deceleration, and the brake system pressure.

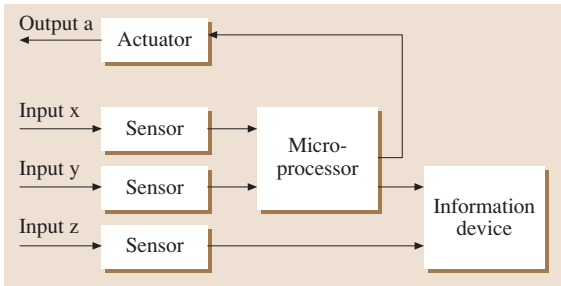

Fig. 13.59 Electronic elements in a car and their connections

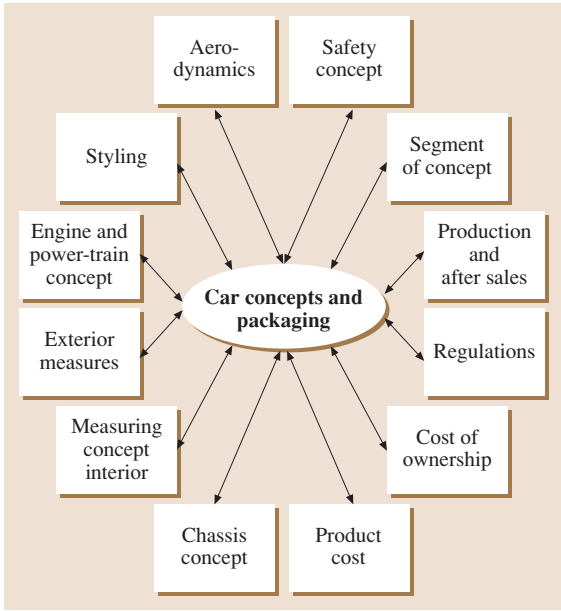

Fig. 13.60 Requirements to be taken into account when defining a car concept [13.15]

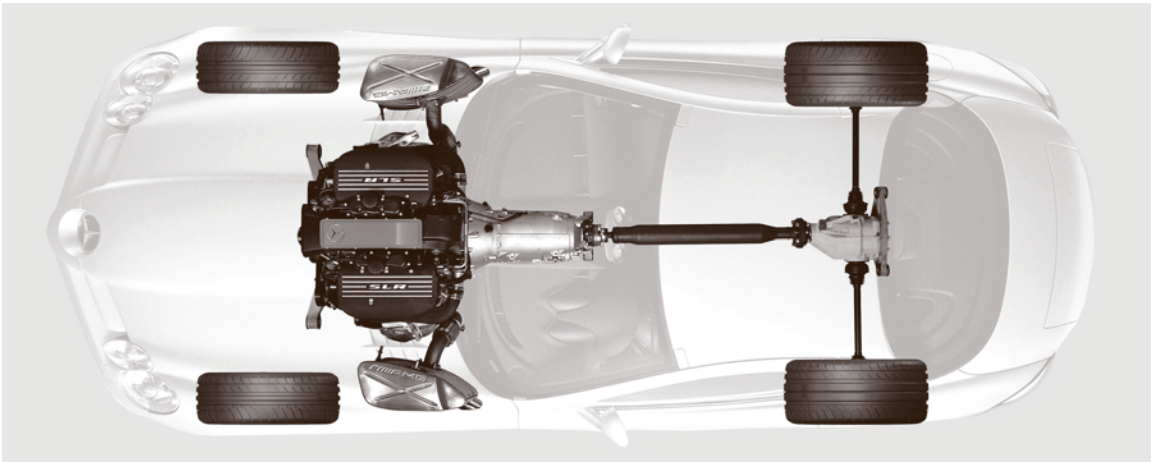

Fig. 13.61 Integration of engine and power-train components into the car concept (courtesy of Mercedes Car Group)

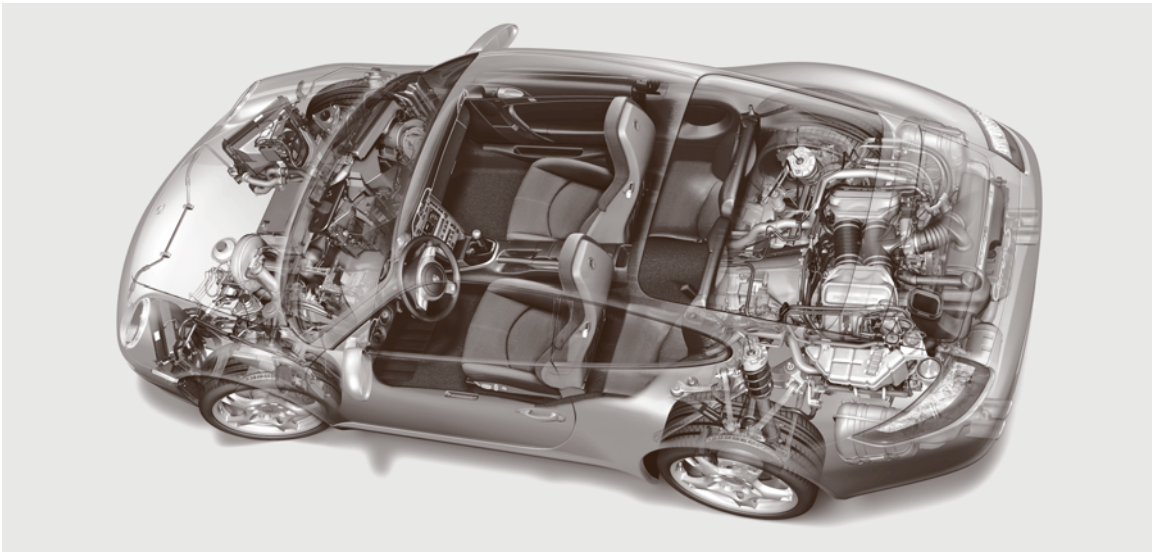

Fig. 13.62 Packaging of components in a sports car (courtesy of Dr. Ing. h.c. F. Porsche AG)

Due to their physical working principle, sensors can be divided into various categories (Table 13.5).

Besides sensors, actuators are another important group of elements in an electronically operating system. Actuators range from starting generators, supplementary drives to different actuators in the surrounding of the engine (crankshaft actuation, electromechanical gear shifting), those used for implementation of safety features (tightening seat belts, electrical brakes, electrically actuated rollover safety in convertibles), for comfort functions (powered windshields, powered sunroof, memory-based electric seat readjustment), for information functions (CD player, navigation system), and to provide active light management depending on the external brightness, to mention only a few.

With the large number of electric and electronic components in a car, electrical energy consumption becomes a critical issue. Even during standstill, most modern cars need a certain voltage to be in a standby position for remote opening systems and for theft-protection devices. Since especially in cold outside temperatures, the driver and the passengers demand a large number of electrically supported functions (defrosting, seat heating, etc.) the management of these

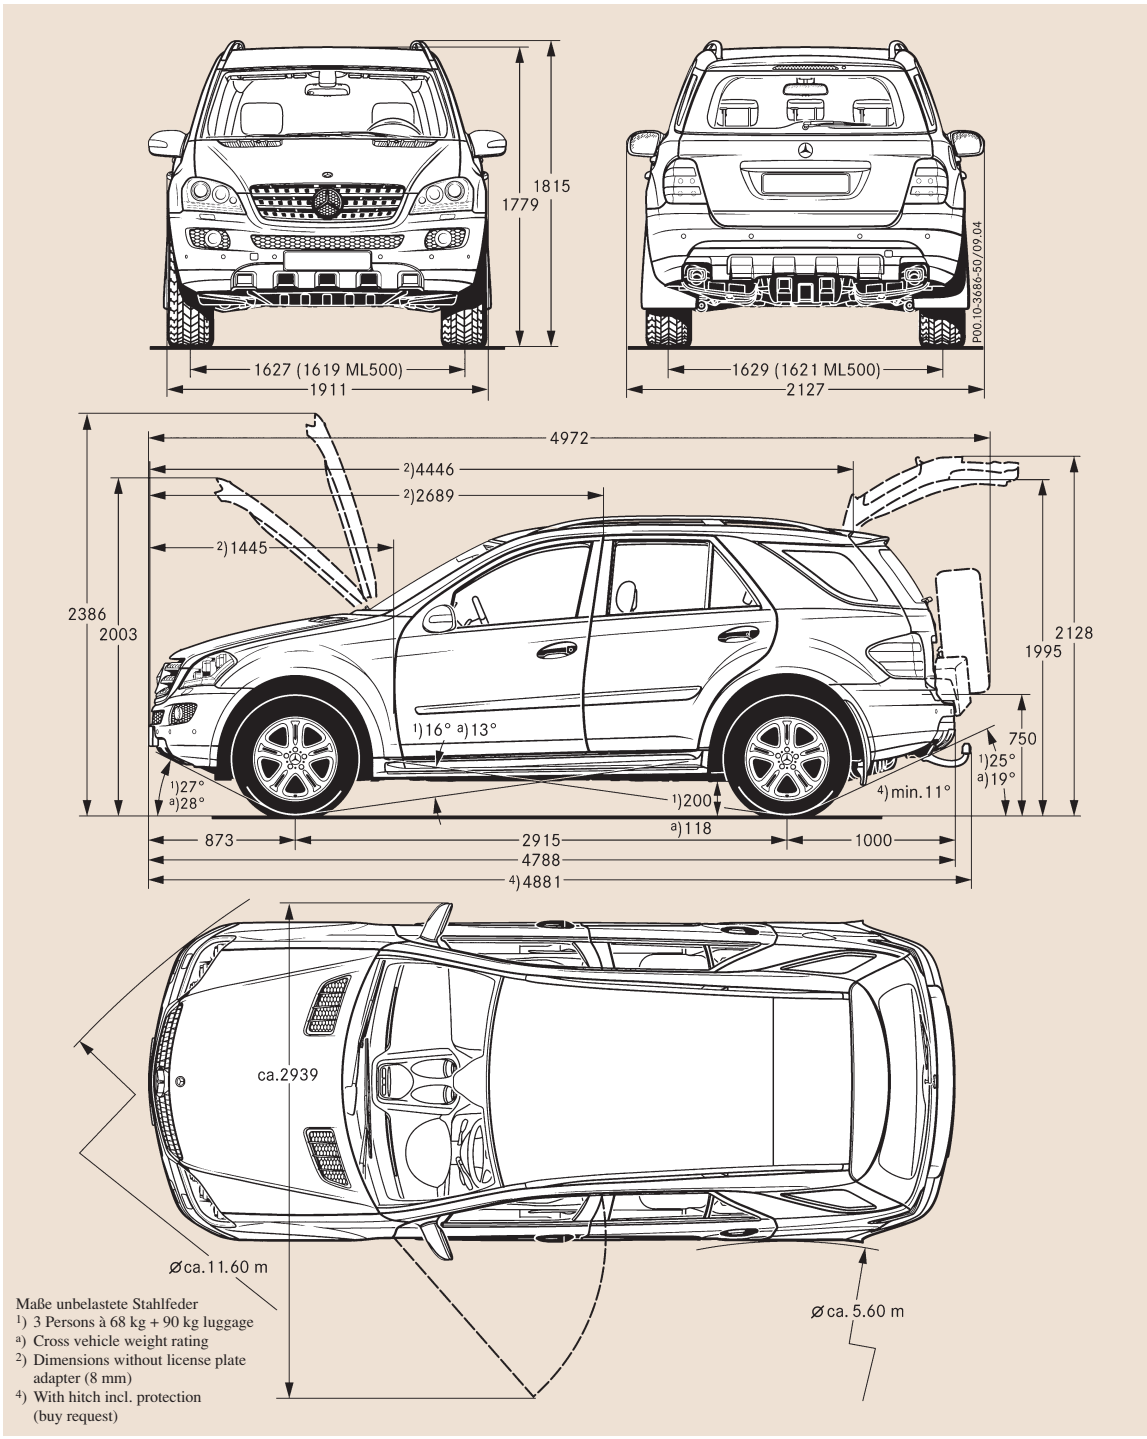

Fig. 13.63 Dimensional concept of a sports utility vehicle (courtesy of Mercedes Car Group)

Table 13.5 Overview of sensor categories [13.15]

Magnetic sensors	Revolutions, position, angle
Electrical sensors	Position, angle, seat occupation identification
Micromechanical sensors	Knock, pressure, acceleration, torque
Chemical sensors	Air quality, composition of exhaust gas
Thermal sensors	Intake air mass flow, part temperature
Ultrasonic sensors	Distance, relative speed
Radar sensors	Distance, car surrounding
Optical sensors	Position identification, driver identification, object identification

units in order to cover the demands of the passengers while enabling the car to get into a stable operating condition is a challenging task. Reaching stable (i.e., constant) operating conditions in the electric network of the car can sometimes take over 1 h. Further increases in the need for electrical power in cars is leading to the development of 42 V electric systems instead of today's 12 V electric system [13.60].

Nearly every area of car functionality is supported by or implemented in combined electronic hardware–software systems. The most challenging of these systems are these for safety: clear determination of a situation where airbag deployment is needed, and airbag deployment at exactly the right time in the right fashion is a highly complicated systems design task. Precrash sensing and initiating preventive actions such as tightening the safety belts, closing the sunroof, etc., which are even more demanding functions than crash detection, are now available first in luxury cars.

For further information about electrics and electronics in automotive application refer to [13.62–69].

Packaging

Packaging's primary task is to collect the different requirements and targets for a car and implement them

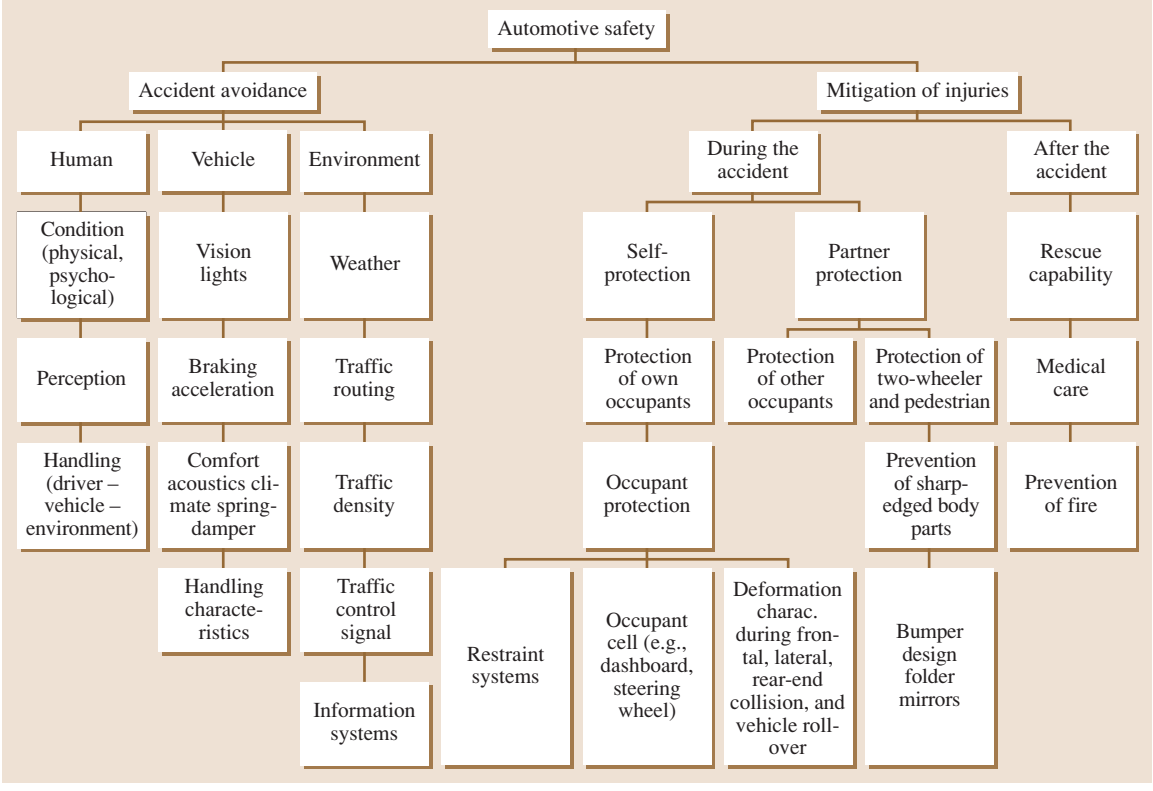

Fig. 13.64 The field of automotive safety [13.61]

Fig. 13.65 Crash simulation and hardware crash (courtesy of Mercedes Car Group)

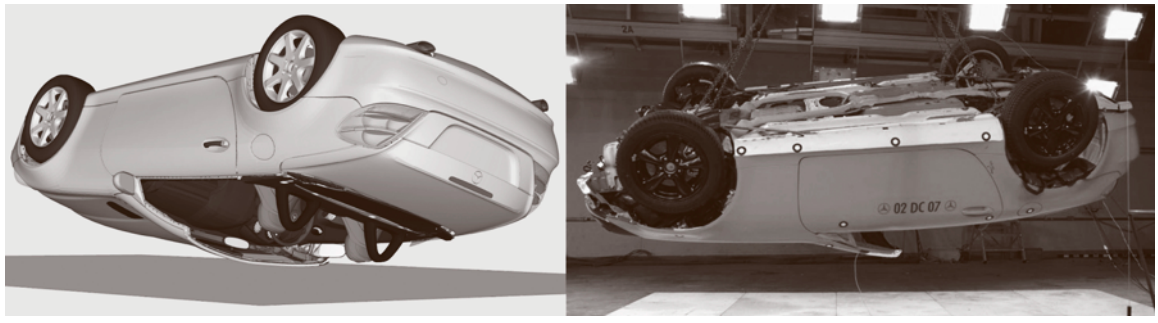

Fig. 13.66 Crash simulation and hardware crash of a convertible (courtesy of Mercedes Car Group)

into a basic design with main dimensions and definition of the placement of the most important components in the car (Figs. 13.60–13.63).

The result of packaging is a compliant arrangement of components in terms of space and functional dependencies. The major influences on the defined car concept resulting in the car packaging are [13.15]:

- Technical data
- Primary competitors
- Range of use (leisure, city, off-road, sports, etc.)
- Body versions
- Safety concepts including crash structures
- Seating capacity and ergonomic requirements for seats
- Trunk volume
- Engine and power train concepts

One of the results of packaging is the dimensional concept of a car where all main measures of the car are defined.

For further information about packaging and ergonomic aspects in automotive engineering refer to [13.70–72].

Automotive Safety

As well as dealing with crash safety, automotive safety is a broad area covering many aspects. Figure 13.64 gives an overview over the whole field of automotive safety.

Active and passive safety are prime selling arguments. The responsibility for the health of the driver, the passengers, and other traffic participants is also taken very seriously by automotive manufacturers.

Active safety is the area of measures aiming at avoiding an accident. Passive safety is the area of measures minimizing the consequences of an accident when it happens. Besides technological provisions in the car concerning safety, the factor most strongly influencing the probability of an accident and its consequences is the driver: careful, defensive driving is the best precaution.

Various coefficients describe the criticality of body stresses induced by an accident, and regulations demand that test data are below a certain level for each of these. These coefficients include the head protection criterion (HPC), the thorax compression criterion (TCC), and the tibia compression force criterion (TCFC).

Table 13.6 Dummy types defined in *Federal Motor Vehicle Safety Standard 572: Antropomorphic Test Devices* (http://www.nhtsa.gov), NHTSA, Washington USA

FMVSS 572 Subpart B	50th percentile male
FMVSS 572 Subpart C	Three-year-old child
FMVSS 572 Subpart D	Six-month-old infant
FMVSS 572 Subpart E	Hybrid III test dummy
FMVSS 572 Subpart F	Side impact dummy 50th percentile male
FMVSS 572 Subpart I	Six-year-old child
FMVSS 572 Subpart J	Nine-month-old child
FMVSS 572 Subpart K	Newborn infant
FMVSS 572 Subpart L	Free motion headform
FMVSS 572 Subpart M	Side impact hybrid dummy 50th percentile male
FMVSS 572 Subpart N	Six-year-old child test dummy, beta version
FMVSS 572 Subpart O	Hybrid III 5th percentile female test dummy, alpha version
FMVSS 572 Subpart P	Hybrid III three-year-old child crash test dummy, alpha version
FMVSS 572 Subpart R	CRABI 12-month-old infant crash test dummy, alpha version

Designing the car to meet these regulatory demands impacts on the car structure, the materials used, and the shape and location of interior components, and safety measures such as airbags and their deployment algorithms have to be adapted.

For the verification and validation of the crash performance of a car, crash simulation and hardware crashes are used (Figs. 13.65 and 13.66).

For the tests, various dummies are used. Table 13.6 shows the different dummy types used in today's crash tests.

For further information about automotive safety refer to [13.73–76].

13.2.3 Car Development Processes

Overview

The development of cars is – like every other product development – a company-specific process. Many influences such as the size and level of globalization of the company, its product portfolio, the number of produced cars, and the proportion of outsourcing during the product generation process affect the characteristic of the specific development process.

Generally, the development of cars consists of three main elements:

- The strategic phase
- The car development project
- The adaptation phase

The following picture gives an overview of the car development process (CDP). Like any other product development process, car development starts from the global point of view and the rough concept.

During the strategic phase the car is planned, one could say, from above. Aspects considered at this stage come from the environment, the market, and the company itself and lead to the strategic specification of the car.

Aspects that influence strategic decisions are, for example, social trends such as increasing awareness of environment or the increasing necessity for safety, the need to substitute technologies as a consequence of improvements or to provide replacing technologies as a political move (e.g., the fuel cell as an alternative drive mechanism), the product portfolio of competitors, rationalization of the companies own workflow, and new functions to be implemented in order to make the product more attractive such as active light illumination or headway distance control.

The variety of aspects influencing the strategic definition of the car is huge but there are just as many approved methods to support this phase of economical and political decisions. The methods are general and there are many good summaries on this topic in the literature [13.77].

The main specifications which have to be defined during the strategic phase of a car are summarized in Fig. 13.67. One important boundary condition for the development of a car is the definition of the product family. For this step the needs and trends of the market have to be analyzed, the product portfolio of the competitors compared with the company's own portfolio, and the profitability of the possibilities calculated.

By defining the key performance indicators the characteristics of a car are determined which are decided by the customer target group which will be reached. Besides the factors price, design and general affection for the brand have a big influence to. Examples are the horse power to be supplied, the noise and

consumption allowances, the kind of air-conditioning system, and the need for automatic locking of the entire car. The basis for the definition of the key performance indicators and the major technical features to be implemented are again the general trends and circumstances in the market. Moreover, methods and technology are advanced in principle in order to achieve competitive advantage. The paragraph *Project-Independent Predevelopment* focuses on car-specific development in this context.

If an advantage is to be expected when, for example, an important customer need will be fulfilled (e.g., providing driving comfort in what is actually a sporty car by an additional feature called active body control) or requirements resulting from political discussions can be satisfied (e.g., discussions of the wrecked-car regulation) then advanced development will be described. The achievement aimed for in this context can be the result of project-independent or project-specific predevelopment, but is also a topic of general research. In this case the results are not available at the time of description. During the verification of the concept, which is an early stage of the car development project, it has to be established whether the research is ripe to be realized or not. In the paragraph *Project-Specific Predevelopment*, the aim of this kind of development will be made transparent and examples will be described.

A further fundamental declaration at this stage of car development is that the project promises to be profitable. A car can be profitable when it achieves a monetary profit due to the price and the calculated number of pieces planned. On the other hand a car can also be nonmonetarily profitable, as is the case when it is of strategic importance (for example, the Maybach or SLR for the Mercedes Car Group, of the Phaeton for VW).

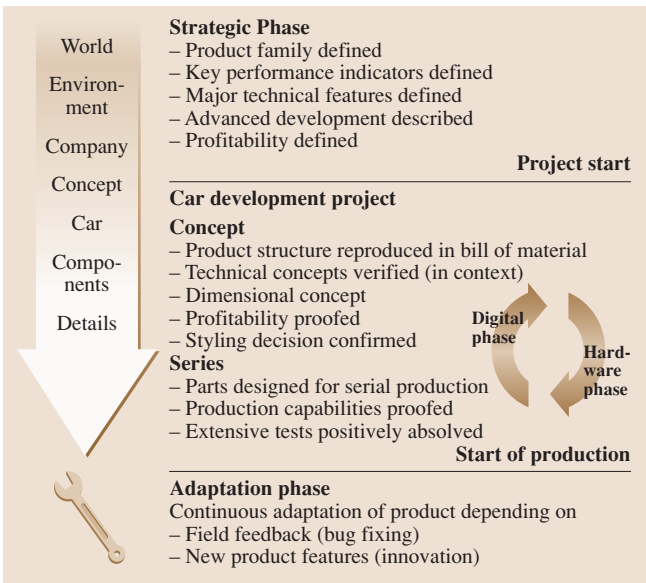

Fig. 13.67 Car development process

The car development project describes the period of time during which the car and its production is specified in all necessary details in order to start the so-called *job number one*, meaning manufacturing.

The car development project (CDP) is carried out in two steps: development of concept and series (Fig. 13.67).

In the concept phase it is determined whether the set of rough outlines and technical features defined during the strategic phase are compatible. For this purpose the dependent system or even the entire car has to be investigated in context. By defining the dimensions of the concept the size of the car is determined and with it one major specification of the entire car set. Already at this stage of development all outer measurements are fixed and the functional spaces inside the car, such as overhead space, leg room or trunk capacity, are provided (Fig. 13.68).

Parts and components are defined and created. The basis for car development however is the product structure of the car, which is reproduced in the bill of materials (BOM). The bill of materials is the connection to production, regardless of whether it is a prototype or the series model that is to be manufactured. Since the configuration of the car and its possible variants are realized within the BOM, the BOM is used to order materials, parts, and components and hence forms the basis for logistical processes. In the section *Product Structure and Bill of Materials* the importance of the product structure with respect to the BOM is clarified.

Furthermore, styling decisions generally have to be confirmed during the concept phase. One has to ensure that the functional components can be accommodated and that the dimensional concept can be realized within the body prepared by the styling. Although changes of design will be accepted during the concept development, the fundamental design features are agreed upon before the car project starts.

Two main streams of development overlap in the development of both the concept and the series vehicles: the digital and hardware phases (Fig. 13.69).

Development always starts with the digital phase. Parts and components are designed for prototype or serial production in computer aided design (CAD) systems. Assemblies are generated using the bill of

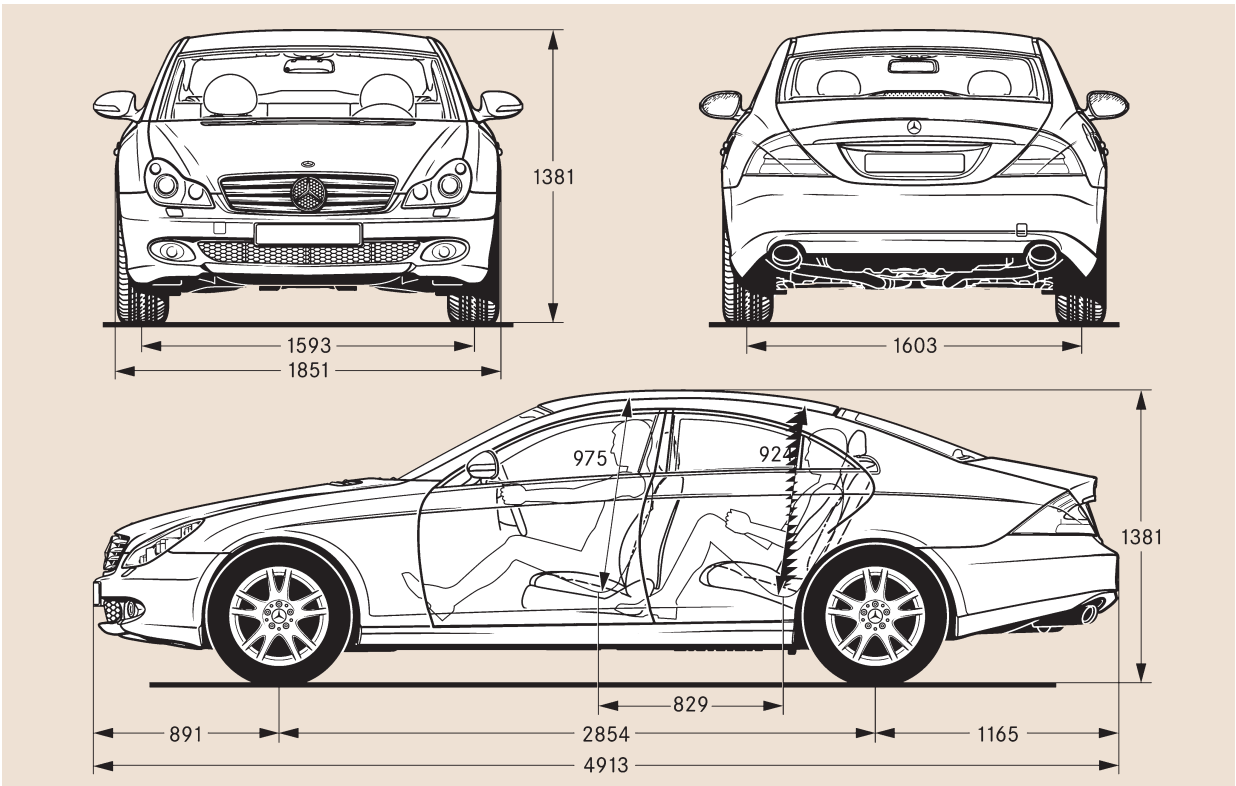

Fig. 13.68 Dimensional concept of Mercedes CLS (courtesy MCG)

materials, product data management (PDM), and CAD functionality (see the section of *Product Structure and Bill of Materials*).

The digital model of the car is used for simulations such as package investigations via a digital mock-up (DMU) or kinematics calculations to ensure stability or check thermal behavior, as well as simulations to plan the production process.

After a certain delay the hardware phase starts. Here the digital models are physically generated (in the form of a physical mock-up) in order to verify the digital simulations. The tests conducted vary depending on the level of progress of development. Examples are tests of concept and structure, functional tests of components on a mule or in a running car, and crash tests to ensure the safety features of the car in different accident situations and for different passenger combinations. The results of these tests are used to optimize the simulation models for the digital testing (for more details on interactions between the digital and hardware phases see also Sect. 13.2.4).

When the concept is verified, the series development starts, which means that parts and components are now redesigned for serial production using the results from tests carried out during the concept phase. Extensive tests are used to try to ensure the quality of the mature product. Whether specific noise requirements are met and whether the car works under extreme climatic conditions can only be fully verified by testing the car in its final realization. In preparation for production the capabilities of the plants also have to be proofed.

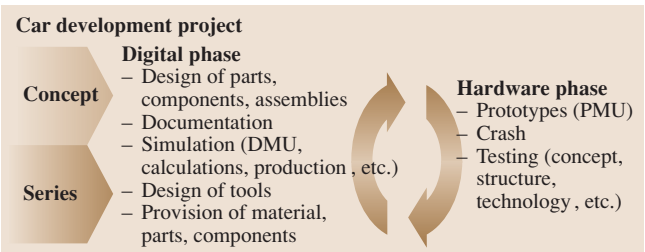

Fig. 13.69 Car development project (CDP)

After a specific level of development is reached, the tools to produce the parts will be designed, and materials, parts, and components delivered by suppliers are ordered on the basis of the digital models, organized in the product structure of the BOM.

At a certain point, the start of production (SOP), the development has to be completed and the car will be produced. The development however is not yet finished, because continuous adaptations of the product are necessary due to field feedback (bug fixing) and innovations that should be implemented in order to stay competetive.

Project-Independent Predevelopment

Aside from car development projects intending to result in the series production of cars for end consumers, there are also development activities as a preparation to be able to do so.

These activities can generally be divided into different classes (Fig. 13.70).

The main distinction in project-independent predevelopment is between methods, technology, and styling concepts.

The definition of key technologies and features where there is substantial differentiation from other OEMs is a strategic trigger for the definition of predevelopment projects.

Roadmaps of upcoming regulations in the different markets are also used to derive predevelopment projects.

Methods. The demand for shortening product development time, reducing cost and development risk, providing new features (e.g., direct fuel injection), and coverage of new regulations (e.g., pedestrian protection) lead to the need to develop new methods to cover these demands. Thus, the methods can also be divided into methods for improving efficiency and those for meeting new demands.

All of these methods are usually developed with a specific target car development project in mind, where they will be used the first time. Evaluation of these methods is either a separate project or is done during the real application of the methods in a car development project, in many cases accompanied by conventional fall-back or back-up methods if the new method does not work properly. An example is the use of computational fluid dynamics (CFD) methods for aerodynamic layout, where the fall-back method is a scaled model in a wind tunnel.

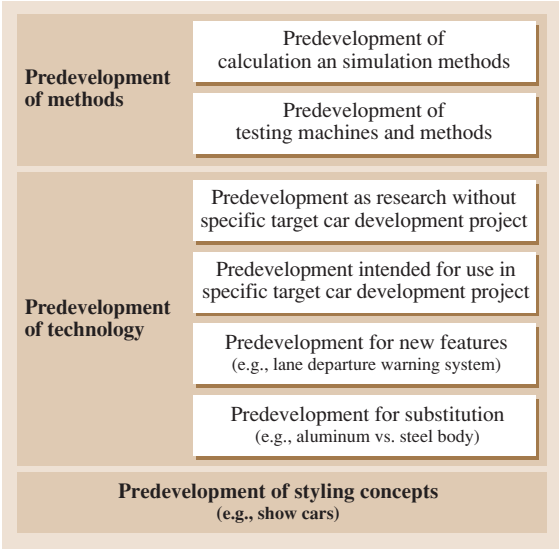

Fig. 13.70 Different kinds of predevelopment projects

However, general research done outside the OEMs also influences car development; for example, developments of new materials (alcantara or plastics), new manufacturing techniques that achieve greater stability (tailored blanks), and mathematic algorithms for calculating stress and strength in parts such as finite element modeling (FEM) are successfully applied in car development today.

Technologies. Technologies are predeveloped, driven either by external demands such as regulations or by the company's own impulse. One internal trigger may be the need to reduce weight in a certain area of the car in order to meet future weight and weight distribution targets for new car concepts, thus leading to the development of substitute materials, part structures, connection technologies, and production technologies. Another trigger is the fulfilment of expected customer needs for comfort (automatically shading roof glass), safety (lane departure warning systems), and entertainment (several infotainment components) [13.78, 79].

Styling Concepts. Styling concepts are developed

- In order to check whether a certain styling proportion or styling theme will meet the customer taste, especially for the intended market segment
- To identify whether there is customer acceptance for a completely new car (and thus styling) concept

- To show the fitness of the automotive company, and for marketing purposes

Styling concepts that receive a positive resonance from the customer base are often used for car development projects. Here it is especially important to reach the SOP in a short period due to shifting customer tastes. Car shows such as those in Detroit or Geneva are often used to present these styling concepts to a broad group of people and to obtain direct feedback or feedback through the press.

Dependencies. One example of the need to develop new methods and technologies in the past was regulation for pedestrian protection, which is gradually being implemented in different stages. To cover the demands of pedestrian protection, various predevelopments had to be undertaken, including:

- Methods for simulation of the body under contact with the car front and the resulting load on the car body parts
- Methods for calculating the critical points in the car exterior which have to be analyzed
- Methods for testing a real car front with a dummy head and measuring the deceleration of the head
- Car concepts and technologies to meet the demand for deformation zones in the affected area of the car front (passive technologies such as providing enough space between the exterior shell and the underlying stiff components, and active technologies such as parts of the car front being raised during impact to enlarge the deformation zone and distance)
- Styling concepts for different variants of car fronts taking passive technology with larger deformation zones into account

Project-Specific Predevelopment

Unlike project-independent predevelopment, activities in project-specific predevelopment focus on the approval for the start of a car development project.

In project-specific predevelopment various activities take place, including:

- The packaging concept for the car is roughly defined.
- Technologies to be used in the car – also from project-independent predevelopment – are identified and decided on.
- Styling proportions and major styling elements are decided on.
- Targets for cost and weight are defined in the upper levels of the product structure.
- Strategic development partners for specific components and/or modules are selected.
- The time frame for car development until SOP and major milestones are defined.
- The project organization is defined at least at the upper levels; the need for engineering resources is roughly estimated.
- The expected economics of the project over its lifetime until end of production and spare parts provision is calculated based on extrapolation from previous car projects.

If the technological and styling concepts meet the expectations of the management, the economics is expected to be above the margin defined in the automotive company, and if the project can be handled with the existing resources, the project is likely to be approved.

Concept Development

Concept development starts when the car development project starts, and ends when series development starts, usually with the milestone of *styling freeze*, at which point styling hands over leadership to body-in-white (BiW) development. Its main goal is to define the technological concepts and secure their function in the context of the car.

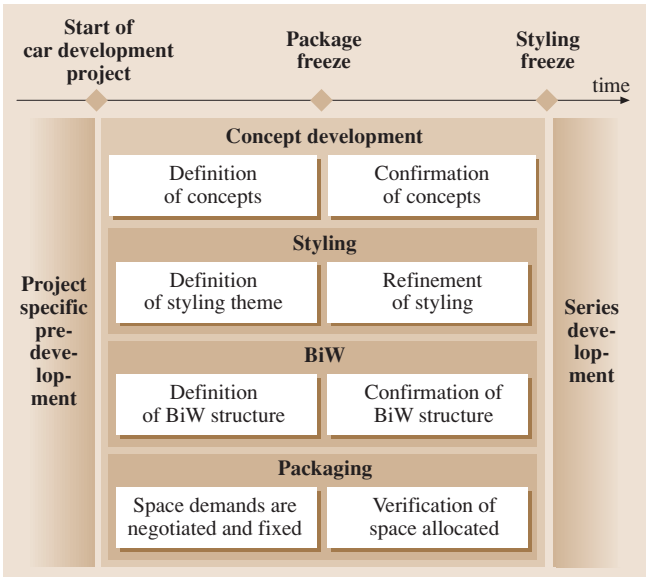

Fig. 13.71 Overview of activities of concept development

At the start of concept development, many activities start in parallel. Exterior and interior styling, packaging and ergonomics, body-in-white design, aero-/thermodynamics, and concepts of all other technology departments are defined and validated in the functional context of other concepts and taking space restrictions into account.

In Fig. 13.71, the main activities of concept development are shown at an abstract level.

Package freeze is a milestone in concept development when all space demands from all parties have been announced, and conflicts have been resolved by trade-offs under guidance from packaging. From this point onwards, violations of space utilization are monitored by packaging and measures for resolving the conflicts identified.

Near the end of concept development, the first hardware prototype is crashed to confirm the structural concept of the car.

During concept development the set of options from which the customer will be able to choose when ordering a car is confirmed. This set of options will be developed during the car development project as well, bearing in mind that there will be different SOPs for the different options after the SOP of the car with the first set of options to be offered. During car development there will be further decisions relating to additional options, resulting from market research and customer feedback, which will be integrated into the project as well (Fig. 13.72).

Series Development

Depending on the internal definitions of the automotive company, series development starts with the milestone of styling freeze or styling release and ends at the start of series production (SOP). The major task during series development is to transfer a car concept that has been proved during concept development to a car series that can be manufactured under series conditions in high volume, at high quality, in the variants offered to the customer, at a competitive production cost.

For this purpose, a number of milestones have to be passed:

- Prototype tests are finished with positive results.
- Tools for series production are released.
- Contracts with the suppliers for series production are concluded.
- All regulations and country-specific requirements are fulfilled.

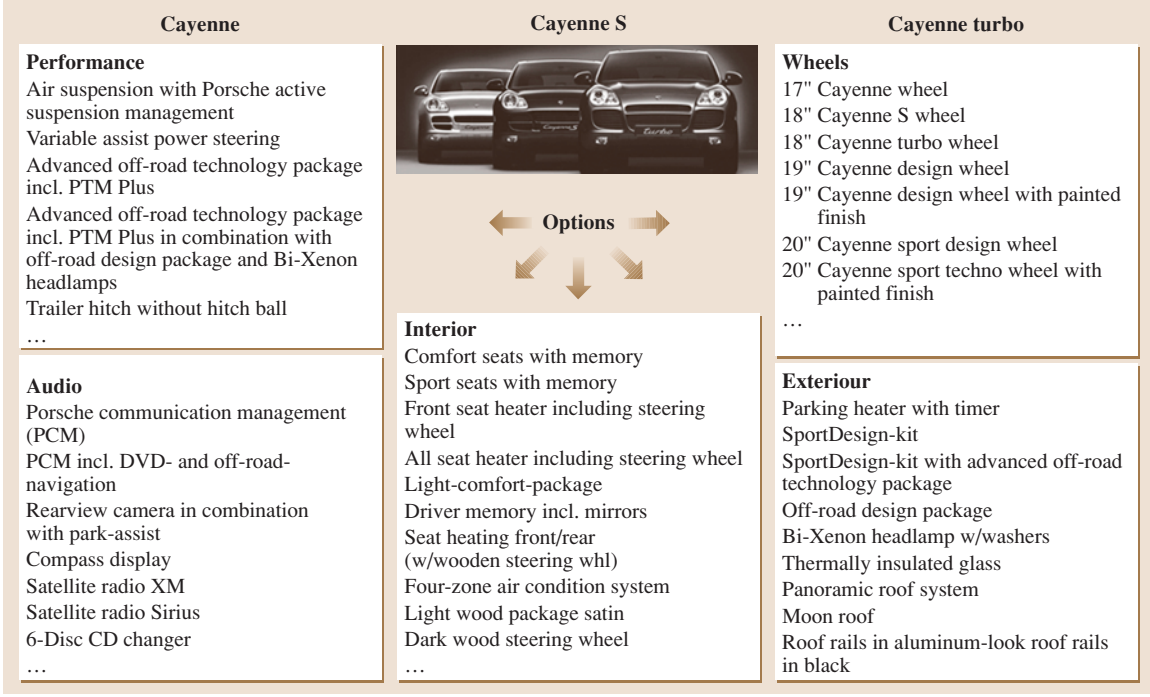

Fig. 13.72 Options the customer can choose from – example of the Porsche Cayenne

- Sample delivery of parts produced with series tools are positively approved.
- Logistics processes are defined and verified; ability to handle the logistics according to the planned production volume is proved.
- Marketing concept (advertising strategy) is defined.
- The dealer organization is informed about the product and its maintenance.

Series development is done in even closer cooperation with the suppliers than concept development, since sourcing for all parts is defined during series development, whereas during concept development often only strategic suppliers are directly integrated in the car development process.

With the start of series development at the latest, the project team structure is defined and fully operational. The teams consist of members of design, production, sales, purchasing and quality and are responsible for the development of the assigned components within the given limits of cost, time, quality, functionality, and performance.

Activities After Start of Production

After the start of production, the car development project is finished. At this point two major activities are still ongoing:

- Development of further options to be offered to the customers at a later point of time
- Support of series production

Further options are usually planned with the car development project in total. The production schedule of these options is integrated into the overall production scenario of how many cars will be sold at which time in what markets.

Support of series production is an ongoing activity which is usually not planned together with the car development project but is rather a support function which is continuously improved. Here:

- Changes of parts are made in order to optimize production processes in terms of cost and reliability.
- Design changes according to feedback from the customers and dealers are implemented.
- Design is optimized in order to reduce material cost.

Depending on the type of change of the part design, effects have to be taken into account up to spare parts provision, thus each change is evaluated in detail in terms of overall cost and benefit.

Depending on the product life cycle and competitors' product developments, facelift projects are established in order to upgrade a car which has been in the marketplace for a certain time with additional features, better performance, and adapted styling. After another period of time, the next generation of car development starts.

13.2.4 Methods for Car Development

As with the development of most technical artifacts, car development makes use of various methods for defining and verifying form, function, and performance. The methods used can be categorized into:

- Virtual methods
- Hardware methods

Virtual methods operate on a product description, usually contained in a computer-based product definition. Computer-aided tools are used to generate and verify the current state of the product definition (Fig. 13.73).

Hardware methods make use of real parts, components, assemblies or products (in car development projects, usually prototypes and pre-series cars). On testing machines, on special driving courses, or out on the street, the product or parts of it are tested for function, performance, and durability (Fig. 13.73).

Virtual and hardware methods usually go hand in hand when a car is being developed (Fig. 13.74).

Generally, with virtual methods a large number of design alternatives can be generated and/or evaluated in a comparatively short amount of time, whereas hardware methods cover more aspects of the real behavior of the product, since not all aspects of product behavior are modeled in the virtual methods.

In the following some of the most important methods for car development will be highlighted and it will be explained how they are used in the development process.

Methods for Product Layout and Conceptual Development

In the early phase of a car development project, styling, package, the body-in-white structure, and aero- and thermodynamics are the key factors which have to be harmonized in order to generate a suitable overall car concept.

Styling

Virtual. Computer-aided styling (CAS) tools allow the definition and manipulation of two-dimensional

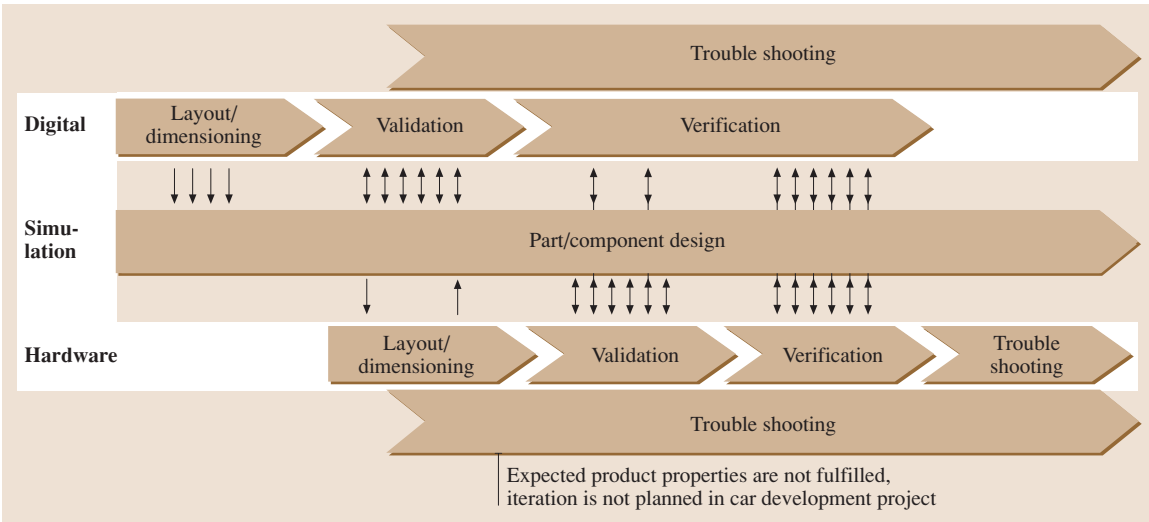

Fig. 13.73 Support of part and component design by virtual and hardware methods

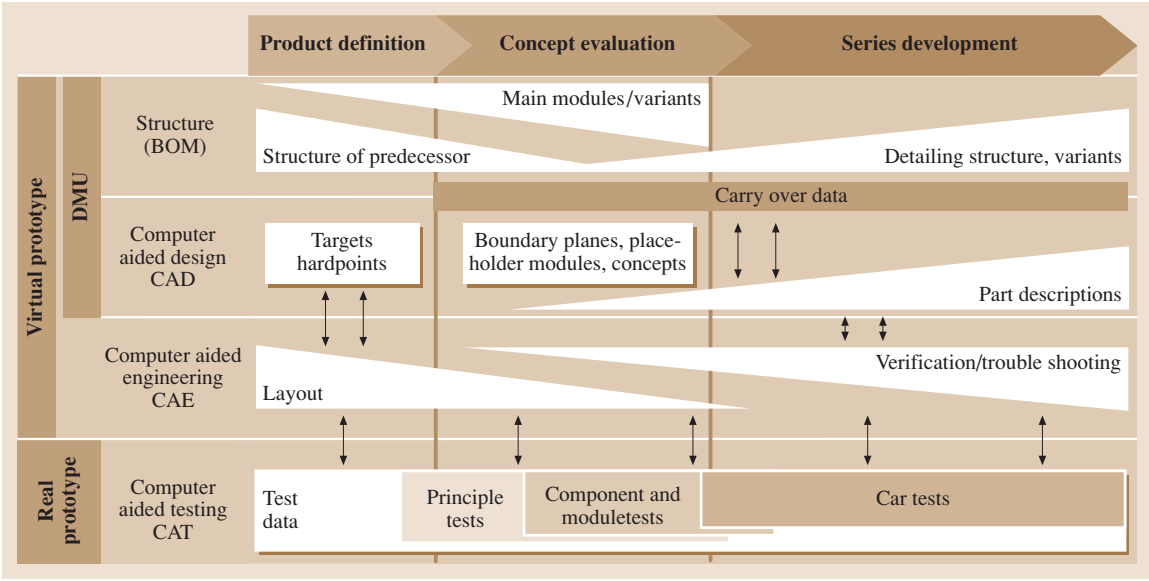

Fig. 13.74 Milestones of virtual development and verification in hardware [13.80]

(2-D) sketches and three-dimensional (3-D) geometry, and have special capabilities for texturing and shading in order to obtain the most realistic pictures or models from the styling definition. Visualization can be done using high-definition printers or monitors, and for realistic 3-D-viewing virtual-reality (VR) equipment can be used. CAS tools allow for the conversion of styling data directly into CAD data, thus making it possible to shorten the time between finishing a styling model and checking, for example, that the car package complies with it. The data transferred into more technically oriented CAD programs can be used as a base to design metal sheets for the body shell. This is a method to define the geometry needed for finally milling the stamps for the outer shell parts, for example. Also, the airflow around and through the car can be simulated using these models.

The major shortcoming of virtual styling process today is that evaluation of a virtual styling model is far more difficult than that of a hardware styling model. Even most sophisticated VR applications and equipment still do not give the same impression as a real car model in real-world surroundings. Therefore, hardware styling models are essential in the styling process as well [13.81].

Hardware. In the early phases of the styling process, scale models (1 : 4 to 1 : 3) can be used to show different proportions and styling topics of a car to be developed. One (or more) of these will be decided on and then refined and used as the base for further styling activities.

Tape drawing is a method for defining the main contours of a car or areas of a car at a scale of 1 : 1 as 2-D models. Black tape is glued to a white surface for the development of styling concepts and their fast visualization and adaptation.

Styling models at a scale of 1 : 1 are mostly made out of clay, and then finished with painted foil to give the styling model a more realistic appearance. Evaluation of the styling model should be done under different light conditions in different surroundings. With special preparation, the styling model can also be used for aerodynamic evaluation. Changes necessary in the hardware styling model to address aerodynamic needs are less easily implemented compared with the adaptability of a virtual model.

Interaction Between Virtual and Hardware Models. Virtual styling models can be milled in styling foam, a painted foil can be applied, and the model can then be used for evaluation purposes. The milled model can also be worked on further with conventional methods (clay modeling, Fig. 13.75), and later the modified model can be digitized with 3-D digitizing machines (3-D scanning).

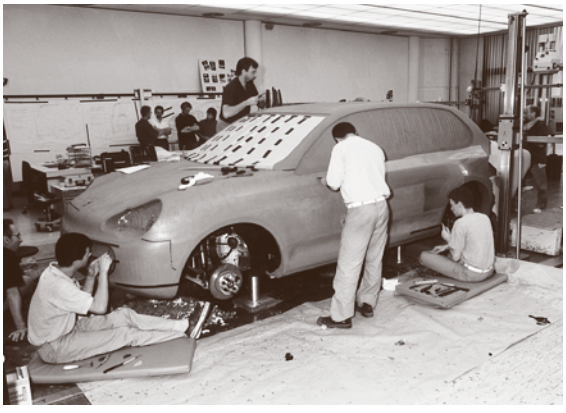

Fig. 13.75 1 : 1 clay styling model (courtesy of Dr. Ing. h.c. F. Porsche AG)

For interaction with other processes in car development (technical checks on the car package, straken) it is important to ensure that the version of the styling model evaluated is the same version that is used for technical checks and strak activities. For this purpose, team data management systems are used.

Both virtual and hardware models are used (Figs. 13.76, 13.77):

- For purposes internal to styling (evaluation, discussion)
- For evaluation by management
- For checking the acceptance of the styling by potential customers (car clinics)

During these car clinics, one or more alternative styling models intended for use in a car development project are usually presented, together with models of the main competitors' models in the target market segment. Customers' responses are used to validate whether the styling fits the taste of the customers, and that the styling is sufficiently differentiated from that of the competitors' cars.

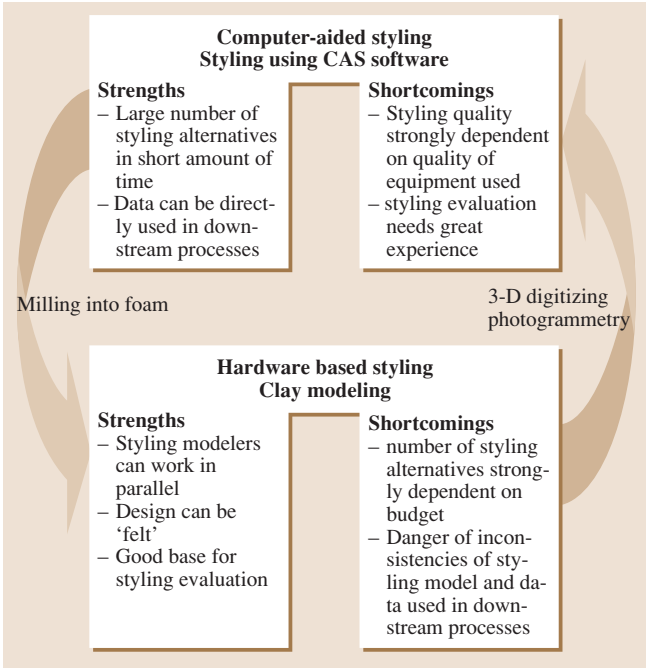

Fig. 13.76 Interaction of virtual and hardware methods in styling

Table 13.7 Strengths and weaknesses of various methods and tools for ergonomics development [13.71]

Method/tool	Strengths	Weaknesses
Design recommendations and checklists	• Quick • Easy to use	• Relevance to specific users, tasks or vehicle type may be dubious • May have little scientific validity • No account taken of compromises • Either too specific (i. e., should be 457.2 mm) or too general (i. e., should be comfortable)
Anthropometry and biomechanics	• Quick • Good for novel designs • Useful for asessing the influence of age, sex, race, etc. upon design	• May be a lack of data relevant to user or task • Data may be out of date • Data often relate to standardized postures, not necessarily working postures • Design may become too academic, mistakes being hard to identify
3-D human modelling CAD systems	• User- and task-specific predictions, quick and accurate for geometric issues such as fit, reach, and vision • Enables effective communication at an early stage • Compromises can be objectively explored	• Expensive to set up (hardware, software, training), but very cost effective thereafter • Does not assess personal preferences, psychological space, fatigue, task performance
Mock-ups and fitting trials	• Control selection of users and their tasks • Study comfort and performance over time • Sound basis for identifying good and poor designs using both objective and subjective methods • Essential for novel designs • Compromises can be investigated • Design problems are quickly identified	• Can be time consuming and expensive • Can be difficult to obtain representative subjects • May not be a very realistic simulation of task or environment
Owner questionnaires and interviews	• Valuable information direct from the user population • Small details may be detected which the casual observer may have overlooked • User involvement	• User may take poor design for granted • Opinions can be strongly biased • Cannot be used for novel designs until after production • Biased sample – does not include those people who chose not to use the existing equipment • Biased sample – low response rate from postal questionnaires, who returns them? • No detailed assessment of body size, performance or comfort
User trials and road trials	• Control selection of users and their tasks • Study comfort and performance over time • Sound basis for identifying good and poor designs using both objective and subjective methods • Allows comparative testing	• Can be time consuming • Require production and/or prototype vehicles to test • Can be difficult to obtain representative subjects

Packaging and Ergonomics

Virtual. Packaging in the early phase of a car development process means defining prescriptions for space utilization by the different technical departments. Also, the main space features of a car such as the size of the trunk are defined here. Space prescription is usu-

Table 13.8 Sample chart for definition of car configurations for geometrical space checks using DMU

Geometry influencing specifications	Car configuration 1	2	3	4	5
Left-hand drive	×		×		×
Right-hand drive		×		×	
Automatic transmission	×	×			×
Manual transmission			×	×	
Small engine	×			×	
Large engine		×	×		×
Convertible			×		×
Coupé	×	×		×	

ally done using packaging boundary shapes which are used to define the most critical areas in terms of building space in a car. They also reflect geometrical demands derived from regulations such as minimum sight angle etc. Ergonomics of a car (driver position, accessibility of steering wheel and switches, driver's view) are checked by using virtual manikins, representations of human bodies which are derived from a statistical analysis of the main geometrical body features of human beings. One example is the manikin RAMSIS [13.82], which is a software package that can be used for any kind of geometrical simulation of a human being, and can be integrated into CAD models (Figs. 13.78, 13.79).

Various methods and tools are used in car development to identify the needs of the customers and thereby to derive design guidelines for the design, shape, and location of interior components. Table 13.7 gives an overview of methods for ergonomics development.

Packaging in the early phase is also responsible for the interface between the *technical world* and the *styling world* and trade-offs between them.

During the car development project, the packaging activities change from prescription to verification, ensuring that the parts developed will fit together in the virtual and hardware assembly.

A digital geometrical product description, a combination of all 3-D models of all relevant parts in their correct position in space is called a digital mock-up (DMU), and is used for the detection of collision between parts and for the simulation of the assembly process (Fig. 13.80).

To build up a DMU, it is necessary to have a bill of materials for the specific car. It can then be analyzed whether all part geometries necessary for a complete DMU have been provided by the engineering design or whether any part geometry are missing (Table 13.8). Since car development usually involves the development of a number of different car variants (left- and

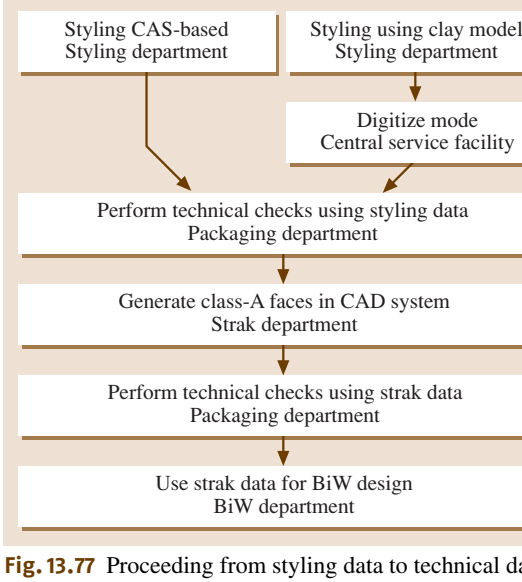

Fig. 13.77 Proceeding from styling data to technical data

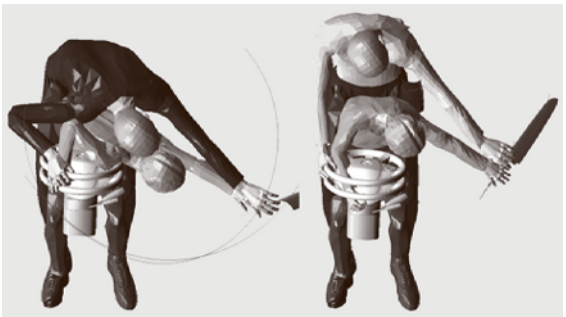

Fig. 13.78 RAMSIS application for verification of accessibility of door closing mechanism [13.82]

Fig. 13.79 RAMSIS application for verification of accessibility of rear door closing grip [13.82]

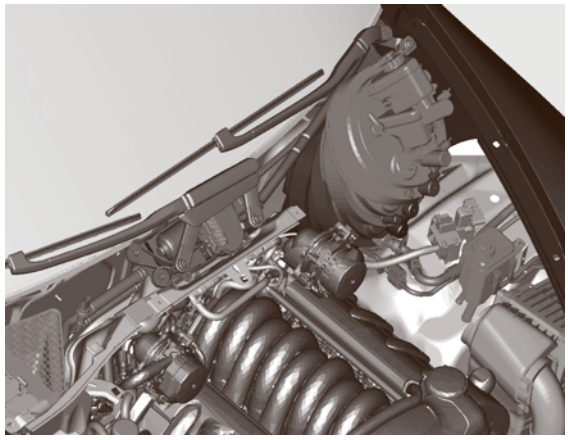

Fig. 13.80 DMU of components in the engine bay of a sports utility vehicle (courtesy of Dr. Ing. h.c. F. Porsche AG)

right-hand drive, automatic and manual transmission, different engines, and different customer-specific equipment), packaging has to define the most critical (in terms of space) car configurations, and will track the fitting of parts with respect to each other on the basis of these configurations. Based on experience, a trade-off is made between complete coverage of all car variants that are potentially critical and the expense of this level of coverage.

In order to be able to generate a DMU automatically, the designer has to assign his 3-D CAD model to a node in the bill of materials, and has to position it in each relevant car configuration. Positioning can be done either in absolute coordinates (relative to the vehicle null point) or in relative coordinates describing the position relative to another part on which it is, for example, mounted.

Part collisions can be checked on demand (when the designer wants to verify his part design in his specific geometrical surrounding), or on a regular basis as a complete geometrical car check. Conflicts between two parts are documented, and a recommended action is communicated by packaging to the two part owners.

Hardware. Most automotive companies use hardware to verify the space allocation of parts and the ergonomic suitability of the position of interior components. The engine bay, which contains flexible parts (cables, tubes) that cannot be appropriately modeled in CAD systems today, is one example. The seat box is another example, where hardware verification is used in order to check the ergonomic position of every element in the future seat. Both have their virtual counterparts, which are used earlier in the process.

Body Structure The main physical structure of a car is the body-in-white structure (BiW structure). With the layout of this structure, the basic performance features of a car are determined, too. To a certain extent, the BiW structure accounts for the weight of a car, the bending and torsion stiffness, and its crash behavior. If changes in the layout of the BiW structure are necessary later in the process due to conflicts in space management or unsatisfactory crash performance, these changes result in heavy additional cost, since changing this structure leads to necessary changes in all other sections of the car connected with the BiW structure and in the highly automated manufacturing lines in the factory which are planned, ordered, and built early in the process, too. Thus, methods for a thorough layout of this structure according to the goals defined for the car to be developed are used.

Virtual. Since body-in-white structures are developed in the early phases of car development, when no hardware is yet available, the focus of methods for layout of the BiW structure is on virtual methods. For the layout of a structure, generative algorithms can be used. One set of algorithms widely applied in the automotive industry is implemented in the package *SFE CONCEPT*. According to the definition of load cases, material coefficients, and major geometrical boundary conditions such as free space for the passenger compartment and trunk, the algorithm identifies at which points of space material is needed in order to fulfill the demands for smooth load flow and minimum deflection of the beams of the BiW structure. The result of this algorithm is a space structure of voxels which then can be used for a first layout of the structure in the CAD system. The result of this structure is then taken for finite element analysis to prove that the performance criteria are still met after the structure has been designed in such a way that it can also be manufactured.

Modal analysis of the BiW structure will show which frequencies will lead to resonance reactions, resulting in noise and discomfort for the passengers, and which therefore have to be avoided when guiding the load path into the BiW structure.

Depending on the car family the BiW structure is intended to cover, precautions for reinforcements in the structure have to be taken into account. An example is the need for reinforcement when the BiW structure of a coupé is intended for use in a convertible, since bend-

ing and torsion stiffness will decrease in this case due to the missing roof, in order to give the coupé additional stability.

Hardware. To ensure that the results of the calculation are correct, one of the first BiW structures to be manufactured as a prototype structure is often used for the verification of bending and torsion stiffness on testing machines. Since these tests are also quite inexpensive and the correct layout of the BiW structure is fundamental, this approach is reasonable. The first prototype with the new BiW structure, in most cases built shortly before the end of the concept phase, is used for first driving tests and, most important for the verification of the structure, in case of accidents. Due to the highly dynamic processes and its high dependency on dynamic material properties, the results of the simulation of a crash are still uncertain, which is why hardware verification is still needed before series development can start.

Aero/Thermodynamics The basic aero- and thermodynamic behavior of a car is determined by the layout of the exterior, the main air channels inside the car, and the position of the engine and other power-train components. Thus, this behavior has to be checked early in the process, when the styling process is not yet finished, in order to allow for necessary design changes to be made due to flaws in the aerodynamic performance [13.83–85].

Virtual For prediction of the aero- and thermodynamic behavior of a car, computational fluid dynamic (CFD) methods are used. With the help of these methods, the air flow around and inside a car can be visualized, a key performance indicator of a car – the c_w coefficient which contributes to the fuel consumption, especially at high speeds – can be determined, and air flow can be analyzed. Minimum air mass flows are defined, for example, for the cooling needs of the engine through the the radiator, and of the brakes.

The normal force to the road consists of the weight of the car and of the force generated by the air flow, the down force. The down force is also being calculated in the early phase, as it is critical for driving stability at high speeds. Changes in the exterior car shape and additional aerodynamic spoiler can affect the down force.

Hardware In order to analyze the airflow around and inside a car, flow analysis models can be used. Early in the process, scaled models can be used to evaluate exterior airflow and provide criteria to decide on a styling alternative that is more suitable in terms of aerodynamic performance. Later in the process, 1 : 1 scale models can be used for analyzing both exterior and interior airflow.

Fig. 13.81 Test with sports utility vehicle to verify performance in dry and dusty environment (courtesy of Dr. Ing. h.c. F. Porsche AG)

The hardware-based approach is losing favor against the use of virtual simulations.

Methods for Series Development

With the concept confirmed, the series phase starts. Increasingly virtual methods are substituting and being complemented by hardware methods.

A huge number of different development and testing methods are used in series development to ensure that

Fig. 13.82 Test with sports utility vehicle to verify performance in cold and snow environment (courtesy of Dr. Ing. h.c. F. Porsche AG)

Fig. 13.83 Test with sports utility vehicle to verify performance in wet environment (courtesy of Dr. Ing. h.c. F. Porsche AG)

Fig. 13.84 Test with sports utility vehicle to verify performance under extreme road conditions (courtesy of Dr. Ing. h.c. F. Porsche AG)

the components developed will meet functional, performance, and quality targets. Each automotive company has its own particular approach in terms of which methods are used for what kind of evaluation at which point in time. Figures 13.81–13.84 give an overview of different tests to be performed in the development of a sports utility vehicle.

Using three example methods, a general insight into the methods for series development is provided below.

Climate Simulation. A climate chamber (Fig. 13.85) is used to simulate extreme climate conditions. Heat and cold are simulated, together with different levels of humidity and sunlight incidence. Different kinds of behavior are analyzed in the climate chamber: car functions such as door opening, and heating and cooling of the passenger cell are analyzed, as well as engine start-up performance under extreme conditions. An extension of the climate chamber is the climate wind tunnel, in which different wind flow can additionally be generated with the car standing still or using its engine to turn the wheels on rollers mounted to the floor.

Climate simulation on the test track is usually combined with analysis of the behavior of the car and especially its cooling system at high speeds. To simulate the car being parked in a garage with a hot engine, after these tests the car can be put into a closed chamber to simulate this extreme operating condition.

Climate simulation is also done in extensive tests in different climate zones in the world such as Northern Canada and Death Valley. Here, it is important to minimize the effort in transporting the test cars between the different test locations while maximizing the difference in climatic conditions, in order to minimize cost and time lost during transportation. Snow, sand, different road conditions, and stop-and-go traffic in metropolitan areas are also covered during these tests.

Chassis Tuning. For tuning of the chassis system different driving situations are simulated by test drivers. Additional adaptations in terms of springs, dampers and, most important, electronic stability systems are derived. In order to cover all combinations in which a car can be driven by a customer, the variants of tire size and type, usage of winter chains, and the different engine, chassis, and body types have to be taken into consideration. Therefore, with the large number of car variants that a customer can order, the effort required to tune the chassis can increase greatly. Table 13.9 shows a sample combination matrix for chassis tuning tests.

Fig. 13.85 Car test in climate chamber (courtesy of Mercedes Car Group)

Table 13.9 Sample combination matrix for chassis tuning tests

Tire size	18″	19″	20″	
Tire type	Summer	Winter	All season	Off-road
Winter chain	Without	With		
Engine type	3400 ccm	4500 ccm	4500 ccm turbo	
Chassis type	Normal	Comfort	Sport	Adaptive
Car body type	Small	Wide		

Besides tuning of the chassis, it also has to be verified that there is enough space between the tire (all potentially usable tires) and the fender liner under all driving conditions. For this purpose, early in the process wheel covers are generated as boundary faces for the movement of the tire under every condition in the CAD system, on the basis of which the fender liner is designed. The correct sizing of the fender liner is then verified in hardware tests later on. Most critical in terms of space needed are large tire sizes with a sporty chassis layout and the usage of winter chains.

Hardware-in-the-Loop. Hardware-in-the-loop (HIL) is an approach to test certain hardware components in their future operating environment, when this environment is not already available, i. e., when other interoperating components are not available yet. In this case, the other components as well as the environmental conditions are simulated by a computer program in real time, and the simulation parameters are input to the component to be tested. HIL is used for mechanical, electronic, and electromechanical components.

The HIL approach is used to decouple the behavior of components such as controllers in an interconnected network (for example, the CAN bus). With clearly defined interfaces between the components and the definition of the communication bus structure, the HIL method is similar to the methods used in software engineering for some time already.

An example of the utilization of HIL is the testing of controllers for active body control in a test-bed with simulated signals from sensors and actuators before the controller is put into the networked car environment in a prototype.

Tests of a component can be reproduced, and thus also critical conditions in terms of operating behavior can be reproduced and used as test criteria for approving the release of the component.

With the decoupling approach of HIL, product development time can be reduced, since it is not necessary to wait for the last component in a network to be available in hardware. Also, due to the modular structure of the network of components, the complex interaction of components can be controlled.

Cross-Functional Methods

Product Structure and Bill of Materials. The car is logically and/or functionally structured. The power train, the doors, and the cockpit might be high-level elements of this structure which are substructured further. The leaves of the structure tree represent the parts or components. The part or components describing data is matched via PDM software and transformations that describe the position of the specific part or component are added. The functionality of the PDM software enables the digital generation of assemblies or the entire car. For this purpose the product structure will be interpreted, and the geometrical description of the parts and components can be loaded and positioned element by element using the attached transformations. This functionality is the basis for all kind of simulations (Fig. 13.86).

The product structure again is the basis for the BOM (Fig. 13.87). In the bill of materials the leaves of the structure of the car are focused upon. The geometrical description itself is neglected; its existence and the level of quality are of importance and, hence, represented. Instead, further information is added which enables the configuration of the car. The BOM describes the contents of the accessory packages to be offered, the specifics of the American, European or Japanese versions, the colors that will be available, the options that can be chosen, and the dependencies that exist between these configurations.

The BOM, and the system in which it is handled, form the basis for all logistical activities. Material and supplier parts are ordered using the BOM for prototypes as well as the final, customer-specific car. The plants in which the cars will be assembled can be planned with respect to capacities, required tools, robots etc. and manufacturing costs can be calculated since the part-

specific costs are also added in the BOM, to name just a few applications of the BOM.

Since the role of the BOM is essential, its quality is a major aim in car development.

Data Quality. Since the virtual models of parts, components, and assemblies are used for diverse simulations (see *Methods for Product Layout and Conceptual Development*) the representation of the real pendant has to be of high quality. Only by guaranteeing high data quality can costs be effectively saved by substituting physical prototypes by virtual ones early in the process.

The parts have to be *technically* mature, which means they have to meet the requirements by fulfilling the function specified and have to be manufacturable. With respect to the car, they have to fit in the system and their assembly has to be possible. On the other hand the parts have to have a high quality with respect to *formal* demands. For example, it is important that guidelines, both general and company specific, have been taken into consideration in order to prevent unnecessary correction iterations. The parts have to be described completely and all required extended information has to be provided. This information completes the geometrical description of the part, component or assembly and gains importance during development process.

Examples are material, weight, center of gravity, tolerances as well as metadata such as the person in charge of the part, the supplier name or in which context the part will be used or assembled (depending on the type of car, accessory package, or options to be chosen by the customer).

The responsibility for the quality of data belongs to the part owner. To achieve technical quality the part owner is supported by departments that investigate the packaging (see *Packaging and Ergonomics*) and digitally secure the assemblability. Companies often use tools to check the quality of the geometrical data, particularly when data comes from suppliers. These tools check whether planes are closed, parameters are set, and so forth. The formal quality can be controlled by monitoring tools which check specifically defined parameters. Sometimes the part owner is actively supported in completing the nongeometrical information by departments that are in charge of product data management. These departments finally check the data set of a part, component, and assembly. The positive result of a check leads to the release of the part, component or assembly. This release also means that the digital model is reliable and can be used in further development (see the following section).

Release. The importance of high quality of data has already been discussed (see *Data Quality*). The measure by which the required quality of data will be

Testing	Homologation
Production	Quality
Sales	After sales
Controlling	

finally checked is the release, which concludes the development-specific activities at a certain version of the part, component or assembly. The label "released" for an object makes the virtual model visible for downstream processes such as design of tools, logistical processes, and planning of manufacturing units and plants. The released model is guaranteed to have the required level of maturity and quality in order to start hardware processes. Hence, every part which is needed to be manufactured and/or assembled has to be released. Only released parts can be ordered, regardless of whether the part is used for the production of a prototype or the final assembly of the car.

The release processes differ slightly from OEM to OEM. Nevertheless a general process can be recognized. The release process described below is a generalized example which demonstrates the major characteristics of the process.

The prerequisite for the common release process is the completed design of the part, component or assembly. It has to fulfill its function(s) and meet all defined requirements at the specific point of development. The geometrical description has to be complemented by all required information. What this information is depends on the point of development; for example, only a few pieces of technological information, such as tolerances and connecting details, are required in the early phases, whereas the weight and the center of gravity have to be available as precisely as possible from the start of design.

The release itself requires a positive evaluation during several steps. An overview of the process is presented in Fig. 13.88.

Design is *inventing* the part and secures its function. Before the release process is started several aspects should be taken into consideration. Tables 13.10 and 13.11 show examples of these aspects.

When the part has the required maturity and shall be released, the person in charge of the part has to lock the model in order to prevent further manipulation. At this time the required data quality has to be secured by design or related departments. Data has to be checked by sight or specific tools for the aspects to be considered (Table 13.11). Depending on the process specifications and the specific release level during the car development process these aspects differ with respect to the expected maturity of data (Fig. 13.82).

The locked and prechecked part will then be passed onto the *drawing check*. Now the model can, for example, be checked for:

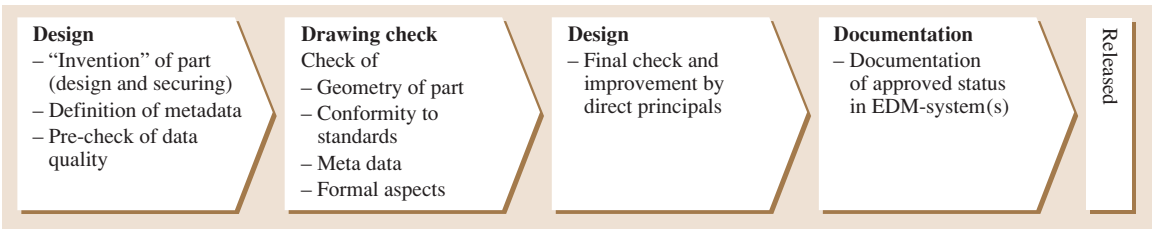

Fig. 13.88 General proceeding of a release

- The manufacturing specific design of the part
- The conformity of geometry, material etc. to standards
- The existence of the required technological data
- The existence of the required metadata
- The existence of the required attributes

After a positive evaluation of the draw check, the part and its evaluation results are *transferred* back to the design where the persons responsible for design have to confirm the evaluation from their point of view. Aspects that have to be considered by the person(s) representing the specific design department where the part was created include whether the part is technically acceptable and whether recent decisions prevent a release of the specific part.

When the confirmation release is successful this information is documented in the engineering data management (EDM) system. The part, component or assembly is now labeled as "released". This attribute is also transferred to the BOM. In this way downstream processes can now access the geometrical description of the part, and the release process is completed.

The various forms of releases are differentiated in Fig. 13.89.

Car development is a complex process in which suppliers develop a large share of the car. The parts, components or assemblies will be designed at the OEM or be provided to the OEM by the supplier. Although the supplier naturally checks the required maturity for the development to be delivered, the release of the data is done by the OEM in order to achieve uniform data quality supplied to the process.

Release without application	
→ New part	(general design, i.e., standard parts or generally applicable parts like tubes, clamps, surgical gloves, washer fluid)
Release with application	
→ New part	(specific design, i.e., body parts or the specifically adjusted tube)
→ New application of existing part	
→ Change of design	(part has to be replaceable in all applications)
→ Change of level of maturity	(no changes of design have been made, development phase changes by definition)
Examples	
⤷ Part looses validity	(for a specific application, another application might stay valid)
⤷ Exchange of part	(for a specific application)
⤷ Change of relevant equipment package	
⤷ Change of quality	

Fig. 13.89 Kinds of release

Not covered by this description of release processes and particularly challenging is the release of software. Since all OEMs handle the securing of software maturity differently and the processes are often handled very flexible it is not currently possible to describe a representative process.

As mentioned above the aspects to be checked in a release depend on the specific milestones of the car development process of the particular OEM. Figure 13.90 shows some examples of the form of a release with respect to maturity of car development.

Prototype and Test Management. The different departments in car development have special needs for tests. During tests, certain aspects of the behavior of the car are analyzed. In order to achieve the most efficient utilization of prototypes, tests are scheduled and assigned to prototypes in a way that minimizes the number of prototypes and the effort required to rebuild prototypes, while maximizing the usability and special needs of prototype equipment and maturity for the design departments. Prototype and test management is usually a central facility that covers all car development projects (Fig. 13.91).

Weight Management. The weight of a car is a basic layout parameter and influences fuel consumption, and the distribution of the weight between the front and rear axles of the car is a parameter that influences the driving performance of the car.

Therefore, the definition of weight targets and weight management during the car development process is important to ensure that the car will meet the expected performance criteria.

In the target building process, the weight target for a car is defined by:

- Benchmarking of car weight of competitors in the market segment
- Key performance parameters of the car to be met (such as fuel consumption)
- Top-down definition of targets by proportional ratio of weight from the predecessor car
- Consideration of negative and positive weight contribution of new components (such as infotain-

ment components) or technologies (aluminum body structure)

Weight targets are broken down from the whole car into modules and components to parts, and the designer has to meet the weight target while keeping the cost and time targets as well as the function in mind.

As soon as weight targets are defined and agreed upon, weight management is started to control the current status of the car weight at each step of the car development process. The quality of the weight status can be divided into three different categories. In the early phases, when there is no 3-D part geometry available, the weight declaration is in the state of *estimate*. With engineering judgment, the responsible designer will feed this value into the weight management process.

As soon as a reasonable 3-D part geometry is available and the material is defined, the weight can be *calculated* by using CAD functionality for calculating the volume times the material density. The third level of weight status is reached as soon as parts are available in hardware. The weight can then be measured using a scale. The quality of the weight state *weighed* depends on whether the parts are made out of series material and series tools or whether prototype material and tools are used, and eventually corrective factors are used to forecast the final part weight (Fig. 13.92).

During most of the car development process, there will be parts concurrently in the state of *estimated* and *calculated* or *calculated* and *weighed*, making the overall weight state a combination of both states until near the start of production (SOP).

Weight is usually tracked in the BOM.

Weight targets are defined for a number of different car variants, and these have to be checked continuously. Finally, it is important to meet the needs of homologation of a car in the different countries to which the car will be exported, and the different regulations for measuring the car weight (tank full or empty, supposed number and weight of passengers).

Change Management. The dynamics of car development does not end with its introduction to the market. A car will continuously be developed further. On average each part of a car will be changed approximately three times, and engine parts about eight times. Up to the point that a car model line ends, the number of spare parts increases by a factor of five.

Changes can become necessary because of field feedback (guarantee and warranty, quality, customer ex-

Proceeding of product development

Kind of release	Release for planning	Release for tools	Release for purchasing	Release for disposition
Prerequisites	Part design is mature for testing	Results of testing positive for step-by-step release	Part desing finished, test results are sufficient	Evaluation by production is positive
Activities before starting release process	– CAD model created – Part information defined – BOM adapted – Signed by principals	– CAD model, BOM and part information changed due to results from testing – Signed by principals	– Part design finished – BOM and part information finally adapted – Signed by principals	– Sample delivery and testing positive
		Release		
Activities triggered by release	– Evaluation in terms of DFM by production – Definition of production methods and tools – Purchasing of prototype parts – Disposition for tests – Check series delivery capabilities of supplier	– Generation of manufacturing BOM – Order of tools for series production – Finish planning for logistics processes	– Adaptation of manufacturing BOM – Planning of SOP – Planning of production capacity – Securing of ramp up of series production by contrasts – Purchasing of pre-series parts	– Contract for unlimited part delivery according to volume planned

pectations, requirements from sales), measures due to legislation, optimization (costs, production, and quality), and technical development.

Change requests always have their reason. Nevertheless not each request can be realized since each change requires enormous effort, as a complex process is necessary to realize a change. An idea of what has to be carried out to implement a change is in a new car is presented in Fig. 13.93.

When a change request (Fig. 13.93 (4)) is generated for a model line that is in production (3) the change process starts in development again (5). Although the process of adaptation (6) differs slightly from the general development process, the main steps are the same as shown in Fig. 13.93 (6). When the necessary adaptations of production tools and proceedings are implemented the changed car (8) can finally be manufactured (7).

The entire process of realization of a single intention to change costs about 20 000–50 000. This is the reason why a change request has to be considered carefully. It has to be considered whether the reason to change specific features of a car is profitable enough to cover the costs resulting from the process necessary for its realization.

In Fig. 13.94 the main steps to evaluate an intended change are shown. The two-level release process helps to extract unnecessary or unprofitable change requests early in the process. When the change request or intention is described by an expert, for example, a principal of the specific design department can evaluate it. This evaluation functions as an early filter, when only little effort is invested. An approval leads to a phase of detailing of the design of the intended change. The de-

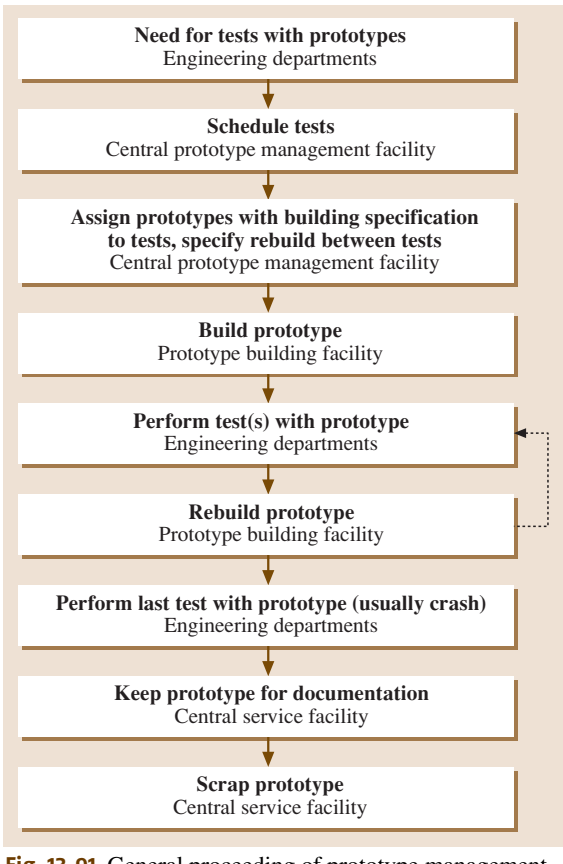

Fig. 13.91 General proceeding of prototype management

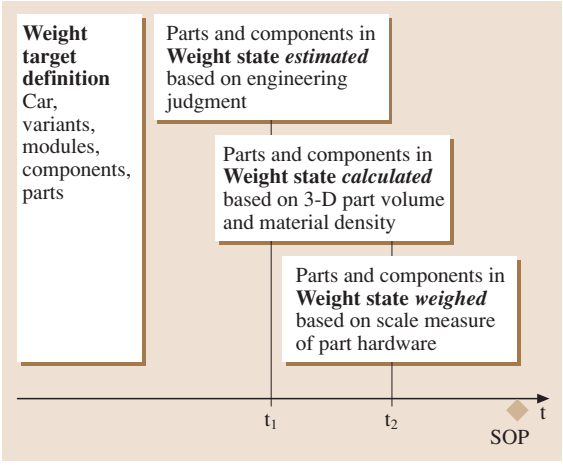

Fig. 13.92 Total weight state based on different part weight states (examples t_1 and t_2)

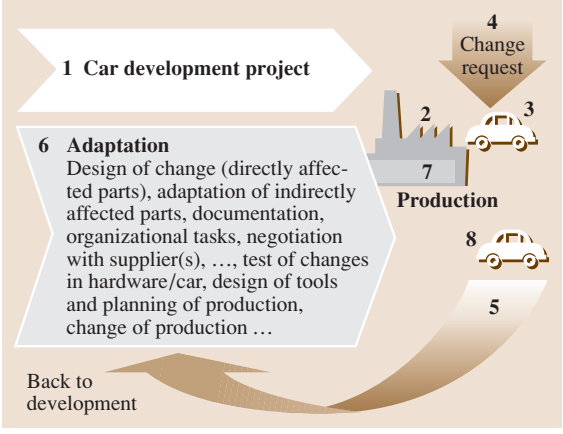

Fig. 13.93 Effort resulting from the realization of a change intention

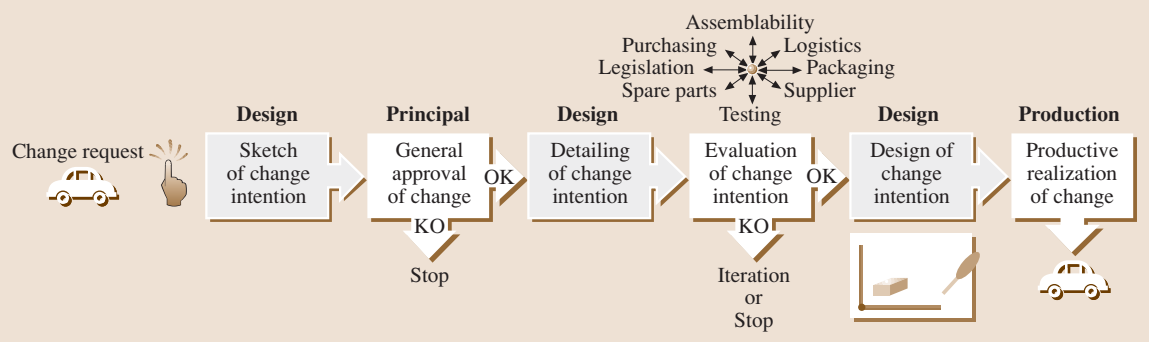

Fig. 13.94 Example of a change approval and realization process (after CAD/CAE in Automotive Industry, Technical University of Berlin, Institute of Vehicle Technology) (KO = knock-out)

tailed change request is then evaluated by all affected departments, as shown in the figure. Due to the more detailed specification an evaluation of the intended change with respect to affected topics by the experts is now possible. When these experts approve the request the realization of the intended change starts with the design.

The process of the evaluation and realization of a single change itself causes an enormous effort. However, during the car's lifecycle and in the various departments involved in car development many change requests are generated. Since there are about 8000 changes in one car model line and approximately 50% from that after start of production, one can imagine that it is not possible to realize each change intent in the production line once it is completely defined. A change in production might, for example, request a standstill of the line. This is expensive and must be coordinated so that many changes are carried out at the same time.

Another aspect which needs coordination is the testing of changes in hardware. In order to keep costs low several changes should be tested in one production vehicle used for testing series aspects. A prerequisite is that the changes do not affect one another. Hence, the realization of changes has to be planned in detail.

Integration of Development Partners. Tier 1 suppliers today have in-depth knowledge of their technologies, components, and their application in a car which auto-

Table 13.12 Nonengineering functions to support car development

Purchasing	In the early phase of the car development project, engineering partners and system suppliers who collaborate in concept development are sourced by purchasing. Contracts are made about the content of engineering service provided up to the provision of prototype parts for first hardware tests. Afterwards, most automotive companies have a global sourcing process in order to identify which supplier will provide the parts for series production and select this supplier on the basis of reliability of supply and price.
Marketing	Marketing represents the voice of the customer. It is mainly involved in the definition of the car development project (positioning of the car to be developed in the market, definition of target price, definition of options to be offered).
Controlling	Each car development project is measured by a number of different parameters, one of the most important of them cost. In most automotive companies, budgets are assigned for each simultaneous engineering team responsible for a specific area of the car. These budgets consist basically of engineering cost (internal and external), prototype material cost, and investment for sourced parts and for production machinery. Controlling keeps track of the predicted budget consumption against real consumption, and provides valuable information to the team for taking necessary corrective actions to meet the cost targets.

motive companies usually can no longer afford to have due to the extreme specialization required for the different technologies. Therefore, the integration of these suppliers of the car development project from the very start is of vital importance. Examples of technologies and components developed by suppliers are headlamps and electromechanical components such as antilock braking systems.

When integrating suppliers into car development, one has to consider:

- The product substance
- Its extent in terms of engineering service
- The interaction between the supplier and the OEM

Depending on this, the following aspects have to be agreed upon in contracts with the supplier:

- The kind of data exchange (mail, direct access to systems from the outside or by resident engineers)
- The kind, form, and contents of the results to be delivered by the supplier
- The kinds of simulations and tests to prove the suitability of the concept and its application in the context of the car
- Delivery of prototype parts, if applicable and necessary
- Delivery of parts for series production, if the supplier will also source the component for series supply

In order to integrate development partners successfully there has to be a trade-off between open transfer of information and retaining specific expertise in the OEM and the relevant supplier.

Nonengineering Support of Car Development. During car development, the engineering departments are supported by various nonengineering functions in the company. Table 13.12 briefly describes the most important functions.

13.3 Railway Systems – Railway Engineering

13.3.1 General Interactions of Modules of a Railway System with Surrounding Conditions

Railways have many technical and economical interfaces to the surrounding world, as indicated in Fig. 13.95. The aims of the railway are usually provided externally, from policy and economics regarding market, finances, and environment. These aims are transformed into strategies be the management of a railway company, defined by instructions to several subareas such as marketing, which define the product in terms of timetable and comfort. The timetable provides lots of information; it defines the locations to be connected and the distances to be overcome. By defining the times of departure and arrival, the travel speed is fixed. Also the frequency of operation of trains is defined.

The railway operation must be able to fulfill this requirements by providing adequate, educated staff in trains and at fixed locations. Energy to move the trains must be provided at the right locations. Communication must be enabled over one or even several lines with many trains. If the schedule fails, disturbance management must be able to restore the system to proper operation as soon as possible, whether failure is caused by exterior or interior reasons.

Infrastructure such as the tracks, perhaps catenary, the design speed of the track and its gage, the structural gage, the axle loads, stations for passengers and/or loading/unloading facilities for goods must all fit the demands. Information technologies for passengers are also gaining in importance.

The type of vehicles chosen must be adequate for the required operation, for instance, locomotives, coaches or diesel multiple units (DMUs). The vehicles must fit the infrastructure and the operation in terms of speed, axle load, etc..

Maintenance must provide reliable system elements by avoiding failures because of the effects of wear. Maintenance is increasingly being outsourced today.

If all of the elements shown in the boxes on the diagonal in Fig. 13.95 are provided by one company it is called an integrated railway otherwise it is known as a segmented railway.

The interaction of the elements produces results in terms of earnings, and the quality of the process (for example, punctuality).

Because of high cost pressures the aim for a economically sound railway system is to run as fast

[(km/(vehicle of the fleet × day)] and as reliably as possible.

A high number of kilometers per vehicle in the fleet is important, as the costs for vehicles, stationary equipment, and operational staff are a function of time, whereas the earnings from passenger and freight traffic is more or less a function of distance. Also fast running in form of fast point-to-point transportation is itself attractive for passengers and goods.

Good reliability reduces the number of spare vehicles and spare staff and also reduces operational risk. Of course this is an important quality measure for clients in passenger and freight operation.

Rail vehicles must therefore be designed according to these requirements.

Duration of Passenger Exchange

As stopping time has a negative effect on the aims mentioned above (covering as long distances as possible per vehicle and day) stopping time should be as short as possible, which results in many technical and operational constraints.

As an example the different elements or modules define the stopping time of a train (Fig. 13.95).

The duration of stops (intermediate stops and in the terminus/stations) is affected by the following parameters:

1. The height difference between the platform and train level, which should be as small as possible.
2. The gap between the train entrance and platform, which should be as small as possible (the ideal being gapless high-level platforms in a straight line and without curves).
3. The ability of passengers to handle the process; large amounts of luggage and disabled persons slow down the loading and unloading process. Disabled persons are for instance small children and older persons.
4. Duration of the door opening and closing process. Modern semiconductor-controlled doors often have very lengthy closing procedures, for instance, 20 s for the InterCity Express 1 and 2 (ICE 1/2) trains in Germany, and similar values for the *train à grande vitesse* (TGV) in France. The reasons for this are the slow processors used for door control and the connection to the vehicle bus.
5. Number of doors. The number of doors should not be to small because of the possibility of door failures, but for long-distance traffic doors are costly because of the door costs itself and because the space behind the door is not usable for passenger seating space.

Especially for trains with frequent stops it is very efficient to have short stopping times. For sure the preprocess and postprocess time are not productive at all and the passenger exchange time is the more effective the shorter the time is for a given number of exchanging passengers (Fig. 13.96).

Lifecycle Costs

The annual distance traveled by rail vehicles is rather high, between 100 000 km/year for tram cars, over

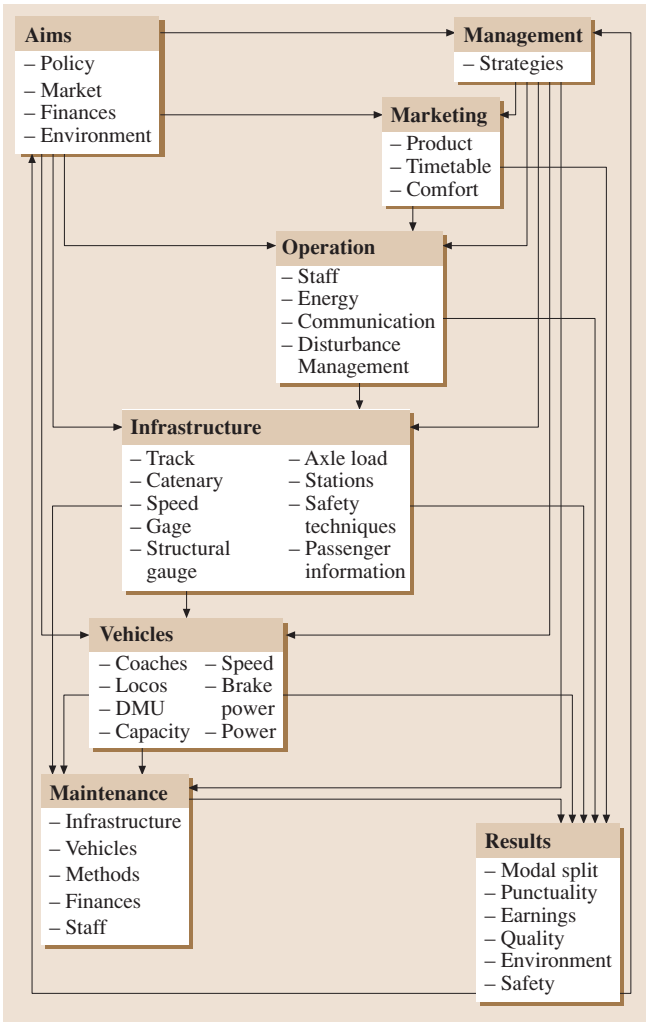

Fig. 13.95 Railway transportation – a system with strong interference

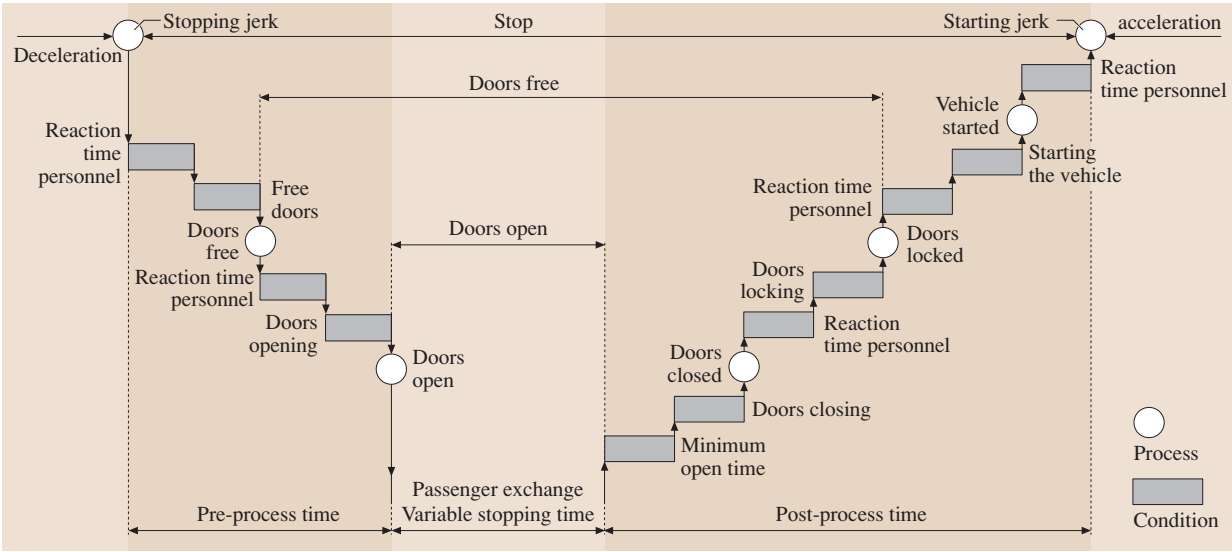

Fig. 13.96 Stopping, door opening/closing, and passenger exchange (after [13.86])

200 000 km/year for regional trains and freight locomotives, and up to 500 000 km/year for high-speed rolling stock. For freight cars it may range between 10 000 and 200 000 km/year. Lifetime is typically 30 and sometimes 40 years. Investment costs are rather high and typically cover one-quarter to one-third of the lifecycle costs. Other costs are maintenance and operation. In countries where wear- and noise-related track prices are charged, at least the difference between the cheapest vehicle and the actual vehicle must be respected in the lifecycle cost as a new component.

Reliability, Availability, and Safety

The basis for reliability, availability, maintainability, and safety (RAMS) is the European standard EN 50126 *Railway applications – The Specification and Demonstration of Reliability, Availability, Maintainability and Safety* (September 1999) (Fig. 13.97).

RAMS is needed due to the increasing complexity of railway systems and to achieve a high-quality process. In a competitive environment (mainly from other modes of transport such as road, air, and even water) this is essential to survive economically. A very reliable transport (for instance, 99% or even more trains on time) with high speeds and therefore little standby time must be arranged. Good reliability reduces the need for spare units and spare personnel; high speeds increase productivity as payments are received on a basis of passenger-km or ton-km measures, whereas the expenses for equipment, both trains and infrastructure, and also personal occur on a time basis.

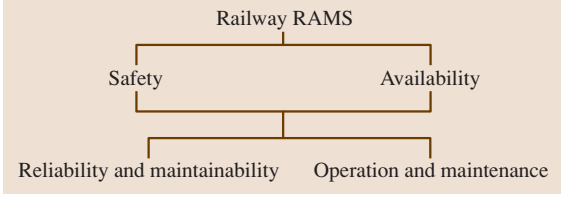

Fig. 13.97 Interrelation of railway RAMS elements

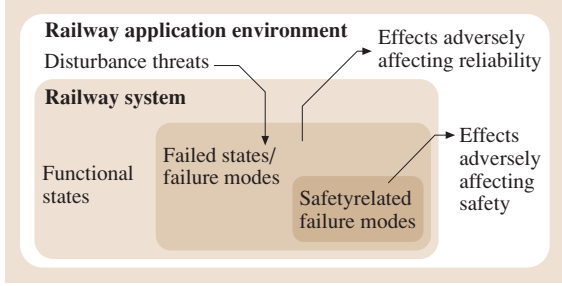

Fig. 13.98 Effects of failures within a system

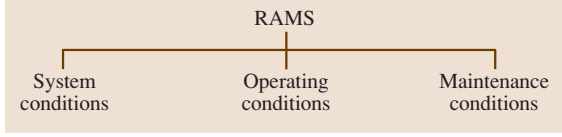

Fig. 13.99 Influences on RAMS

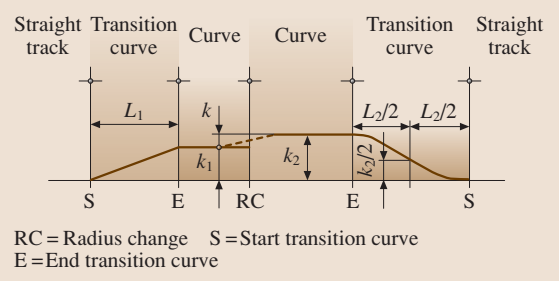

Fig. 13.100 Transition curves and ramps shown as curvature $k = 1/R$

Here mainly the process is discussed; targets are only mentioned as an example. RAMS covers the whole lifecycle of a system, and must be followed by the railway authorities (track and train operators) and the railway industry (system houses and suppliers).

The following definitions are used (Fig. 13.98):

- *Reliability*: the probability that an item can perform a required function under given conditions for a given time interval (t_1, t_2).
- *Availability*: the ability of a product to be in a state to perform a required function under given conditions at a given instant of time or over a given time interval, assuming that the required external resources are provided.
- *Maintainability*: the probability that a given active maintenance action, for an item under given conditions of use, can be carried out within a stated time interval when the maintenance is performed under stated conditions and using stated procedures and resources.

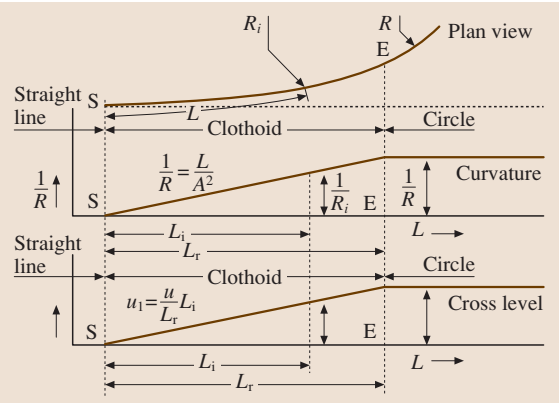

Fig. 13.101 Transition curve with linear ramp, *top*: plan view, *middle*: curvature, *below*: cross level

- *Safety*: freedom from unacceptable risk of harm (note that safety does not mean that no accident occurs at all).

Risk is defined as the product of size of the resulting destruction and the likelihood of the occurrence of the event. This likelihood of occurrence may be reduced by huge safety margins or by diagnosis that improves the probability of the recognition of a defect at an early and still not dangerous stage.

Around 1980 railways demanded an availability of about 80% for their fleet. Some railways operating under difficult conditions, for instance when suffering from the requisition of spare parts for cannibalization for other units, often did not reach 50%. Today figures of 95% for electric rolling stock and 92% for diesel rolling stock or even higher are demanded.

The definition of availability does not include accidents (for instance, at points during shunting) and vandalism (for instance, broken windows or broken chairs due to rioting). Operational retardation is also not included. Because of all of these reasons the number of spare units which are neither available nor down is greater than zero.

The basic equation for availability is

$$\text{Availability} = \text{MTBF}/(\text{MTBF} + \text{MDT}) \,, \qquad (13.2)$$

where MTBF is the mean time between failure, and MDT is the mean downtime.

Technical concepts of availability are based on a knowledge of:

1. Reliability in terms of:
   - All possible system failure modes in the specified application and environment
   - The probability of occurrence of each failure or, alternatively, the rate of occurrence of each failure
   - The effect of the failure on the functionality of the system
2. Maintainability in terms of:
   - Time for the performance of planned maintenance
   - Time for detection, identification, and location of faults
   - Time for the restoration of the failed system (unplanned maintenance)
3. Operation and maintenance in terms of:
   - All possible operation modes and required maintenance, over the system lifecycle
   - Human factor issues

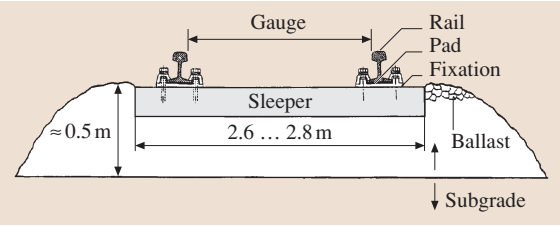

Fig. 13.102 Ballasted track bed (Table 13.13)

Table 13.13 Explanation for Fig. 13.102

Element	Function (construction)
Rail	Guidance of the vehicle, load distribution (rail 1 : 20 or 1 : 40 tilted)
Sleeper	Load distribution
Ballast	Load distribution, elastic element and damping device, distribution of the rail forces in all three directions, noise absorption of rolling noise and gearbox noise

RAMS is influenced by the system conditions (vehicle and track, mainly influenced be the vehicle and track producers), operating conditions (the knowledge of the onboard personal and the available data), and the maintenance conditions (knowledge and equipment of the maintenance personnel and the maintenance facilities) (Fig. 13.99).

Methods to reduce downtime include:

1. Improving information to reduce inspection time by diagnosis
2. Parallel maintenance processes, including simultaneous processes of repair, inspection, refilling of water, sand, fuel etc.

For instance, cleaning of the interior (and probably the exterior) and toilets should be done simultaneous with refilling of water, sand, and probably fuel (while ensuring safety), a small overhaul, and module exchange (wheelsets, drive components, air-conditioning modules, etc.).

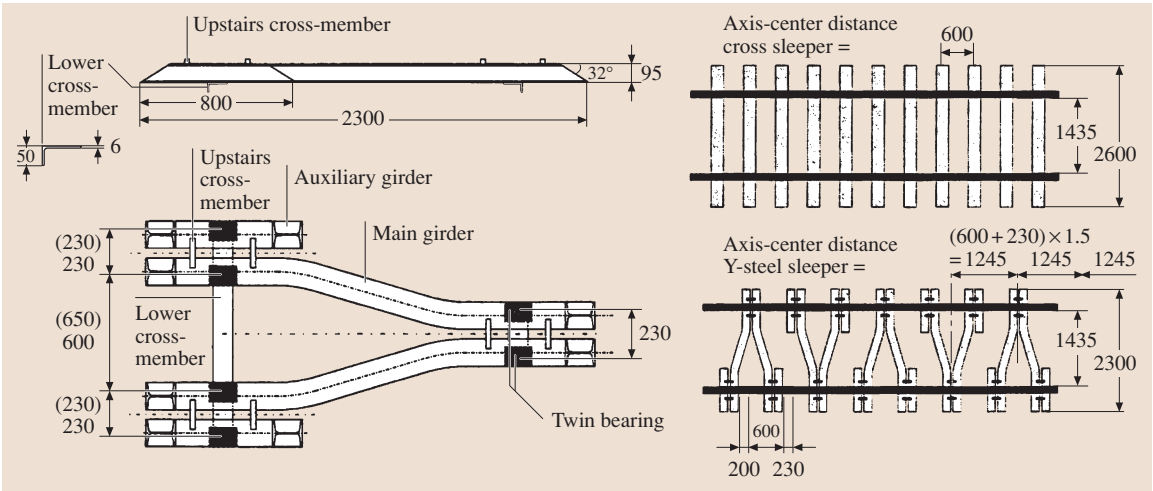

Fig. 13.105 Y-steel sleeper and comparison of steel, wood, and concrete sleeper track beds [13.87]

Simultaneous maintenance of fix train-sets (the locomotive plus wagons) and not locomotives separately from wagons avoids uncoupling and coupling time.

Systems diagnosis is becoming a major issue, and technical systems are becoming increasingly complex. Fault conditions are more difficult to reproduce, but fault analysis times should be reduced. Diagnosis systems for rail vehicles should have three levels:

1. Diagnosis for train personnel, to provide information for greater availability, and advice regarding redundant system operation
2. Diagnosis for maintenance personnel, to provide direct advice for required maintenance operations
3. Diagnosis for technical management, to provide data for reliability statistics as a basis for system improvements or at least spare parts management (to enable the greatest reduction of spare-parts storage)

Two requirements of the diagnosis system that must be fulfilled are:

1. All data must be collected in one system for the whole vehicle (not separate systems, for instance, for the diesel motor, drive, doors, toilets, etc.).

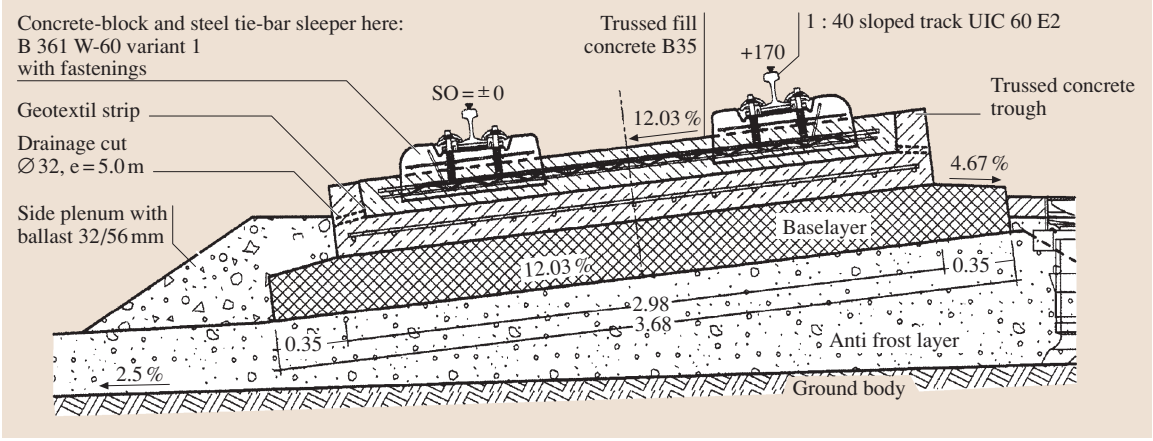

Fig. 13.106 Ballast-less track at the Cologne–Frankfurt high-speed line in a curve with maximum superelevation of 170 mm (Walter-Heilit, Munich) [13.88] (UIC = union internationale des chemins de fer)

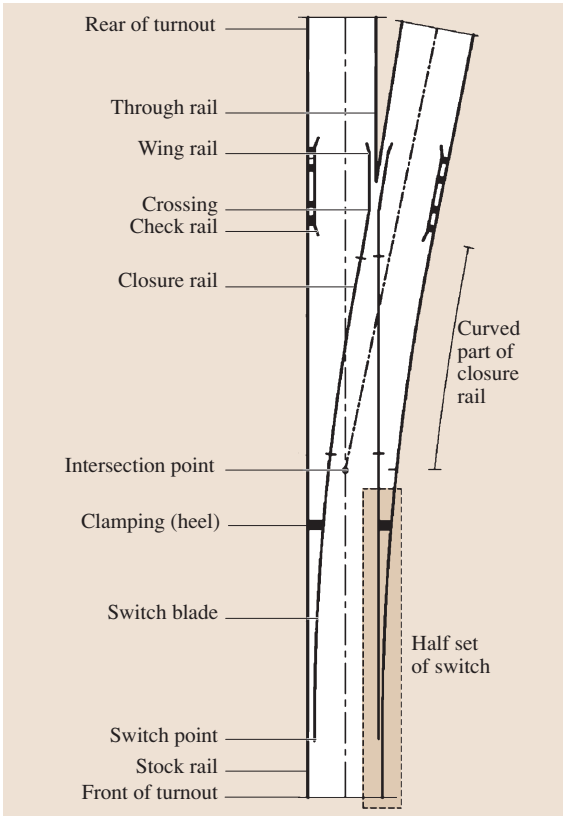

Fig. 13.107 Switches and their elements

2. The diagnosis criteria must be adaptable live during vehicle operation. This means that software skills must be available in the maintenance groups.

The reason for this is that the supplier cannot deliver a diagnosis system fulfilling all needs of the operator because:

1. Not all operation circumstances are clear for the producer or even the operator
2. Operation conditions may alter during vehicle operation (for instance, due to speed increase, longer trains, or movement from full to inferior service after 10 years or more)

It is recommended to order two or even more releases of diagnosis software after vehicle acceptance (and homologation) has been achieved. Operation experience can then be integrated and the correct level of information attained.

Helpless statements should be avoided and making sure that information is given for real problems. Also transfer from industry personnel to railway personnel must be achieved.

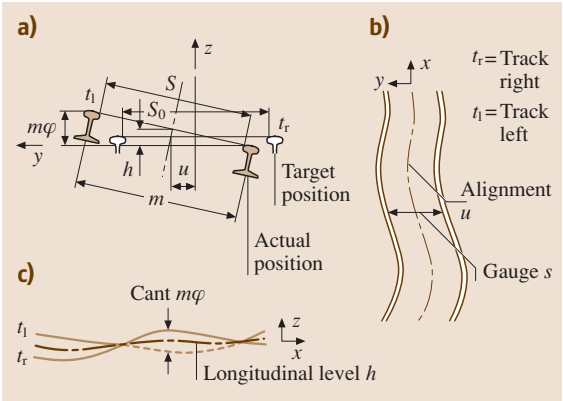

Fig. 13.108a–c Geometric track components: **(a)** coordinates in the measurement plane, **(b)** horizontal track coordinates: gauge s and alignment u, **(c)** vertical track coordinates level h and cant m_φ

13.3.2 Track

Interoperability of railways id affected by the track gauge very much, see Table 13.14.

Track Geometry Components

The track geometry defines the position of the track in the landscape [13.89]. The following components are used:

1. Vertical: level track, gradients, and gradient changes

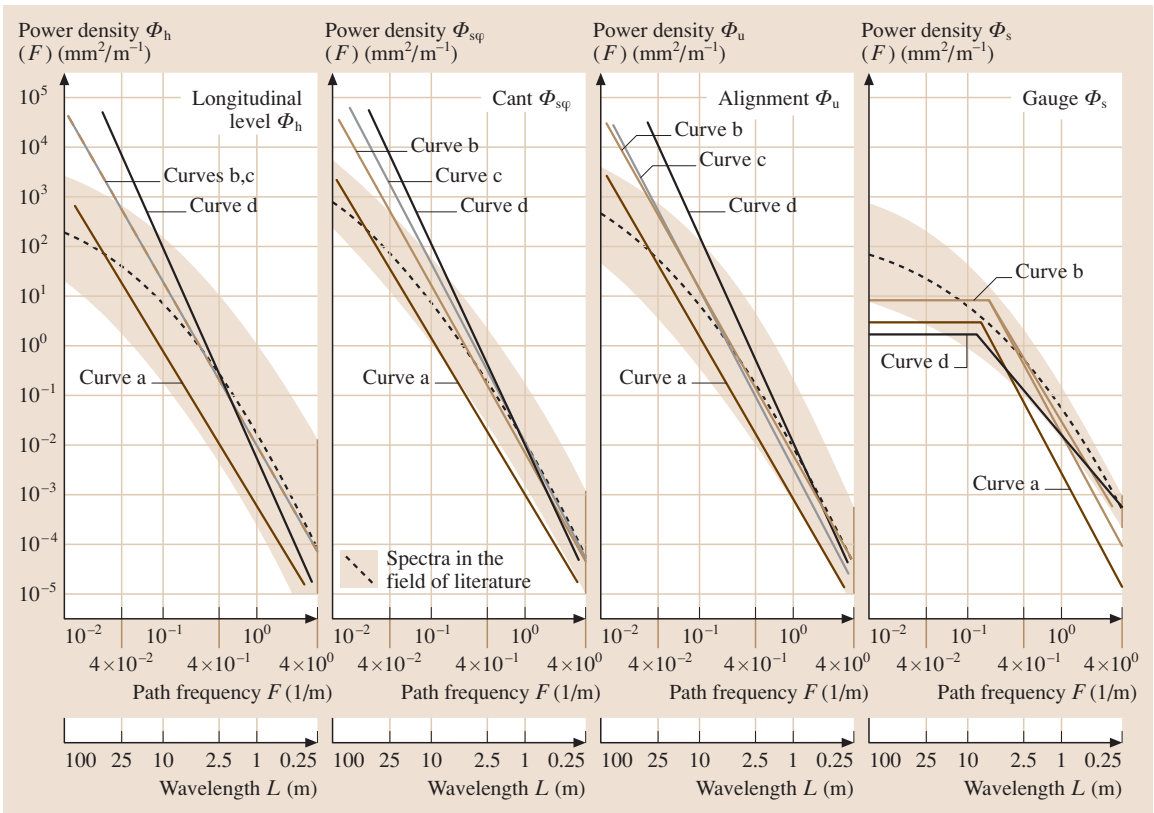

Fig. 13.110 Examples of track power spectral densities. *Curve a* – standard gauge; *curve b* – city railway flat bottom rails (route track); *curve c* – city railway flat bottom rails (driving school track); *curve d* – city railway grooved tramway rails track

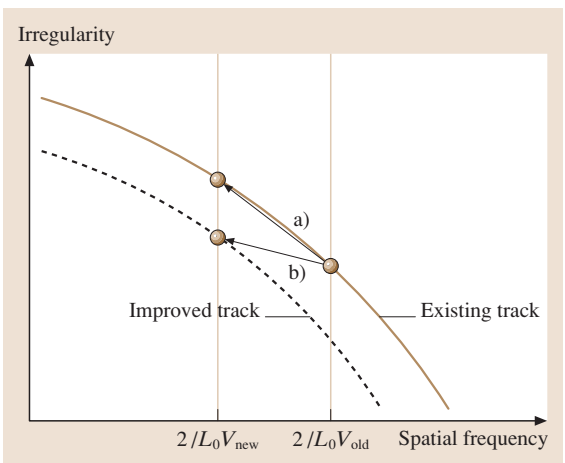

Fig. 13.111 Effect of speed increase on track amplitudes for a specific eigenfrequency of the vehicle

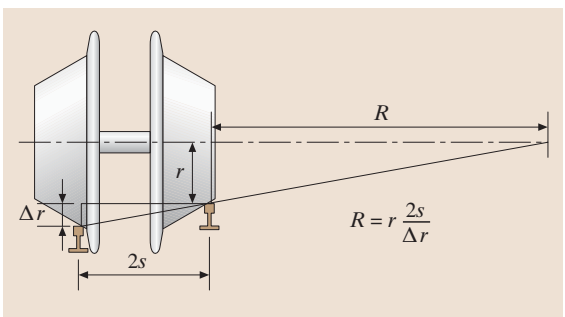

Fig. 13.112 Steering effect of a slip-free wheel-set in a tight curves (radius R) related to the inner rail. $2s$ is the distance of contact points (typically 1500 mm at standard gauge); r is the rolling radius at the inner wheel; Δr is the radius difference between the outer and inner wheel

2. Curves: radius R, transition curves with continually adapted curve radius, curvature k as inverse radius $k = 1/R$. Clothoid for curvature of transition curves $k = L/A^2$, where A is the clothoid parameter that limits the jerk r (change of acceleration) in the lateral direction (m/s^3); limit $\leq 1\,m/s^3$ (Fig. 13.100)
3. Lateral: cant to reduce lateral accelerations (maximum for standard gage with mixed traffic 150 mm) in transition curves ramps must be foreseen (Fig. 13.101).

Track Bed Configuration

The sleeper in the track bed (Fig. 13.102) not only distributes the weight in the vertical and lateral directions but also in the longitudinal direction. All forces caused by thermal stresses in the continuously welded rail must be transferred via the sleepers to the ballast. The continuous welding process is done at medium temperatures to minimize temperature effects. In summer at high temperatures buckling of the track is avoided by high lateral resistance.

Rails are described with letters, which define the shape of the rail, and a figure, which normally gives the weight per meter in kg or lb (Fig. 13.103).

The VST36 is a rail for light axle load, for instance Swiss narrow-gage railways. 49E1 is used on lightly used European standard-gage lines. 60E2 is a rail for European main lines and AREA141AB is a rail for American main lines.

60Ri2 is a grooved rail for tramway applications. Though the axle load of trams seldom exceeds 8 t the stiffness of the tram rail is similar to the other rails. In this way much smaller displacements of the rail are achieved in the street plane.

Rails today are rolled as long as possible, typically 120 m long, in order to reduce the number of weld spots in the line as much as possible. Welding in the line not only is costly but also the welds are more crack sensitive than the rolled rail.

Concrete sleepers are very durable and environmentally friendly, therefore they have replaced wooden sleepers in many cases. Their heavy weight makes assembly difficult but provides good track stability (Fig. 13.104).

Today the most commonly used sleeper type is concrete, but wood is still used also and Y-steel sleepers have a growing market-share. Y-Steel sleepers have much higher lateral resistance than concrete or wood, therefore no ballast is used to avoid sideways buckling at high temperatures. Also, because of the lower height of the sleeper, less ballast is used in the track bed itself (Fig. 13.105). This is an advantage in tunnel construction. On intensively used lines, ballast-less track construction has the advantage of less maintenance effort compared with ballasted tracks (Fig. 13.106).

Switch

To enable networks, switches are essential. Compared with other guided transport modes where switches are large and heavy, at the railway switch only the switch blades must be moved. This is done by bending the blades elastically. Relatively small electric motors with gearboxes apply these forces.

In the crossing (also called frog) itself there is a gap where no lateral guidance of the wheel flange occurs.

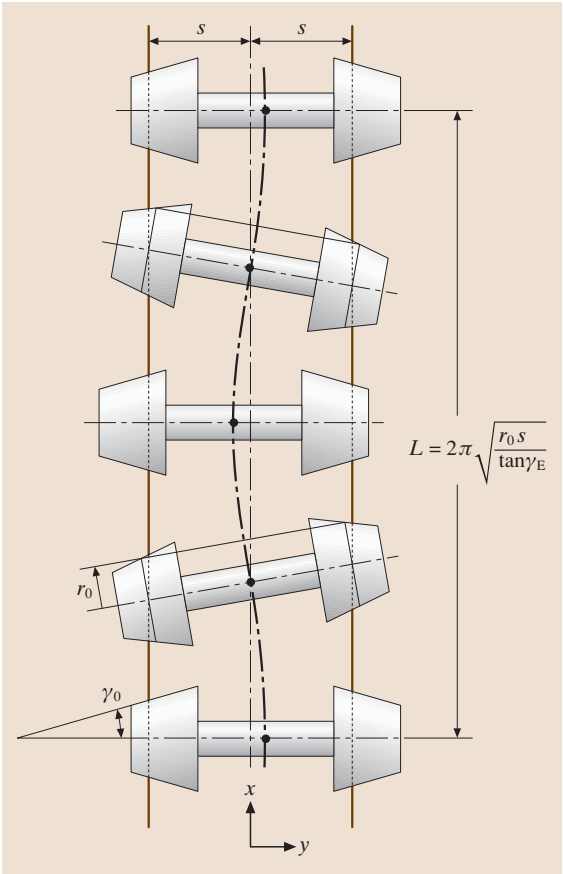

Fig. 13.113 Idealized wheel-set moving: the wavelength L which occurs in slip-free movement [13.90]

Therefore check rails and the running rail result in guidance on both sides of the other wheel of the wheelset (Fig. 13.107).

Track Irregularities

The four degrees of freedom for the track are: gauge s, cant m_φ, alignment u, and level h (Fig. 13.108).

Gauge is defined as the smallest distance between the rail heads in a track 0–14 mm under the top of rail (TOR) cant m_φ is the height difference between the two rails (Table 13.14). Twist is a function of cant over

Table 13.14 Nominal international gauge distribution (caution: large tolerances between −3 and +35 mm are possible)

Name	(mm)	British (in)	Worldwide (%)
Meter gauge	1000	$3-3\frac{3}{8}$	7.5

distance

$$\text{cant} = [m_\varphi(x_1) - m_\varphi(x_2)]/(X_2 - X_1)[-]$$

(possible also (mm/m = ‰)).

Track irregularities are defined as a function of wavelength L or spatial frequency $\Omega = 2\pi/L$. With increasing wavelength the amplitude of track irregularities increases (Fig. 13.110).

The following track irregularities are common [13.91]:

- Level

$$\Phi_z(\bar{\Omega}) = \frac{A_V \Omega_c^2}{(\bar{\Omega}^2 + \Omega_r^2)(\bar{\Omega}^2 + \Omega_c^2)} A$$

- Alignment

$$\Phi_y(\bar{\Omega}) = \frac{A_A \Omega_c^2}{(\bar{\Omega}^2 + \Omega_r^2)(\bar{\Omega}^2 + \Omega_c^2)}$$

13.3.3 Running Gears

Wheel–Rail Interaction

The standard element of railway running gears is a wheelset. This consists of a rotating shaft and two wheels which are fixed on this shaft by a press or shrink fit.

Additionally the wheel profile together with the rail profile generates a steering effect (Fig. 13.112).

To introduce this effect a conical thread geometry is first assumed.

The radius difference Δr in both rolling wheels leads to a self-steering effect, as both wheels have the same rotational speed but the outer wheel is running on a larger radius than the inner wheel.

This desirable behavior is superimposed by an effect called sinus running for conical profiles or wave running for practical profiles.

Equivalent Conicity. The wavelength of the real profile is equal to the wavelength of a wheel profile with constant conicity, as shown in Fig. 13.113.

To characterize the interaction between wheel and rail for different wheel and rail profile shapes Figs. 13.114 and 13.115 show examples for two different rail inclinations. The desired behavior is that the surfaces of wheel and rail make contact on a rather broad level and that the difference in radius Δr reaches high values before flange contact occurs. If the angle of attack between wheel and rail is large, then a two point contact occurs (Fig. 13.117).

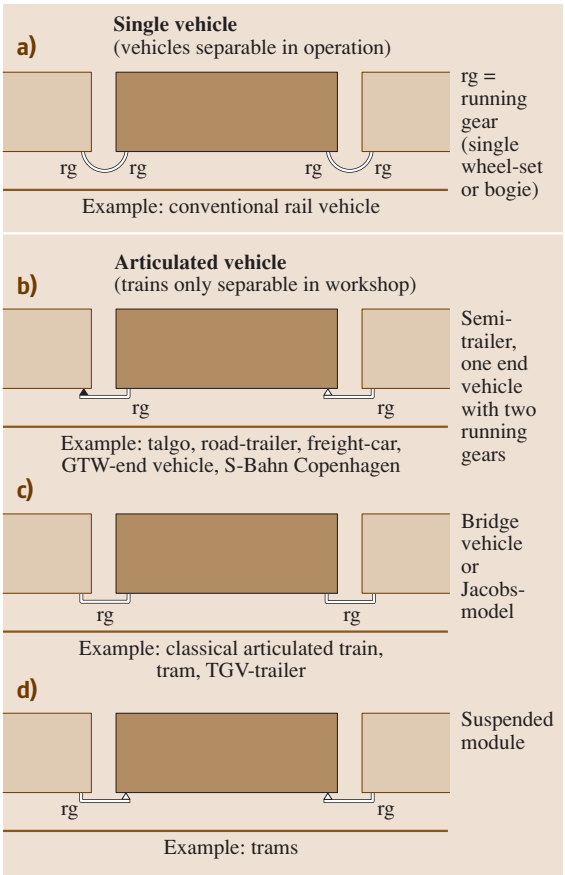

Fig. 13.134 **(a)** Single vehicle supported by at least two running gears (single wheel-sets or bogies). **(b–d)** Articulated vehicles: saddle principle, Jacobs principle, bridge principle, and suspended modules (GTW = Gelenktriebwagen (German) = articulated vehicle)

The running gears of the two-axle wagon are of the link suspension type (Fig. 13.116). The links not only admit lateral but also longitudinal movements. In this way self-steering of the individual wheelsets is enabled. The system is damped by friction, which is load sensitive; the higher the load the greater the friction force. The diameter of the link is increased in the contact zones to increase the friction force.

The spring rate is very much a function of the amplitude. For small amplitudes, for instance, caused by small track irregularities, the system is very stiff. For large amplitudes, for instance, caused by severe rail twist, the system becomes rather soft [13.92] (Fig. 13.118).

Bogie Principle

The wheelsets are spaced with an axial distance $2a$ and situated in a frame (Fig. 13.119). This frame together with the wheelsets forms the bogie. The vehicle body in general is supported in the middle of the bogie frame at z_P. This geometrical configuration leads to the reduction of track regularities. As a function of their wavelength, track irregularities are reduced between two extremes: no reduction at all (for wavelengths equal to the wheel set distance $2a$) and complete reduction (for wavelengths equal to half of the wheelset distance), as illustrated by the equations below:

Geometrical transfer function of a bogie

$$z_P(x_0) = \left[z(x_0 - a) + z(x_0 + a)\right]\frac{1}{2}.$$

Track irregularity $z(x)$

$$z_P(x_0) = \frac{1}{2}\left(z\,e^{i\Omega(x_0+a)} + z\,e^{i\Omega(x_0+a)}\right)$$

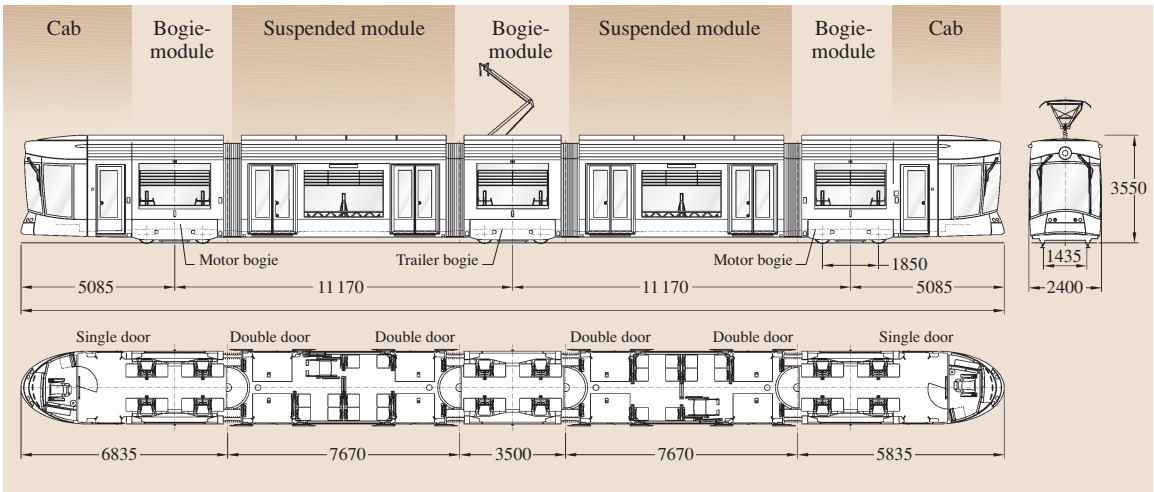

Fig. 13.138 Type of vehicle: Bombardier Flexity outlook, model Marseille: bidirectional, length 32.5 m, height 3.5 m, width 2.4 m, floor height above top of rail (low floor entrance) 320 mm, wheel diameter new/worn 580/520 mm, gage 1435 mm, car weight (empty) 40 t, car weight (loaded) (4 pass./m^2) 54.3 t, maximum axle load 11 t, minimum horizontal curve radius 25 m, minuimum vertical curve radius, crest 450 m, minimum vertical curve radius, sag 350 m, maximum speed 70 km/h, maximum gradient 80‰, nominal current supply: 750 V$_=$, regeneration of energy, low voltage: 24 V$_=$, four three-phase asynchronous motors, motor power: 4 × 115 kW, air-cooled motor, two powered bogies/one trailer bogie, rubber/metal primary suspension, coil spring secondary suspension, eight sanders, anti-slip, anti-skid system, electrical service brake: regenerative, mechanical service brake: disc brake, magnetic brake: 6 × 90 kN (Bombardier Transportation)

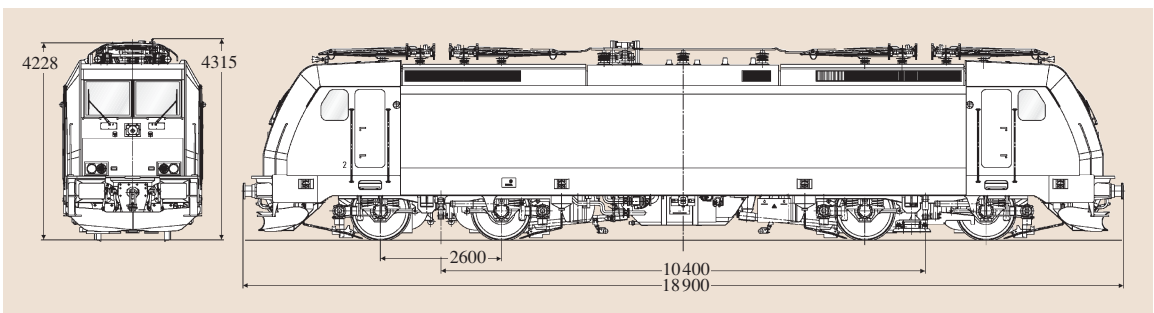

Fig. 13.139 Bombardier Traxx locomotive family, freight and passenger locomotive: weight 86 t, power 5600 kW, max. traction force 300 kN, speed 140 or 160 or 200 km/h

$$z(x) = z\,e^{i\Omega x} \qquad \Omega = \frac{2\pi}{L}$$
$$z_e^{i\Omega(x_0-a)} = z_e^{i\Omega x_0}\,e^{-i\Omega a}$$
$$z_P(x_0) = \frac{1}{2} z\,e^{i\Omega x_0}\left(e^{-i\Omega a} + e^{i\Omega a}\right)$$
$$H = \frac{\text{Output}}{\text{Input}}\,,$$
$$H = \frac{1}{2}\left(e^{-i\Omega a} + e^{i\Omega a}\right)\,,$$
$$e^{i\Omega a} = \cos\Omega a + i\sin\Omega a\,,$$
$$H = \frac{1}{2}\left(\cos\Omega a\, i\sin\Omega a + \cos\Omega a + i\sin\Omega a\right)$$
$$= \cos\Omega a$$
$$= \cos\frac{2\pi a}{L}\,.$$

For railways the lateral dynamics very often are even more important than vertical dynamics and this good behavior of a bogie is valid for the lateral direction also (Fig. 13.120).

Constructive Elements

Wheelsets. For tramways, where the track is always very stiff and therefore rather soft, rubber-cushioned wheels must be used. They also reduce noise (Fig. 13.121).

Low-floor trams do not enable wheelsets but instead need cranked axles, so that the height of the floor can be reduced (Fig. 13.122).

Many wheelsets are hollow-bored. This reduces weight and also provides the ability for ultrasonic testing (Figs. 13.123, 13.124, 13.126).

Bogies

Figure 13.128 shows the so-called three-piece bogie. This is the most common freight bogie type in the world. Several Mio bogies of this type are running outside Europe. There is only a secondary spring according to Fig. 13.127a. The three pieces that give the name to the bogie are the two side frames and the bolster assembly. The wedge (Fig. 13.128) applies load-sensitive damping.

The three-piece bogie has unsuspended side frames, whereas the Y 25 bogie (Fig. 13.129) has individual suspended axle boxes, so-called primary suspension, according to Fig. 13.127b.

The bogie type mainly used in Europe is the so-called Y 25 (Fig. 13.129). The helical springs are responsible for vertical and lateral suspension. Over inclined links in Fig. 13.127a longitudinal friction force is caused in the axle guides which damps the vertical and the lateral movements. This force is load related.

The Leila freight bogie (Fig. 13.130) enables better load distribution by internal bearings and radial steering by the cross arm. The wheelsets are those from Fig. 13.126.

In passenger transport as well interior bearings offer huge benefits with about 30% less bogie weight (Fig. 13.131).

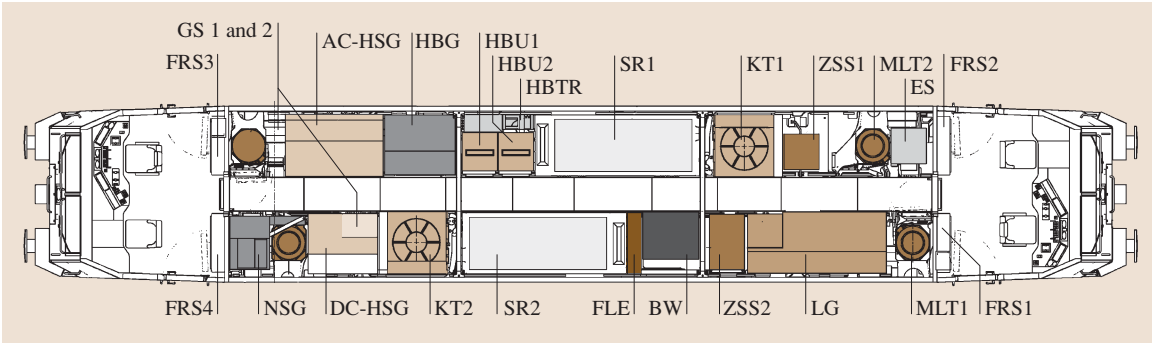

Fig. 13.140 Bombardier transportation (GS 1 and 2 = various nonpermanent equipment (inventory) like track shoes, earthing rod gloves, tools, etc.; AC-HSG = high voltage cell AC; AC = alternative current; HBG = auxiliary power distribution and battery charger; HBU1 and 2 = auxiliary converter; HBTR = auxiliary energy supply transformer; SR1 and 2 = traction converter; KT1 and 2 = cooling tower with blower; ZSS1 and 2 = signal equipment (automatic train control); MLT1 and 2 = traction motor blower; ES = electronic control equipment; NSG, NSGAT = low voltage DC distribution; DC = direct current; DC-HSG high voltage cell DC; FLE = fire detection and extinguishing equipment; BW = braking resistor; LG = compressed air supply and braking equipment; FRS1, 2, 3, 4 = cab rear wall cabinets)

The driving motor is located in the body shell and the momentum is transferred to the axle-hung gearbox via a cardan shaft (Fig. 13.131).

Figure 13.131 shows a bogie for high speed tilting trains with internal bearing wheelsets. With this assembly one obtains huge benefits in terms of weight reduction and good access to the wheels.

The bogie shown in Fig. 13.132 is a very-high-speed bogie for the fastest scheduled passenger service of today.

Low floor trams need bogies with free space in the center (Fig. 13.133).

13.3.4 Superstructures

Principle

With articulated vehicles (Fig. 13.134) normally fewer wheelsets than with standard designs are needed. Fewer wheelsets per car length means less weight, less cost, and less noise, but the maintenance process is more complicated.

The body shells are made either from aluminum intrusion profiles [13.93] or from weldable steel in a sheet and stringer design. This design offers more possibilities to adapt the structure to

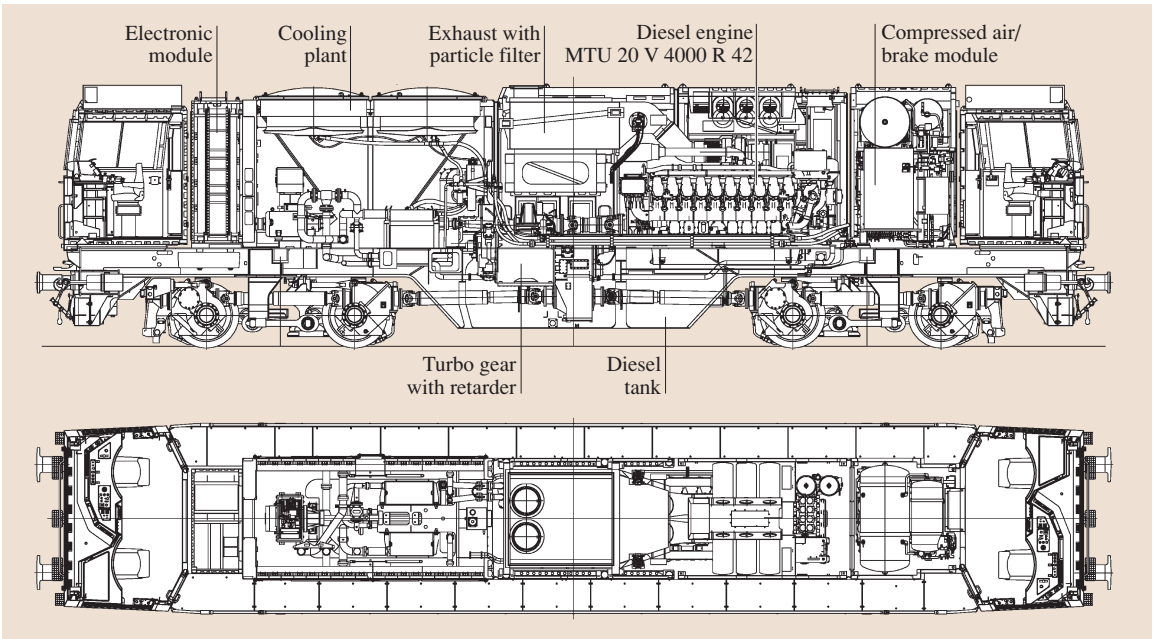

Fig. 13.141 Diesel locomotive MaK 2000-4 BB, axle arrangement BB, track gauge 1435 mm, weight 90 t, length 17 400 mm, height 4259 mm, width 3080 mm, wheel diameter new/worn 1000/920 mm, maximum speed 120 km/h, minimum radius of curve 80 m, starting traction effort 292 kN, diesel engine performance 2700 kW (Vossloh Locomotives GmbH)

the load requirements and enables simpler repairs (Fig. 13.135).

13.3.5 Vehicles

Figure 13.136 shows a freight wagon as an example of a very lightweight construction. The empty wagon weighs only 20% of the fully loaded vehicle. For both situations, loaded and empty, the safety requirements must be fulfilled.

To reduce operation expenses modern metro systems are planned as driverless systems. In this way no space is lost for the driver cabin and all the space may be used by passengers (Fig. 13.137).

Modern tram cars are being built in a modular manner so that capacity can be adapted to local needs. This means that the tram shown in Fig. 13.138 can be lengthened or shortened by further bogie and suspended modules.

Electric locomotives are more powerful than diesel locomotives. To enable free running across borders they are usually equipped to cover all four electric systems in use in Europe (Figs. 13.139 and 13.140). Modern locomotives also fulfill crash concepts, see the section on *Passive Safety* and [13.94].

Diesel locomotives may either have electric or hydrodynamic power transmission. Figure 13.141 shows an example of hydrodynamic transmission.

13.3.6 Coupling Systems

As trains are formed from several vehicles the coupling device between the vehicles is essential. It transmits not only high forces, but also data channels. Coupling and uncoupling must be done very reliable (Figs. 13.142 and 13.143).

Fig. 13.144 Scharfenberg front nose for high-speed trains Talgo 350 (AVE S 102) (Voith Turbo). Technical data: overall length 2985 mm, overall hight 2042 mm, overall width 2866 mm, weight 1020 kg (without coupler), maximum train speed > 350 km/h, aerodynamic loads ± 11 kPa, mechanical carbody interface 10 screws M 16, frontflaps opening angle 64°, material of outside parts, GRP (glassfiber reinforced plastic) sandwich laminate, fire protection according to DIN 5510 S4◀

Coupling

The cone-and-funnel shape of the coupler front face profile ensures a generous gathering range both horizontally and vertically and allows automatic coupling on curves, even with vertical mismatch and very low speed. Minimal force is required for successful coupling.

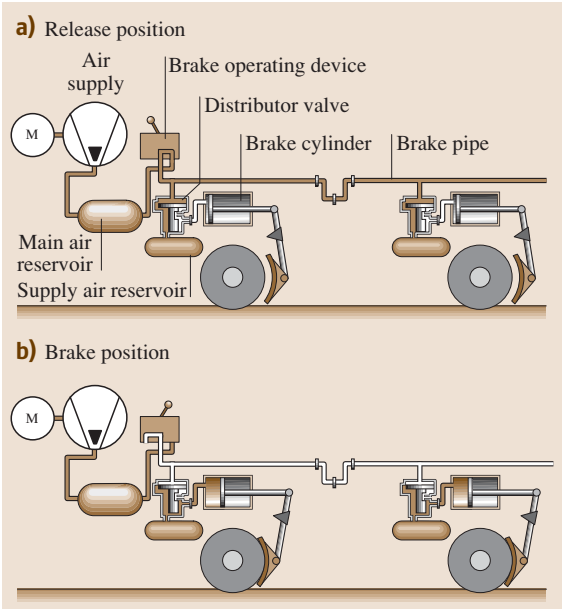

Fig. 13.145a,b Indirect (automatic) train brake. **(a)** Release position, **(b)** brake position

Coupled

The coupler faces and the locking system form a rigid connection both vertically and horizontally. The parallelogram arrangement of the coupler link provides uniform distribution of the draft load. This coupler link design ensures minimal wear and maximum coupler longlivity. The rigid and slack-free connection enables jerk-free acceleration and braking, and offers optimum ride comfort. It also prevents the cars overriding one another in the case of an accident.

Uncoupling

The geometry of the coupler lock enables automatic uncoupling even under traction load. Automatic uncoupling is ensured when misaligned, even on gradient changes. The uncoupling operation is irreversible. SCHAKU's safety philosophy does not allow recoupling, unless the cars have moved apart and the couplers have separated.

13.3.7 Safety

Active Safety Systems/Brakes

Brakes transform the kinetic energy of a train into other forms of energy. There are three principle tasks for a brake: bringing the train to a halt (stop braking), maintaining the speed of the train on a gradient (downhill braking), and preventing a stationary train from moving (park braking).

From the mechanical point of view brakes can be categorized into adhesion-dependent and non-adhesion-

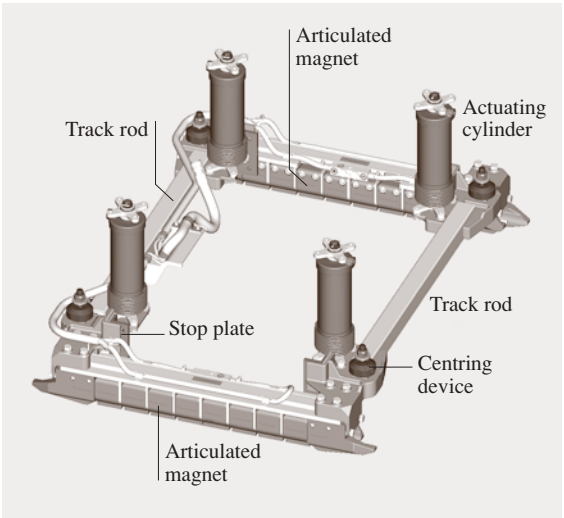

Fig. 13.146 Track brake, speed up to 200 km/h

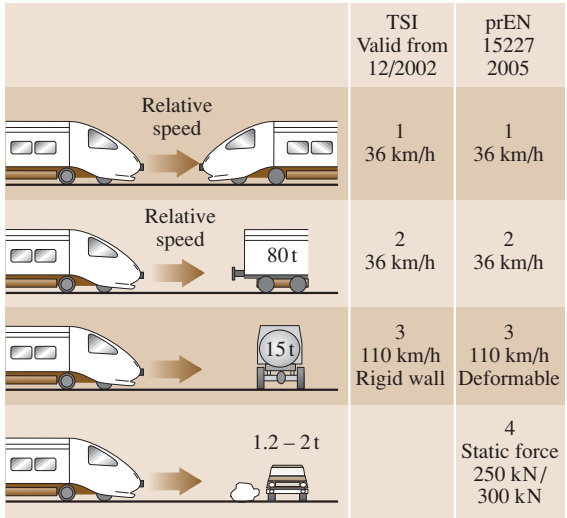

Fig. 13.147 Crash scenarios

dependent brakes. The former type always work via brake moments to wheels, whereas the latter are track brakes or aerodynamic brakes. Adhesion-dependent brakes may be friction brakes (tread or disc brakes) or dynamic brakes (electrodynamic brakes, where a motor works as a generator, or hydrodynamic brakes, which have a hydraulic retarder).

For safety reasons all rail vehicles must be equipped with an indirectly acting pneumatic brake and the brake pipe must run through the entire train (Fig. 13.145).

The indirectly acting brake operates according to the following principle. If the full brake pressure (typically 5 bar) is available and the brake pipe is on that pressure, then the same pressure is in the supply air reservoir and the brake cylinder is released by a mechanical spring in the brake cylinder. If the brake pressure is reduced, for instance, by the brake operating device, then the distributor valve connects the supply air reservoir with the brake cylinder and the brake is applied.

The brake is released by increasing the brake pipe pressure again. Then the distributor valve releases the pressure from the brake cylinder into the atmosphere and simultaneously refills the supply air reservoir with the brake pipe pressure. Because of this indirect or automatic behavior the brakes are also applied if the train breakes apart and the pipe is separated.

Also the brake can be applied from any location along the brake pipe, for instance, by a control van or by an emergency brake device.

The disadvantage of an indirect brake is that it takes a long time for application (up to 30 s for freight trains) and release (up to 60 s for freight trains). Therefore vehicles that must be controlled quickly and precisely, for instance, locomotives, must be equipped with an additional direct brake device.

The brake actuators may operate through one-sided (Fig. 13.128) or two-sided (Fig. 13.129) brake blocks. Because of wear and noise demands, modern brake blocks are no longer made from cast iron but from composite materials.

Higher thermal capacity can be achieved by disk brakes: either wheel disk brakes (Figs. 13.130 or 13.131) or shaft disc brakes (Fig. 13.124).

To reduce the braking distance further rail brakes can be used as they are not dependent on the wheel–rail friction coefficient (Fig. 13.146). If the brake is not used pneumatic cylinders lift the brake to avoid contact because of track irregularities. The magnets are excited by direct current from batteries. The friction force between the magnet and the rail because of the magnetic forces cause the brake force.

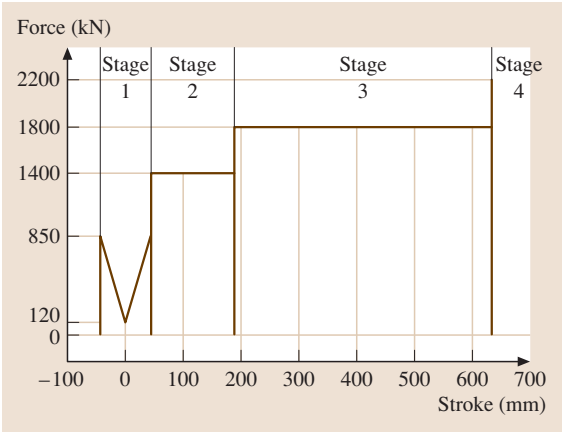

Fig. 13.148 Energy absorption of the coupler from Fig. 13.143. Overall length 2345 mm, telescopic stroke 200 mm, weight 960 kg, vertical swing ±6°, horizontal swing ±20°, tensile strength 850 kN (braking strength 1000 kN), compressive strength 1400 kN (breaking strength 2000 kN), minimum coupling speed 0.6 km/h, admissible impact speed allowing buffer to regenerate: 5 km/h, admissible impact speed before coupler tear-off: 20 km/h. Energy absorption capacity. Stage 1: friction spring 120–850 kN, 44 mm stroke; Stage 2: collapsible tube 1400 kN, 145 mm stroke; Stage 3: collapsible tube 1800 kN, 445 mm stroke; Stage 4: shear-off elements 2200 kN; total energy absorption 1025 kJ

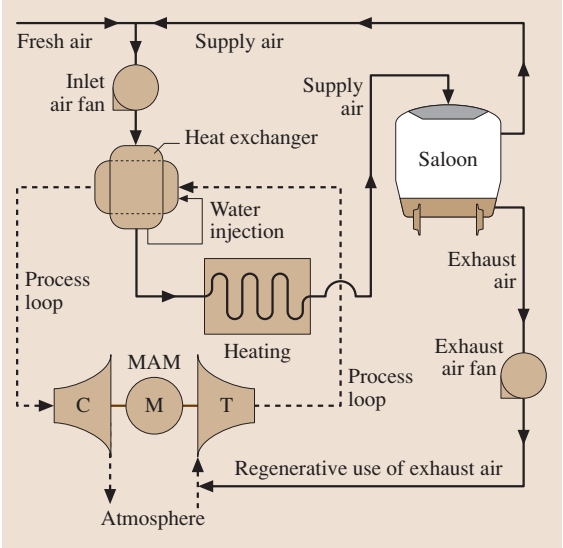

Fig. 13.149 Air cycle concept (Liebherr) (C = compressor; M = motor, T = turbine, MAM = motorized air cycle machine)

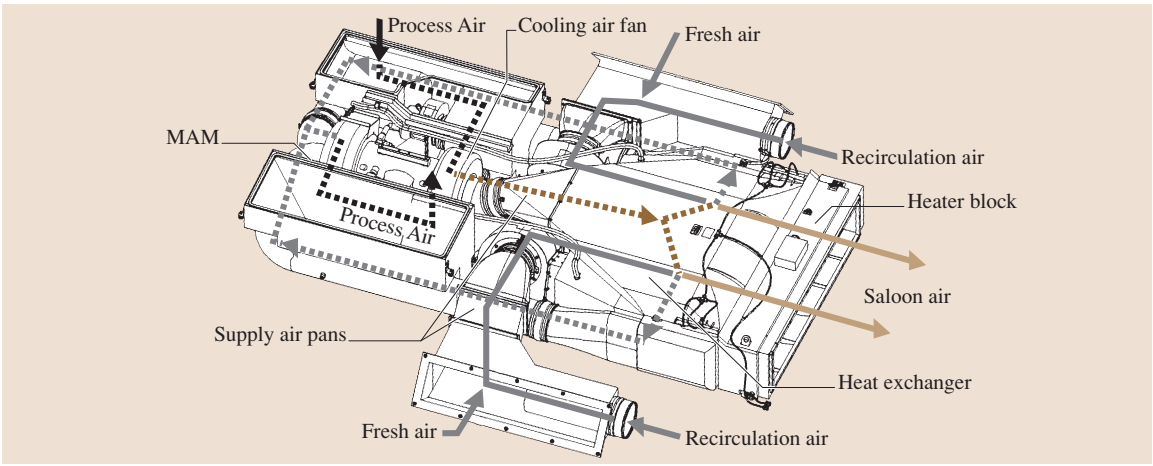

Fig. 13.150 Components and air flow (Liebherr). Roof-mounted air-conditioning unit for high-speed trains, weight 550 kg

For trams the lifting device can be avoided because of the lower speeds (Fig. 13.133).

Passive Safety

Though the active safety of railway systems is very high due to the implementation of signals, brakes, and train control systems [13.95] collisions cannot be totally avoided. Therefore it makes sense to reduce the potential human factor through the use of safety devices.

For various crash scenarios (Fig. 13.147) one must ensure that no severe injuries occur to passengers and staff.

Crash Scenario:

- Scenario 1: collision between two identical trains (single-unit train sets or defined formation) at a relative speed of 36 km/h.
- Scenario 2: collision between a train (single-units train sets or defined formation) and a railway vehicle equipped with side buffers at a speed of 36 km/h. The railway vehicle shall be a four-axle freight wagon with a mass of 80 t.
- Scenario 3: collision at a speed of 110 km/h, on a level crossing, with an obstacle equivalent to a 15 t specially defined lorry.
- Scenario 4: collision with a small or low obstacle such as a car or animal, which shall be addressed by defining the characteristics of an obstacle deflector.

To fulfill these scenarios a certain energy-absorbing capacity must be achieved by the couplers and the body shells. Figure 13.148 shows an example of energy absorption.

13.3.8 Air Conditioning

For high-speed rail vehicles closed body shells with fixed windows are essential for safety reasons. Air conditioning is therefore a must. For environmental reasons air is also used for cooling purposes (Figs. 13.149 and 13.150).

Process Air Loop. In the cooling circuit, the process air is first expanded in the motorized air cycle machine (MAM), and thus cooled. The cold process air passes through the downstream heat exchanger to chill the air supply to the passenger saloon. Subsequently, the now heated process air is taken in by the turbocompressor and released to the ambient.

The cooling process is controlled by the air cycle machine speed. The cooling power is thus infinitely variable between 0 and 100%.

Supply Air Loop. The supply air is a mixture of ambient fresh air and recirculated air from the vehicle. The supply air fan delivers the supply air through a supply air filter to the heat exchanger, where the required temperature reduction is performed in cooling mode.

The conditioned supply air is passed through an air silencer to the passenger compartment. In heating mode, the MAM is turned off so that the cooling process is deactivated. Controlled operation of the main heater adds the required amount of heat to the air flow.

To balance the air flow to the saloon, the equivalent amount of air to the fresh air quantity has to be exhausted. The cooling energy contained in the exhaust air will be used regeneratively in the process loop to improve the system's efficiency.

13.4 Aerospace Engineering

Aerospace engineering is a branch of engineering that deals with the design, construction, and operation of aerospace vehicles.

13.4.1 Aerospace Industry

The aerospace industry is a collection of organizations involved in research, design, construction, test, and operation of aerospace vehicles. In the USA, the aerospace industry consists of 20 prime contractors, 10 major airlines, a large government-supported research agency, and thousands of smaller companies that supply special components to these prime contractors. The total employment in the industry varies somewhat with changing business conditions, but in recent years has averaged about 2.5 million people, of whom approximately 75 000 are employed as engineers. The aerospace industries in developed countries such as Russia, Japan, and the European countries are not quite as large as that of the USA in terms of number of employees, but are similar in nearly every respect. Aerospace industries are growing rapidly in populous countries such as China and India.

Aerospace Industry Product Classifications

The products of the aerospace industry are many and varied, meeting a number of mission requirements. The broadest product classifications are related to the customer purchasing the product, giving rise to the classification into civil and military products [13.96]. More specific product classifications are derived from the type of aerospace vehicle and the particular use to which it is put. The section is organized in this manner.

13.4.2 Aircraft

The term *aircraft* is an all-inclusive term for any form of craft designed for navigation in the air. In the years since the first actual man-carrying flight in a hot-air balloon in the late 1700s, there have been a number of types of aircraft that have provided the means for aerial navigation. A brief recap includes the hot-air balloon ascension of de Rozier and d'Arlandes in 1783, the hydrogen balloon flight of J. A. C. Charles and M. N. Robert in 1783, and the successful steam-engine-powered airship (balloon) of Giffard in 1852. The German Otto Lilienthal developed a man-carrying glider that made over 2000 glides before suffering a fatal crash in 1896. As has been well documented, it was the Wright brothers, Orville and Wilbur, who made the first controlled powered flights of an airplane in 1903. Progress in aircraft design was slow in the first few years after the Wright flights, but by the start of World War I (WWI), many flying machines of various types and configurations had been successfully built and flown. During WWI, military requirements gave rise to the development of numerous types of aircraft with very specialized capabilities, which were produced in their thousands. Following the war, the use of aircraft for the transportation of passengers came into widespread use, with the establishment of airline companies and air routes, first between major European cities, but later in America and other parts of world as well. In the period between World War I and World War II, specialized aircraft were used to set nonstop distance records between continents, while other specialized aircraft set records for speed and altitude. World War II saw the introduction of new technology in aircraft design with the advent of practical helicopters, jet engines, rocket propulsion systems, and guided missiles. Following World War II, there was significant growth in private, recreational flying, expansion of the international commercial air transportation system, as well as continuing development of experimental aircraft that flew higher, faster, and farther than previous aircraft. With the creation of the National Aeronautics and Space Administration (NASA) in 1958, a variety of unique aircraft and spacecraft have been designed to meet very specific mission objectives laid down by that Agency. In recent years, there has been increasing military interest in unmanned combat air vehicles (UCAVs).

Aircraft Types

The two major categories of aircraft types are lighter than air (LTA) and heavier than air (HTA). A lighter than air craft is one that rises aloft by making use of Archimedes' principle, that is, by displacing a weight of air that is greater than the weight of the craft itself, and so creating a buoyant force. A heavier-than-air aircraft is one that rises aloft due to Bernoulli's principle acting on the aircraft's lifting surfaces, creating suctions on the upper surface and pressures on the lower surface relative to the ambient air pressure [13.97–127].

The design and operation of civil aircraft in the USA is subject to numerous regulations promulgated by the Federal Aviation Administration (FAA) of the Department of Transportation. Table 13.15 presents a summary of the various types of FAA regulations.

Table 13.15 Summary of Federal Aviation Regulatory (FAR) categories

Regulatory category	FAR part
Certification procedures for products and parts	21
Airworthiness standards, normal, utility, acrobatic, and commuters	23
Airworthiness standards, transport category airplanes	25
Airworthiness standards, normal category rotorcraft	27
Airworthiness standards, transport category rotorcraft	29
Airworthiness standards, manned free balloons	31
Airworthiness standards, aircraft engines	33
Airworthiness standards, propellers	35
Noise standards, aircraft type and airworthiness standards	36
Airworthiness directives	39
Maintenance, preventive maintenance, rebuilding, and alteration	43
Identification and registration marking	45
Aircraft registration	47
General operating and flight rules	91
Special air-traffic rules and airport traffic patterns	93
IFR (instrument flight rules) altitudes	95
Standard instrument approach procedures	97
Ultralight vehicles	103
Certification and operation, domestic, flag, and supplemental air carriers, and commercial operators of large aircraft	121
Certification and operation, aiplanes having seating capacity of 20 or more passengers, or a maximum payload capacity of 6,000 pounds or more	125
Certification and operation of scheduled air carrier helicopters	127
Air taxi operators and commercial operators	135
Agricultural aircraft operations	139

Lighter-Than-Air Aircraft. One can distinguish between the following types of LTA aircraft:

- Hot-air balloon, which consist of a large envelope made of lightweight fabric to contain the hot air, a burner located below the envelope, usually fueled by kerosene, to heat ambient air, causing it to rise into the envelope. A basket hung underneath the burner is provided for the pilot and passengers.
- Light-gas balloon, which is similar in arrangement to a hot-air balloon, but without the burner. The buoyant force is generated by the use of light gasses such as helium in the envelope, which displace the relatively heavier ambient air.
- Blimp or nonrigid airship, which is basically a large gas balloon whose streamlined shape is maintained by internal gas pressure. In addition to the gas envelope, the blimp has a car attached to the lower part of the envelope for the crew and passengers, engines and propellers to develop forward speed, and fins with hinged aft portions for control.
- Rigid airship, a lighter-than-air aircraft with a rigid frame to maintain its shape and provide a volume for the internal placement of light gasbags. The rigid airship also has a car attached to the lower part of the rigid frame for the crew and passengers, engines, propellers, and tail fins similar to the blimp. Rigid airships reached the peak of their development in the mid 1930s, but several spectacular accidents curtailed further development.

Heavier-Than-Air Craft. HTA aircraft can be divided into three main categories.

A *glider* is an aircraft that flies without an engine. The simplest form of a glider is the hang glider, which consists of a wing, a control frame, and a pilot harness. The pilot is zipped into the harness and literally hangs beneath the wing, with his hands on the control bar of the control frame. The wing has an aluminum frame that supports the wing fabric, and internal battens to provide a proper shape to the fabric. Hang gliders are usually launched from a very steep hill or a cliff that affords sufficient altitude for gliding flight. Simple utility gliders which have rigid structural elements similar to an airplane are used primarily for training. These gliders are launched into the air by being towed by a power winch, an automobile, or an airplane. Extremely refined sailplanes, usually made of very lightweight materials and featuring very long thin wings, take advantage of rising air currents, and can soar for a long time and cover distances of hundred of miles in a single flight. A variation of the sailplane is the *motorglider*, basically a sailplane with a small motor and propeller, which is used for take-off and climb to soaring altitude, whereupon the motor is shut off, and is then retracted along with the propeller to revert to the sailplane configuration.

An *airplane* is an air vehicle that incorporates a propulsion system and fixed wings, and is supported by aerodynamic forces acting on the wings. Airplane propulsion systems may be a piston engine driving a propeller, a turbojet engine, or a rocket engine, depending on the required mission. Airplanes range in form from small general aviation aircraft, usually privately owned, with one or two engines, to larger commercially operated air transport aircraft that can carry from 20 to upwards of 500 passengers and can fly distances from 500 to over 8000 miles nonstop. In addition to these civil aircraft types, there a number of military aircraft types designed for different missions, such as fighter, attack, bomber, reconnaissance, transport, and trainer. A very small class of airplanes, known as experimental research aircraft, usually powered by rocket engines, has been built to obtain flight test data at extremely high speeds and altitudes. The ultimate development in this area is the US Space Shuttle, which is a rocket-powered spacecraft for most of its mission, and an unpowered glider for the approach and landing phase of the flight.

A *helicopter* is an aircraft that is supported by aerodynamic forces generated by long thin blades rotating about a vertical axis. The rotor blades are driven by the helicopter's propulsion system, usually a piston or gas turbine engine. Helicopters range in size from small, two-seat personal utility models to large transport types that can carry up to 40 people. Large heavy-lift helicopters are often used in specialized hauling and construction tasks, where their ability to remain airborne over a fixed spot for extended periods of time is unique. Helicopters have also been used in several military applications such as air–sea rescue, medical evacuation, as battlefield gunships, and for special-operations troop transport. Recent developments in helicopter technology have led to hybrid helicopter craft called the tilt rotor. In this machine, there are two rotors to provide the vertical forces required for take-off and landing, but as the name implies, these rotors may be tilted to varying degrees until they are aligned in the direction of flight, acting like the propellers on a conventional airplane. The tilt rotor has small wings to provide the aerodynamic lift required during cruise flight, during which the rotors are used to provide forward thrust.

13.4.3 Spacecraft

Spacecraft fall into two major categories, unmanned, with no humans aboard, and manned, with humans aboard. Examples of unmanned spacecraft include civil communication satellites, military reconnaissance satellites, and scientific probes that gather information on our solar system. Examples of unmanned spacecraft include the Echostar and Eutelsat civil communication satellites, the Aquila and Cosmos military reconnaissance satellites, and the Hubble Space Telescope and Mars Global Surveyor scientific probes. Examples of manned spacecraft include the Vostok, Soyuz, Mir, Mercury, Gemini, Apollo, and Space Shuttle vehicles.

13.4.4 Definitions

The following are some important definitions related to a good understanding of aerospace engineering.

Units

Although there has been a policy in the USA in recent years to convert to the international system (SI) of units, the US aerospace industry continues to use English units in its work. This publication will use English units as primary, since most American engineers are familiar with this terminology. A list of conversion factors between SI and English units is given in Table 13.16.

Table 13.16 Conversion factors between SI and English units

Conversion factors	
Mass	$1.00\,\text{kg} = 0.06853\,\text{slug}$ $1.00\,\text{slug} = 14.592\,\text{kg}$ At the surface of the Earth, an object with a mass of 1.00 kg weighs 9.8 N or 2.205 lb, and an object with a mass of 1.00 slug weighs 32.17 lb or 143.1 N
Length	$1.00\,\text{m} = 3.2808\,\text{ft}$ $1.00\,\text{ft} = 0.3048\,\text{m} = 30.48\,\text{cm}$
Force	$1.00\,\text{N} = 0.2248\,\text{lb}$ $1.00\,\text{lb} = 4.4482\,\text{N}$
Temperature	$1.00\,\text{K} = 1.8\,^\circ\text{Ra}$ $\quad ^\circ\text{Ra} = ^\circ\text{F} + 460$ $1.0\,^\circ\text{Ra} = 0.5556\,\text{K}$ $\quad \text{K} = ^\circ\text{C} + 273$
Pressure	$1.00\,\text{N/m}^2 = 1.4504 \times 10^{-4}\,\text{lb/in}^2 = 2.0886 \times 10^{-2}\,\text{lb/ft}^2$ $1.00\,\text{lb/in}^2 = 6.8947 \times 10^3\,\text{N/m}^2$ $1.00\,\text{lb/ft}^2 = 47.88\,\text{N/m}^2$
Velocity	$1.00\,\text{m/s} = 3.2808\,\text{ft/s} = 2.2369\,\text{mi/h}$ $1.00\,\text{ft/s} = 0.6818\,\text{mi/h} = 0.3048\,\text{m/s}$
Density	$1.00\,\text{kg/m}^3 = 1.9404 \times 10^{-3}\,\text{slug/ft}^3$ $1.00\,\text{slug/ft}^3 = 515.36\,\text{kg m}^3$
Viscosity	$1.00\,\frac{\text{kg}}{\text{m s}} = 20.886 \times 10^2\,\frac{\text{lb s}}{\text{ft}^2}$ $1.00\,\frac{\text{lb s}}{\text{ft}^2} = 47.879\,\frac{\text{kg}}{\text{m s}}$
Specific heat	$1.00\,\frac{\text{N m}}{\text{kg K}} = 1.00\,\frac{\text{J}}{\text{kg K}} = 2.3928\,\frac{\text{BTU}}{\text{lb}_\text{m}\,^\circ\text{Ra}} = 5.9895\,\frac{\text{ft lb}_\text{f}}{\text{slug}\,^\circ\text{Ra}}$ $1.00\,\frac{\text{ft lb}}{\text{slug}\,^\circ\text{Ra}} = 1.6728 \times 10^{-1}\,\frac{\text{N m}}{\text{kg K}} = 1.6728 \times 10^{-1}\,\frac{\text{J}}{\text{kg K}}$
Frequently used equivalents	
1 bhp	550 ft lb/s = 33 000 ft lb/min
1 knot (kn) (i. e., nautical mile per hour)	1.152 statute mile per hour
1 knot (kn) (nautical mile per hour)	1.69 ft/s
1 statute mile per hour	0.868 knot (nautical miles per hour)
1 statute mile per hour	1.467 ft/s
1 ft/s	0.682 statute mile per hour
1 ft/s	0.592 knot (nautical miles per hour)
1 kilometer	0.621 statute mile
1 kilometer	0.539 nautical mile
1 statute mile	1.609 kilometer
1 nautical mile	1.854 kilometer
1 radian	57.3 degrees
Note that the preceeding values are *equivalents*. The conversion factors are the reciprocals.	
Frequently used constants	
γ	1.4 (air)
Gas constant R (air)	287.05 N m/(kg K) = 1718 ft lb/(slug °Ra)
Specific heat c_p (air)	1004.7 N m/(kg K) (J/(kg K)) = 6006 ft lb/(slug °Ra)
Gravitational constant at sea level g_0	$9.8\,\text{m/s}^2 = 32.17\,\text{ft/s}^2$
Radius of the Earth r_0	$6.378 \times 10^6\,\text{m} = 20.92 \times 10^6\,\text{ft}$

Flight Speed Terminology

One of the key performance parameters for an airplane is its maximum level-flight speed. For a variety of technical and economic reasons, various airplanes are designed to operate at speeds most appropriate to their design missions. Modern airplanes operate at speeds

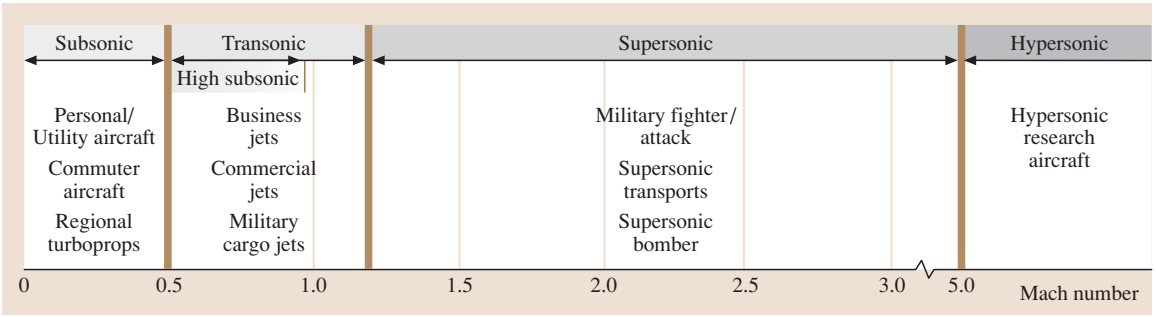

Fig. 13.151 Flight speed terminology

ranging from a low of around 60 kn to highs of around 1450 kn. Over such a wide range of flight speeds, the characteristics of the airflow around the airplane change dramatically. These changes, associated with the compressible nature of air, are directly related to the flight Mach number, defined as the flight speed divided by the speed of sound in the ambient air in which the airplane is flying. This situation has given rise to some general terms to describe airplane flight speeds in terms of Mach number, as shown in Fig. 13.151. Also shown are the types of airplanes having maximum level-flight speeds within the various speed regimes.

Standard Atmosphere

For design and performance calculations, it is appropriate to establish a standard set of characteristics for the Earth's atmosphere in which aircraft operate. The US standard atmosphere is a widely used set whose essential characteristics, that is, the temperature, pressure, density, and viscosity, as a function of altitude have been derived using

$$p = \rho RT\,,$$
$$\mathrm{d}p = -\rho g\,\mathrm{d}h\,,$$

where

p = pressure in lb/ft^2,
ρ = density in slug/ft,
T = absolute temperature in °Ra,
R = gas constant (1718 ft lb/(slug °Ra)) for air,
g = gravitational constant (32.17 ft/s^2),
H = height above sea level in ft.

With these equations, only a defined variation of T with altitude is required to establish the standard atmosphere. The defined variation, based on experimental data, is shown in Fig. 13.152.

Once the temperature variation with altitude is defined, the characteristics of the standard atmosphere can be calculated directly.

The characteristics of the US standard atmosphere are tabulated in Table 13.17. From sea level to 36 089 ft the temperature decreases linearly with altitude. This region is called the troposphere. Above 36 089 ft the temperature is constant up to 65 617 ft in the region called the stratosphere. Above 65 617 ft the temperature increases linearly to 100 000 ft, the upper level of interest for current or foreseeable aircraft.

Although the concept of geometric altitude, the altitude above sea level as determined by a tape measure, is most familiar, of prime importance for aircraft design and performance calculations is the pressure altitude, i.e., the geometric altitude on a standard day for which the pressure is equal to the ambient atmospheric pres-

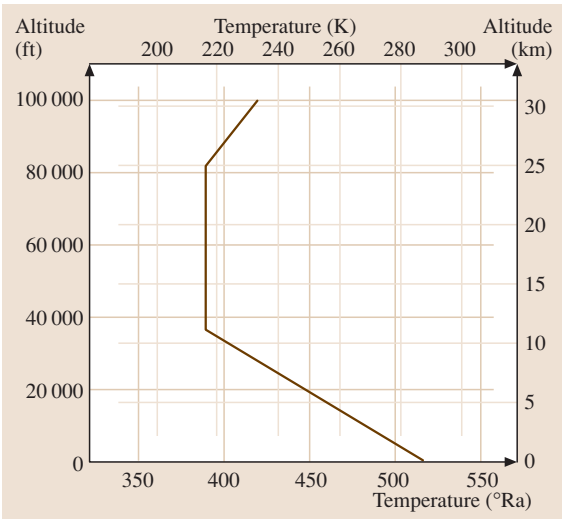

Fig. 13.152 Temperature variation with altitude in the US standard atmosphere

Table 13.17 Characteristics of the US standard atmosphere

Altitude	Temperature		Pressure	Density	Density ratio	Kinematic viscosity	q/M^2	Sonic velocity

sure. Aircraft altimeters are pressure gages calibrated to read pressure altitude. Also important is the density altitude, the geometric altitude on a standard day for which the density is equal to the ambient air density. Pressure altitude, density altitude, and temperature are related through the equation of state $p = \rho RT$.

It should be noted that another standard atmosphere has been defined by the International Civil Aviation Organization (ICAO). The ICAO standard atmosphere and the US standard atmosphere are identical up to 65 617 ft. Beyond 65 617 ft the ICAO standard atmosphere maintains a constant temperature up to 82 300 ft, while the US standard atmosphere reflects an increasing temperature with a constant gradient to beyond 100 000 ft.

Axis Systems

The airplane design process, with respect to achieving performance objectives of altitude, speed, range, payload, and take-off and landing distance requires analysis of the airplane in motion. The Newtonian laws of motion state that the summation of all external forces in any direction must equal the time rate of change of momentum, and that the summation of all of the moments of the external forces must equal the time rate of change of moment of momentum, all measured with respect to axes fixed in space. If the motion of the airplane is described relative to axes fixed in space, the mathematics becomes extremely unwieldy, as the moments and products of inertia vary from instant to instant. To overcome this difficulty, use is made of moving or Eulerian axes that coincide in some particular manner from instant to instant with a definite set of axes fixed with respect to the airplane. The most common choice is to select a set of mutually perpendicular axes defined within the airplane as shown in Fig. 13.153, with their origin at the airplane center of gravity (c.g.). The airplane's motion

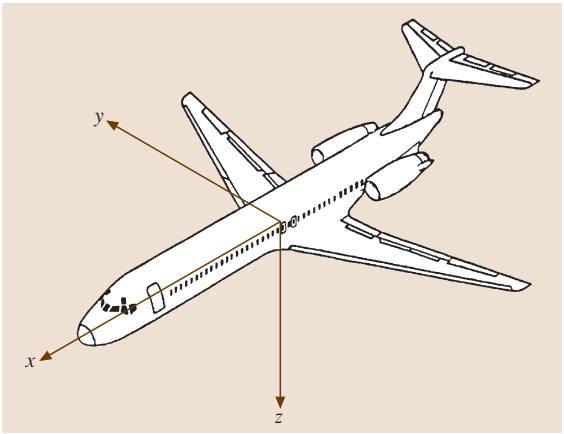

Fig. 13.153 Airplane axis system

in space is defined by six components of velocity. This is a right-hand axis system with the positive x- and z-axes in the plane of symmetry and with the x-axis out the nose of the airplane pointing along the flight path. This is called a wind axis system, since the x-axis always coincides with the airplane's velocity vector. The z-axis is perpendicular to the x-axis, positive downward, and the positive y-axis is out the right hand wing, perpendicular to the plane of symmetry.

For most aircraft design analyses, the airplane is considered to be a rigid body with six degrees of freedom: three linear velocity components along these axes, and three angular velocity components around these axes. The angular motion around the y-axis is called pitch; the angular motion about the x-axis is called roll; and the angular motion about the z-axis is called yaw. Nearly all of the airplane motions encountered in aircraft preliminary design and performance are in the plane of symmetry. The other three components of the airplane's motion lie outside the plane of symmetry. The symmetric degrees of freedom are referred to as the longitudinal motion, and the asymmetric degrees of freedom are referred to as the lateral-directional motion.

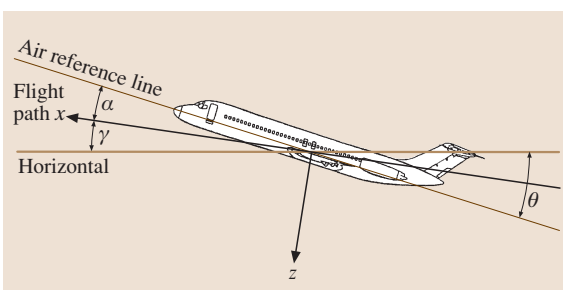

Fig. 13.154 Axis system in the plane of symmetry

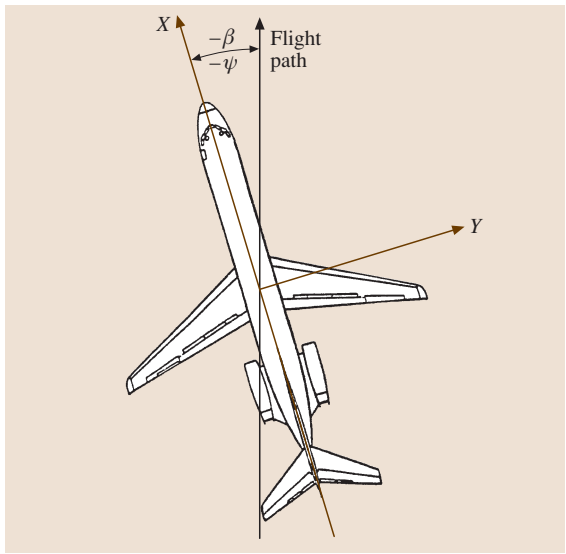

Fig. 13.155 Axis system in asymmetric flight

In the plane of symmetry (Fig. 13.154) the inclination of the flight path to the horizontal is the flight path angle γ and the angle between the flight path and the airplane reference line is the angle of attack α. The angle between the airplane reference line and the horizontal is the airplane's pitch angle θ.

When the flight path does not lie in the plane of symmetry (Fig. 13.155) the angle between the flight path and the airplane's centerline is the yaw angle ψ. For straight flight in this situation, the yaw angle is equal in magnitude but opposite in sign to the sideslip angle β. In roll about the flight path, the angle between the y-axis and the horizontal is the roll or bank angle. A summary of all of the angles involved in flight performance and flight mechanics calculations is presented in Table 13.18.

The other three components of the airplane's motion lie outside the plane of symmetry. The symmetric degrees of freedom are referred to as the longitudinal motion, and the asymmetric degrees of freedom are referred to as the lateral-directional motion. In the plane of symmetry (Fig. 13.154) the inclination of the flight path to the horizontal is the flight path angle γ and the angle between the flight path and the airplane reference line is the angle of attack α.

The angle between the airplane reference line and the horizontal is the airplane's pitch angle θ. When the flight path does not lie in the plane of symmetry

Table 13.18 Summary and definition of the angles involved in flight performance and flight mechanics calculations

In the plane of symmetry		
γ	Flight path angle	Angle between the horizon and the velocity vector
θ	Pitch angle	Angle between the airplane reference line and the horizon
α	Angle of attack	Angle between the airplane reference line and the velocity vector
In asymmetric flight		
β	Angle of sideslip	Angle between the airplane centerline and the velocity vector
$\varnothing$	Angle of roll	Angle between the airplane's y-axis and the horizon

(Fig. 13.155) the angle between the flight path and the airplane's centerline is the yaw angle ψ. For straight flight in this situation, the yaw angle is equal in magnitude but opposite in sign to the sideslip angle β. In roll about the flight path, the angle between the y-axis and the horizontal is the roll or bank angle. A summary of all of the angles involved in flight performance and flight mechanics calculations are presented in Table 13.18.

Aerodynamic Forces and Moments

The aerodynamic forces acting on an aircraft consist of two types: pressure forces, which act normal to the aircraft surface, and viscous or shear forces, which act tangentially to the aircraft surface.

The physical parameters that govern the aerodynamic forces and moments acting on an aircraft have been developed through a method called dimensional analysis. This procedure is treated in detail in many textbooks on aerodynamics, and will only be summarized here. Dimensional analysis considers the dimensions or units of the physical quantities involved in the development of aerodynamic forces and moments, and divides them into two groups: fundamental and derived. The fundamental units are mass, length, and time, and all physical quantities have dimensions that are derived from a combination of these three fundamental units. Equations that express physical relationships must have dimensional homogeneity; that is, each term in the equation must have the same units in order for the equation to have physical significance. The broad physical relationships are postulated by logic, reason, or perhaps some experimental evidence, and then the specific relationships are derived by dimensional analysis. For aerodynamic forces and moments acting on an aircraft in the plane of symmetry the broad physical relationships are postulated as

$$F_{\text{aero}},\ M_{\text{aero}} = f(\text{shape, size, altitude, velocity, fluid properties}) .$$

The specific relationship for aerodynamic forces, derived from dimensional analysis, is

$$F_{\text{aero}} = K\rho V^2 L^2 f\left(\alpha, \frac{\rho VL}{\mu}, \frac{V}{a}\right) ,$$

where

K	is a constant of proportionality or dimensionless coefficient,
V	is the velocity of the aircraft,
L	is an arbitrary characteristic length,
ρ	is the air density,
μ	is the coefficient of viscosity for air,
α	is the altitude of the airplane with respect to the flight path,
$\rho VL/\mu$	is a dimensionless quantity called the Reynolds number Re,
a	is the speed of sound in air,
V/a	is a dimensionless quantity called the Mach number Ma.

The aerodynamic forces and moments acting on the airplane in the plane of symmetry are shown in Fig. 13.156. The resultant of the aerodynamic forces is resolved into the lift component, acting perpendicular to the flight path or velocity vector, and the drag component, acting parallel to velocity vector. The lift and

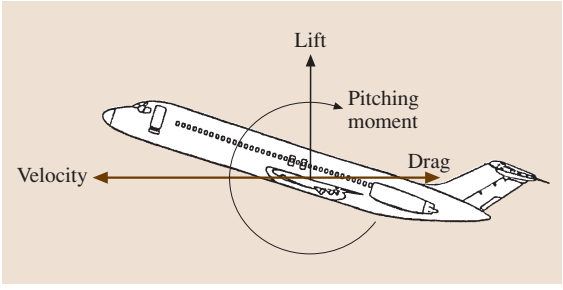

Fig. 13.156 Aerodynamic forces and moments in the plane of symmetry

drag components are defined as acting at the airplane center of gravity, while all of the moments acting on the airplane are lumped into one couple acting around the airplane center of gravity. The equations for lift and drag of the airplane may be written as

$$\text{lift} = C_L \frac{\rho}{2} V^2 S \,,$$

$$\text{drag} = C_D \frac{\rho}{2} V^2 S \,,$$

where C_L and C_D are the lift and drag coefficients, respectively, and the area term in the equation is arbitrarily taken to be the wing area, S. To make the equation for the aerodynamic moment about the center of gravity dimensionally correct, the length of the wing mean chord, c, the mean distance from the leading edge to the trailing edge at the wing is arbitrarily selected. The moment equation in the plane of symmetry is

$$\text{Moment} = M_{cg} = C_m \frac{\rho}{2} V^2 S c \,,$$

where C_m is defined as the pitching moment coefficient. As noted, while the primary relationship between the physical quantities involved in the development of aerodynamic forces and moments is expressed in terms of the dimensionless coefficients, these coefficients are functions of both the Reynolds and the Mach number. The aerodynamic forces and moments acting on the airplane in asymmetric flight are shown in Fig. 13.157. The side force acts normal to the airplane center line, while the aerodynamic moments acting around the z-axis through the c.g. are lumped together and called the yawing moment. In addition, the aerodynamic moments acting around the x-axis are lumped together and are called the rolling moment.

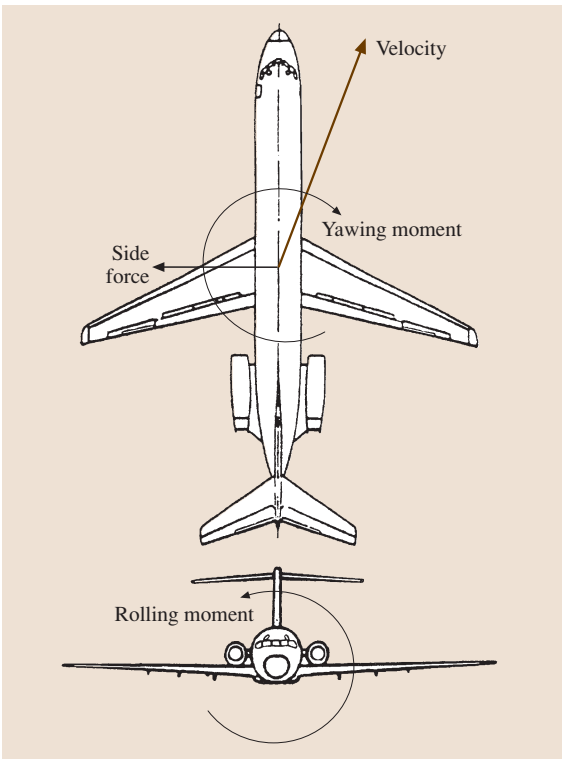

Fig. 13.157 Aerodynamic forces and moments in asymmetric flight

The equations for side force, yawing moment, and rolling moment are

$$\text{side force} = C_\gamma \frac{\rho}{2} V^2 S \,,$$

$$\text{yawing moment} = C_n \frac{\rho}{2} V^2 S b \,,$$

$$\text{side force} = C_l \frac{\rho}{2} V^2 S b \,,$$

where C_γ, C_n, and C_l are the side force, yawing moment, and rolling moment coefficients, respectively, and b is the airplane wing span, selected as more appropriate than the wing mean chord for use with the asymmetric moment coefficients.

In summary, then, there are three defined aerodynamic forces acting along the airplane axes, and three aerodynamic moments acting around the airplane axes (Table 13.19).

Relative Wind

Up to now, the aerodynamic forces acting on the airplane have been defined in terms of the airplane velocity vector. It should be noted that the aerodynamic forces and moments depend only on the relative velocity between the airplane and the air that it is flying through. The same aerodynamic forces are generated if the airplane moves through the air with a velocity, V, or if the airplane is held fixed in space, as in a wind tunnel, and the air moves past the airplane, coming from the direction of the relative wind, opposite to the flight path, with a velocity, V, equal and opposite to the actual velocity, as shown in Fig. 13.158.

Table 13.19 Aerodynamic forces and moments acting along the airplane axis

Axis	Force along	Moment around
x	Drag	Rolling moment
y	Side force	Pitching moment
z	Lift	Yawing moment

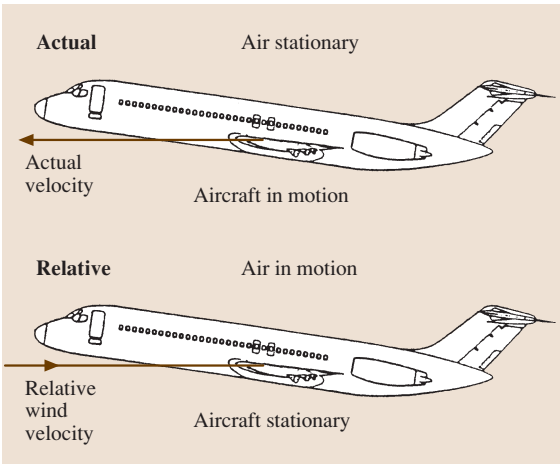

Fig. 13.158 Relative velocity and relative wind

Dynamic Pressure

In the discussion of aerodynamic forces and moments, the expressions for all of them show a dependency on the quantity $(\rho V^2)/2$. This quantity, which appears throughout aerodynamic theory, is equal to the kinetic energy of a unit volume of air, and is defined as the dynamic pressure:

$$q = \frac{\rho}{2} V^2 \, .$$

Another form of the equation for dynamic pressure which is especially useful in aircraft design and performance calculations is

$$q = \frac{\gamma}{2} p \mathrm{Ma}^2 \, ,$$

where

γ is the ratio of specific heats for air, equal to 1.4,
p is the ambient pressure, and
Mais the flight Mach number.

Airspeed Terminology

Since the very early days, airplanes have been equipped with airspeed indicators, which are operated by the pressure difference between two pressures sensed by devices mounted on the airplane. One pressure used in airspeed measurement is the impact or total pressure, usually sensed by a Pitot or total head tube (Fig. 13.159a), which has an open hole at the front end to capture the total pressure. The other pressure used is the static pressure, that is, the ambient pressure at the operating altitude of the airplane, usually sensed by small flush holes located on a static tube (Fig. 13.159b). On many airplanes, the Pitot tube and the static tube are integrated into one device called the Pitot-static tube (Fig. 13.159c). On larger aircraft, the static pressure is sensed by flush holes in the fuselage called static ports

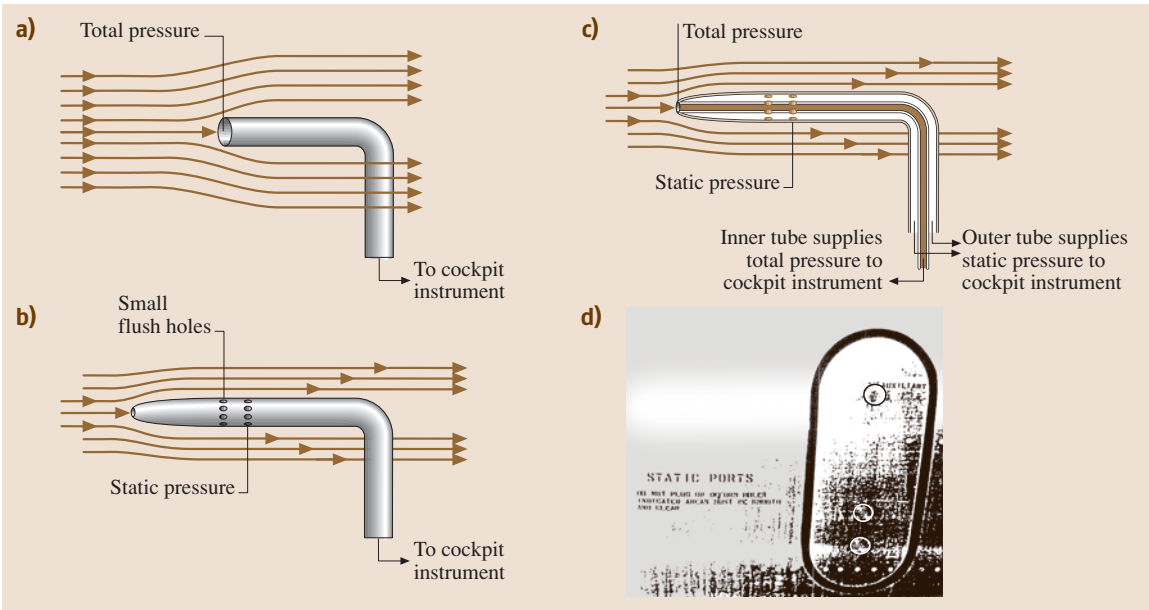

Fig. 13.159a–d Airspeed sensors

(Fig. 13.159d), which are located in an area where the static pressure is equal to the ambient static pressure. Airspeed indicators are calibrated to read airspeed as a function of the difference between total and static pressure. In order to develop some meaningful definitions of airspeed over a range of aircraft operational altitudes, some specific terminology has been adopted as follows.

Indicated Airspeed (IAS). This is the airspeed registered on the cockpit instrument, corrected for any instrument calibration errors.

Calibrated Airspeed (CAS). This is the indicated airspeed reading corrected for static source position errors. Usually it is not possible to locate a Pitot–static tube or a static port in a place that senses the exact ambient static pressure, so corrections for this so-called position error are made. Calibrated airspeed refers to the fact that airspeed indicators are calibrated in airspeed units, usually knots, through the difference between total and static pressure at sea-level standard day conditions by the equation

$$V_{\text{cal}} = \sqrt{\frac{2(P_{\text{total}} - P_{\text{static}})}{\rho_{\text{sea-level}}}} V_{\text{true}} \,.$$

Equivalent Airspeed (EAS). This is the calibrated airspeed adjusted for what are termed compressibility effects. Equivalent airspeed is a very important parameter in aircraft preliminary design and performance calculations. Equivalent airspeed is defined as

$$V_{\text{EAS}} = \sqrt{\frac{\rho_{\text{ambient}}}{\rho_{\text{sea-level}}}} V_{\text{true}} \,.$$

The idea behind equivalent airspeed is that, for any flight condition, i. e., any combination of true airspeed and ambient density, and therefore dynamic pressure, there is an equivalent airspeed at sea-level standard day conditions that produces the same dynamic pressure. In equation form

$$q = \frac{\rho_{\text{ambient}}}{2} V_{\text{true}}^2 = \frac{\rho_{\text{sea-level}}}{2} V_{\text{EAS}}^2 \,.$$

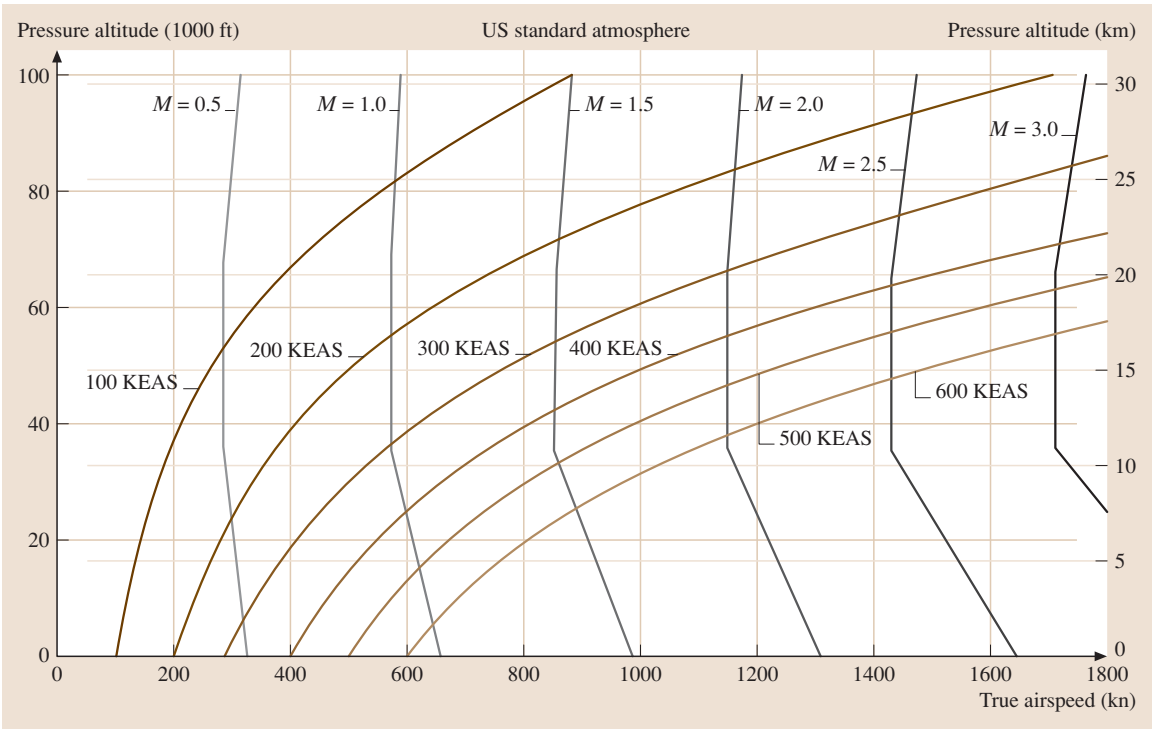

Fig. 13.160 V_{EAS} and V_{true}

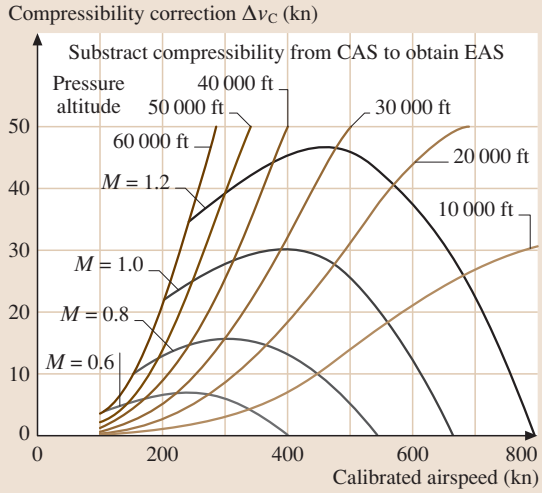

Fig. 13.161 Airspeed compressibility correction

A chart showing the relationship between V_{EAS} and V_{true} for the US standard atmosphere is shown in Fig. 13.160. Equivalent airspeeds are reasonably close to the indicated airspeeds shown by the cockpit instrument.

The difference is the compressibility correction to CAS in order to obtain EAS. The compressibility increment, ΔV_C, is a function of both the Mach number and altitude, as shown in Fig. 13.161. This correction arises as follows.

For a compressible fluid such as air,

$$(P_{total} - P_{static}) = \frac{\gamma}{2} p \mathrm{Ma}^2 \times \left(1 + \frac{\mathrm{Ma}^2}{4} + \frac{\mathrm{Ma}^4}{40} + \frac{\mathrm{Ma}^6}{1600} + \ldots\right) .$$

Since CAS is directly related to $(P_{total} - P_{static})$, and EAS is directly related to the dynamic pressure q, the correction is the Mach number series in the brackets.

True Airspeed (TAS). The true airspeed is the actual airspeed of the airplane at ambient conditions in the atmosphere, and may be obtained by converting or correcting equivalent airspeed as follows

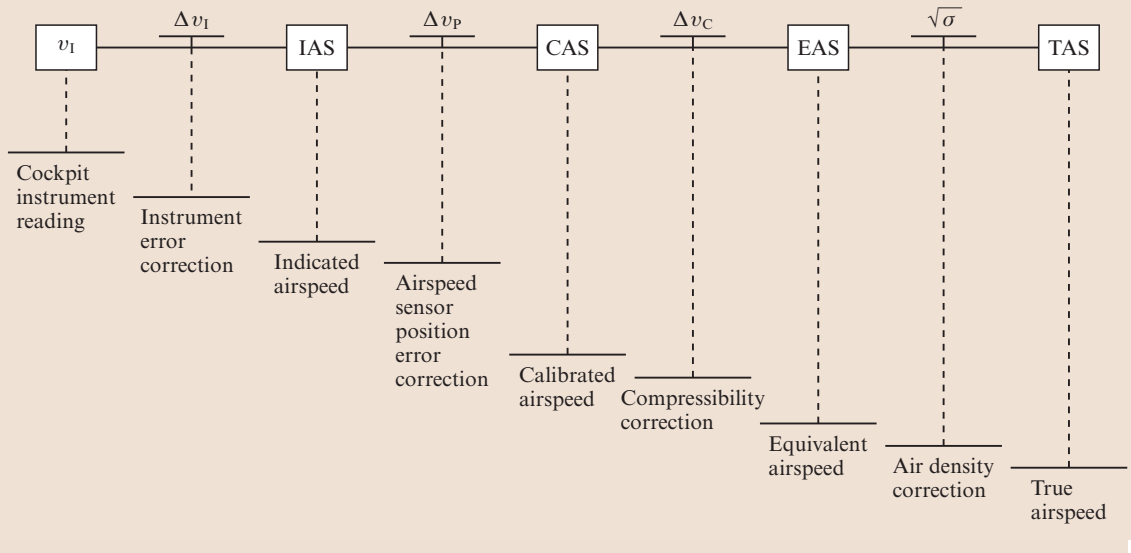
$$V_{true} = V_{EAS} \sqrt{\frac{\rho_{sea\text{-}level}}{\rho_{ambient}}} .$$

A summary of the airspeed indicator correction sequence is presented in Table 13.20.

13.4.5 Flight Performance Equations

In order to examine the major characteristics of the airplane's performance, equations involving the summation of forces and moments in the plane of symmetry

Table 13.20 Airspeed indicator correction sequence



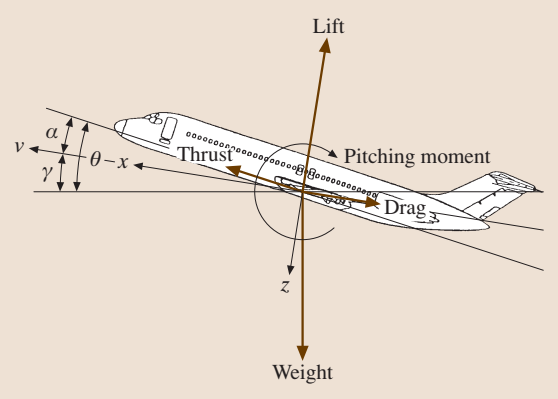


Fig. 13.162 Aerodynamic forces and moments in unaccelerated straight flight

have been developed, so that Newton's laws of motion may be utilized. For unaccelerated symmetric flight along a straight path, the complete forces and moments are as shown in Fig. 13.162.

The summation of the forces and moments for static equilibrium may be written as

$$\sum F_x = T\cos\alpha - D - W\sin\gamma = 0\,,$$
$$\sum F_z = W\cos\gamma - L - T\sin\alpha = 0\,,$$
$$\sum M_{cg} = 0\,.$$

If the assumption is made that the angle of attack is always a relatively small angle, then $\cos\alpha = 1$ and $\sin\alpha = 0$. With this assumption, the force equations reduce to

$$T - D = W\sin\gamma\,,$$
$$L = W\cos\gamma\,. \qquad (13.3)$$

With the small angle assumption of $\sin\gamma = \gamma$, (13.3) may be transformed into an expression for the gradient of climb, that is the gain in altitude over a given distance covered in the horizontal direction.

The climb gradient $= \gamma = (T - D)/W$ and the climb velocity, or rate of climb, is

$$R/C = \frac{(T-D)}{W}V\,. \qquad (13.4)$$

If this is expressed in terms of the lift coefficient, then

$$C_L = \frac{W}{Sq}\cos\gamma$$

or with the small-angle assumption ($\cos\gamma = 1$)

$$C_L = \frac{W}{Sq}\,.$$

13.4.6 Airplane Aerodynamic Characteristics

The concepts associated with the aerodynamic forces and moments acting on the airplane give rise to some important aerodynamic characteristics of the aircraft.

Airplane Lift Curve

In the discussion of aerodynamic forces and moments, it was noted that the lift coefficient is primarily a function of the angle of attack α. The variation of lift coefficient with angle of attack is a very important aerodynamic characteristic of an airplane, and is described in a plot such as that shown in Fig. 13.163, called the airplane lift curve.

It was also noted that the airplane lift coefficient is also dependent on the Mach and the Reynolds numbers, which will be discussed later, but for now, we will focus on the lift curve for a specific Mach number and Reynolds number corresponding to full-scale airplane operation. As seen from Fig. 13.163, the lift curve has a zero value at some, usually negative, angle of attack, a linear region with a well-defined slope $dC_L/d\alpha$, and a departure from the linear slope as the maximum lift coefficient $C_{L_{max}}$ is approached. The characteristics of the lift curve, the zero lift angle, the slope $dC_L/d\alpha$, and $C_{L_{max}}$, depend on certain geometric characteristics of the airplane and its components, as we shall see later. The airplane lift curve has a special relationship to airplane operation in steady, unaccelerated flight. As we have seen for these steady conditions, the variation of the lift coefficient required to balance the weight at various steady flight speeds is as shown in Fig. 13.164. The lowest steady flight speed is called the stalling speed

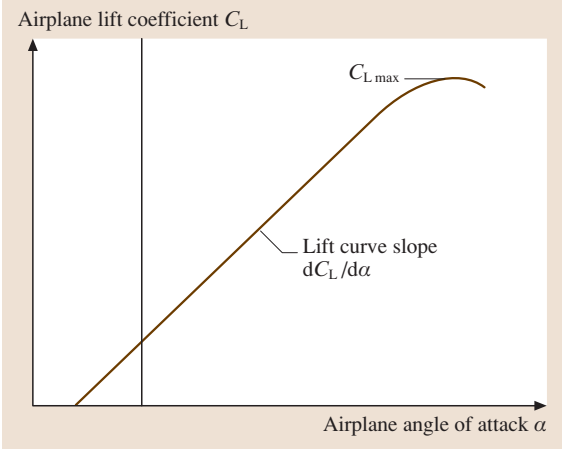

Fig. 13.163 Airplane lift curve

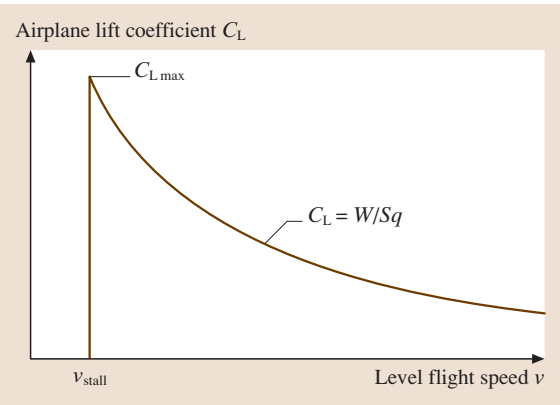

Fig. 13.164 Variation of C_L with airspeed, unaccelerated level flight

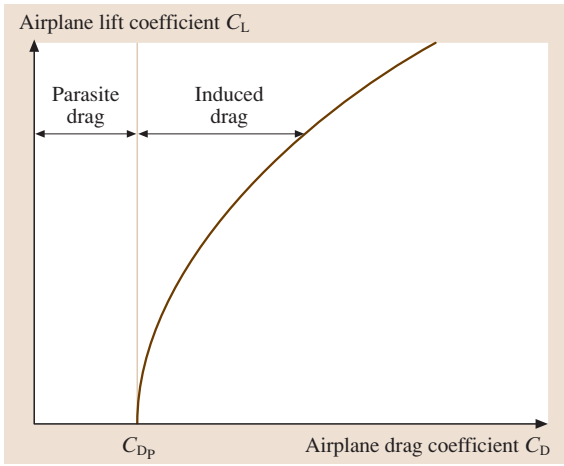

Fig. 13.165 Airplane drag curve

V_{stall} and it corresponds to operation of the airplane at its maximum lift coefficient $C_{L_{max}}$. At high flight speeds, and hence dynamic pressures, the lift coefficients required to balance the weight are reduced as $1/q$ or $1/V^2$. Therefore, the airplane's speed along shallow, unaccelerated flight paths is primarily a function of the lift coefficient, or angle of attack. In order to control the airplane's speed, the pilot must be able to control the equilibrium lift coefficient or angle of attack.

Going back to (13.4), it can be seen that whether the airplane climbs or descends at a given speed depends on the difference between the thrust and drag at this speed. If thrust just equals drag ($T = D$) then the rate of climb will be zero and the airplane will be in level flight. Since the thrust is basically a function of the cockpit throttle setting, under steady unaccelerated flight conditions, the airplane speed is determined by the value of the equilibrium lift coefficient, and the rate of climb or descent is regulated primarily through the throttle. For very large angles of climb or descent, this simple picture does not correspond to actuality, but for the performance methods presented in this chapter, it is a valid concept.

Airplane Drag Curve

Another aerodynamic characteristic of the airplane which is important in range and climb performance is the drag curve or drag polar, a plot of airplane drag coefficient versus airplane lift coefficient. As noted before, the drag varies with angle of attack α but since in the normal operating range of angle of attack, C_L varies linearly with α, it has been found more convenient to describe the drag coefficient as a function of lift coefficient instead of angle of attack. The airplane drag curve, shown schematically in Fig. 13.165, has a value of C_D at zero C_L, called the zero lift or parasite drag coefficient, C_{D_P}. At higher C_Ls, the drag coefficient has a parabolic variation with C_L, due to the induced drag or drag due to lift coefficient, C_{D_i}, which varies as the square of the lift coefficient. As is the case with the lift curve, the drag curve varies in shape with both Mach number and Reynolds number, but for now we will focus on the drag curve that is typical for full-scale airplane operation at one particular Mach number and Reynolds number.

A summary of the physical makeup of airplane drag is presented in Table 13.21

Table 13.21 Physical definition of airplane drag elements

Cruise speed of Ma = 0.5 or less	
Zero lift drag	Skin friction plus pressure drag
Drag due to lift	Subsonic induced drag
Cruise speed between Ma = 0.5 and Ma = 1.0	
Zero lift drag	Skin friction plus pressure drag
Drag due to lift	Subsonic induced drag
Compressibility drag	Drag from local shock waves
Cruise speed greater than Ma = 1.0	
Zero lift drag	Skin friction plus pressure drag
	Supersonic wave drag
Drag due to lift	Supersonic wave drag due to lift
	Subsonic induced drag

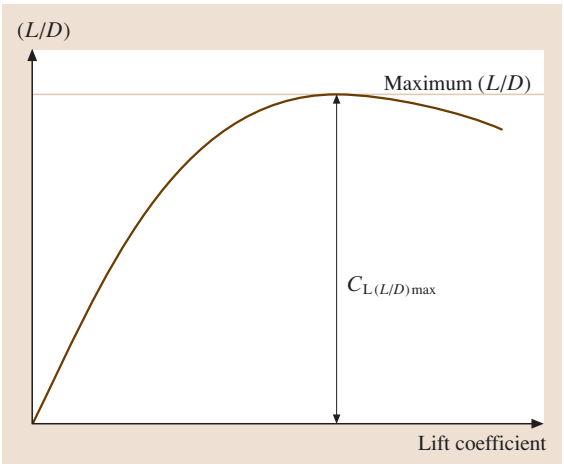

Fig. 13.166 Airplane (L/D) curve

An important parameter in the cruise performance of the airplane, as well as certain aspects of climb performance, is the lift-to-drag ratio L/D. The lift-to-drag ratio may be visualized from the drag polar as shown in Fig. 13.166. At any point on the drag curve, L/D is defined by the ratio C_L/C_D at that point, and also by the slope of a line from the origin to the point in question.

If the L/D values are determined at various points along the airplane drag curve, a plot of airplane L/D versus lift coefficient C_L can be constructed. The L/D value is zero at $C_L = 0$, reaches a maximum value, $(L/D)_{max}$ at some C_L, and then decreases at higher C_L values. Both the value of $(L/D)_{max}$ and the C_L value at which this $(L/D)_{max}$ occurs, $C_{L(L/D)_{max}}$ are important aerodynamic characteristics of the airplane.

Mach Number Effects on Lift and Drag Curves

As noted in the section on flight speed terminology, the characteristics of the airflow around the airplane change dramatically as the flight Mach number is increased due to the compressible nature of air. These changes in the airflow have a significant effect on the airplane lift and drag curves in the various Mach number ranges. For airplanes that operate entirely within the subsonic speed range, there are no significant effects of compressibility of the air on the airplane lift and drag curves, and a single lift curve as shown in Fig. 13.163, and a single drag curve as shown in Fig. 13.165 describe the lift and drag characteristics of the airplane. For airplanes that operate at high subsonic speeds in the transonic speed region, the airplane lift and drag curves will vary as the flight Mach number is increased due to the compressible nature of the air, so that there is a family of lift curves, and a family of drag curves, one for each flight Mach number of interest. The family of lift curves is characterized by an increase in the slope of the lift curve $dC_L/d\alpha$ and a decrease in the maximum lift coefficient $C_{L_{max}}$ as the Mach number is increased in the high subsonic region, as shown schematically in Fig. 13.167.

The Mach number effects may be shown more specifically by plotting the significant parameters as a function of Mach number. For example, the effect of Mach number on increasing the lift curve slope is shown in Fig. 13.168 while the effect of Mach number on de-

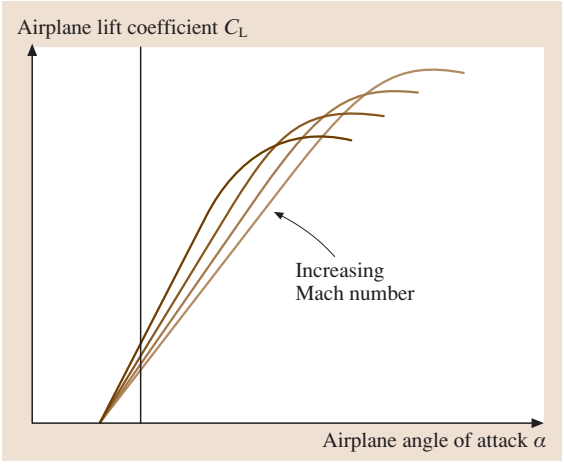

Fig. 13.167 Airplane lift curves at high subsonic Mach numbers

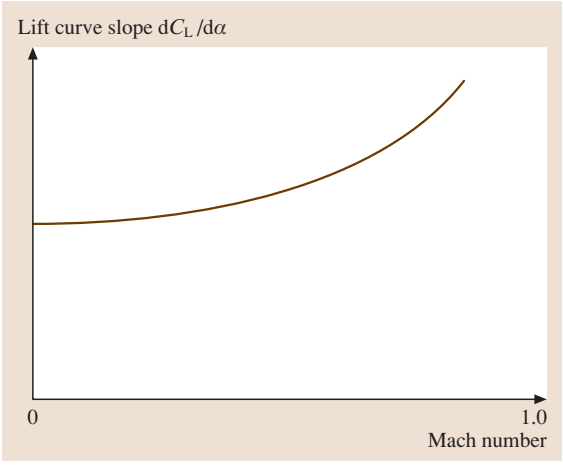

Fig. 13.168 Mach number effect on lift curve slope at high subsonic speeds

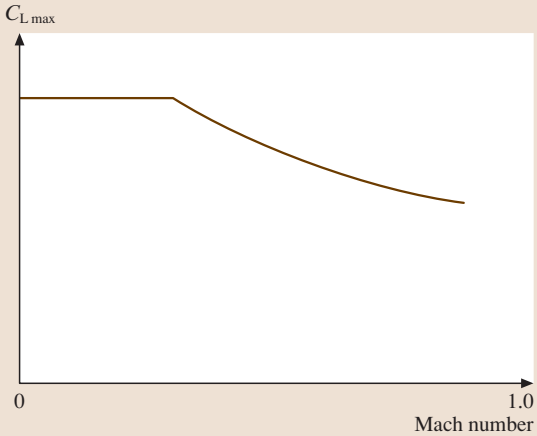

Fig. 13.169 Mach number effect on maximum lift coefficient at high subsonic speeds

creasing the maximum lift coefficient $C_{L_{max}}$ is shown in Fig. 13.169.

The family of drag curves are characterized by increases in the parasite drag coefficient, C_{D_p}, and significant increases in the drag coefficient at higher C_L values as the Mach number is increased, as shown in Fig. 13.170. For the drag curves, the Mach number effects are usually shown in the form of C_D versus Mach number of various values of lift coefficient, as shown in Fig. 13.171.

The explanation of these Mach number effects on the lift and drag curves has been derived from the theory of compressible flow, and confirmed by experimental data obtained in wind tunnels and from flight tests. It

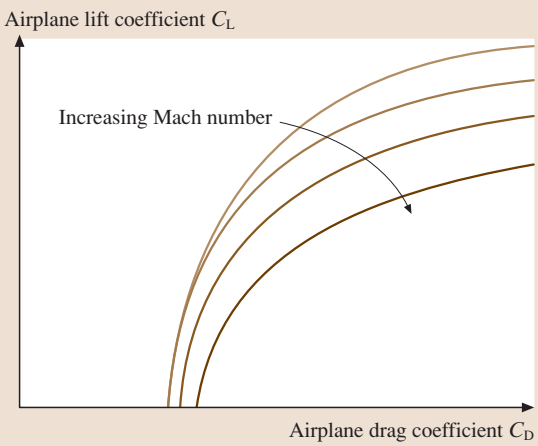

Fig. 13.170 Airplane drag curves at high subsonic speeds

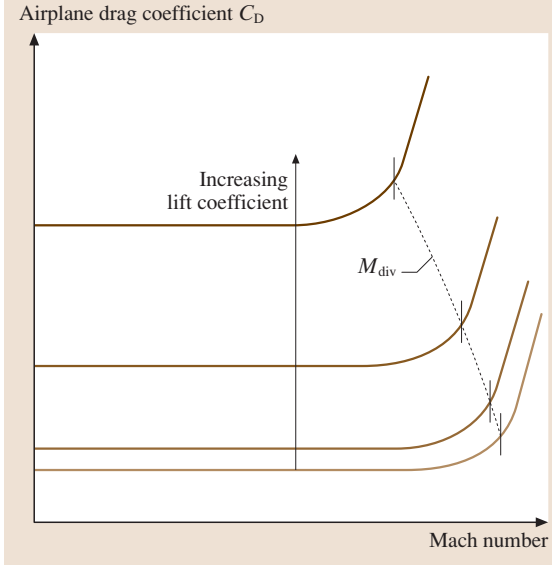

Fig. 13.171 Mach number effect on drag curves at high subsonic speeds

can be shown that, for an airplane at a given angle of attack, the lift coefficient will increase as the Mach number increases, because the suction on the wing upper surface, and the pressures on the wing lower surface tend to grow with Mach number, roughly by the factor $1/\sqrt{1-\mathrm{Ma}^2}$ in the high subsonic speed range, which results in the increase in the lift curve slope as shown in Figs. 13.167 and 13.168. Also, as the Mach number increases, at some flight Mach number, the local velocities on the wing near the leading edge, at high angles of attack near the maximum lift coefficient, become supersonic, which leads to local shock waves and separation, limiting the attainable maximum lift coefficient as shown in Fig. 13.169. As for the drag curves, the Mach number effects are due to the development of local supersonic flow around the wing, which eventually produces normal shock waves, and finally separated flow. Because of the energy loss in the shock wave, and the added pressure drag due to the separated flow, there are significant increases in the drag coefficient at a given lift coefficient as the flight Mach number is increased, as shown in Fig. 13.171. The development of these conditions for a wing airfoil section typical of those used on many current jet transports and business jets is shown in Fig. 13.172. There are some important concepts and definitions associated with the sketches of Fig. 13.172. At the condition shown in Fig. 13.172b, the condition of lift coefficient and flight Mach num-

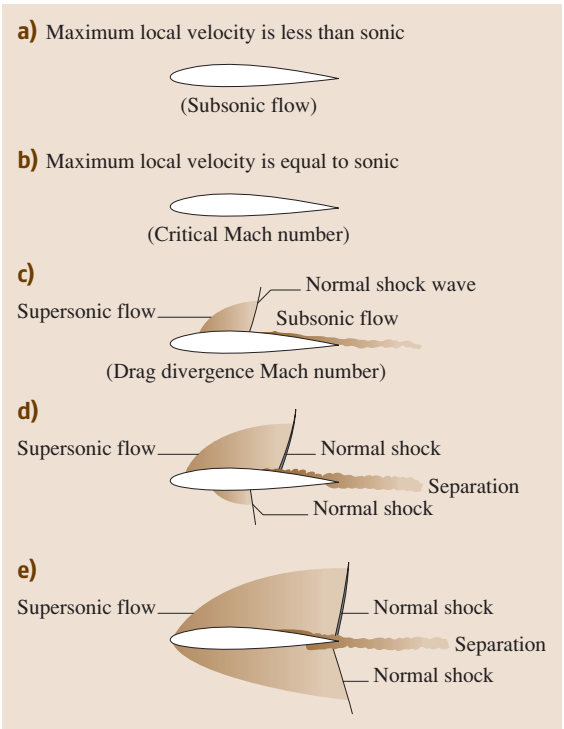

Fig. 13.172a–e Development of flow conditions around a wing airfoil section at high subsonic speeds

ber where the maximum local velocity on the wing surface is equal to the sonic velocity, is called the critical Mach number Ma_C. At a higher Mach number, in the conditions shown in Fig. 13.172c, with a local region of supersonic flow terminated by a normal shock wave, and the very beginning of flow separation behind the normal shock, the drag begins to rise abruptly. This condition is called the drag divergence Mach number Ma_{DIV}, for that particular lift coefficient. At higher flight Mach numbers (Fig. 13.172d,e), the supersonic zones are larger, the normal shocks are stronger, and the drag continues to rise very strongly. Although the wing is the primary source of local supersonic flow, shock waves, and the associated drag increase, all parts of the airplane, i. e., the fuselage, tail surfaces, and engine nacelles will eventually experience these conditions as the flight Mach number approaches 1.0.

For airplanes that are designed to operate at supersonic speeds, the lift and drag curves also vary with flight Mach number. The slopes of the curves are similar

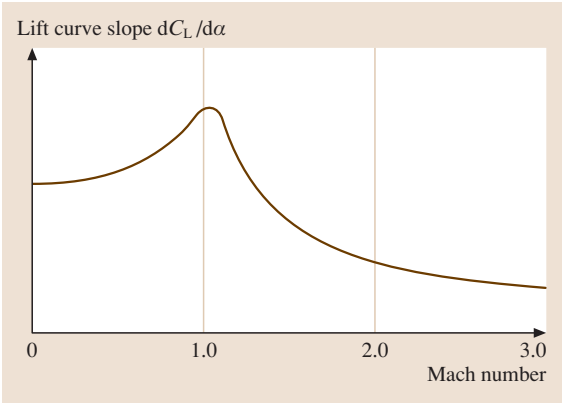

Fig. 13.173 Mach number effects on lift curve slope at subsonic and supersonic speeds

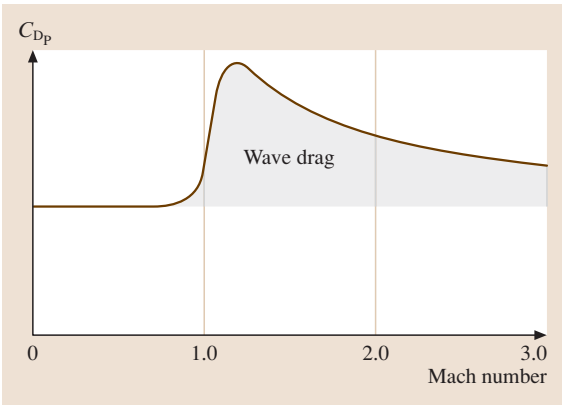

Fig. 13.174 Mach number effects on the parasite drag coefficient

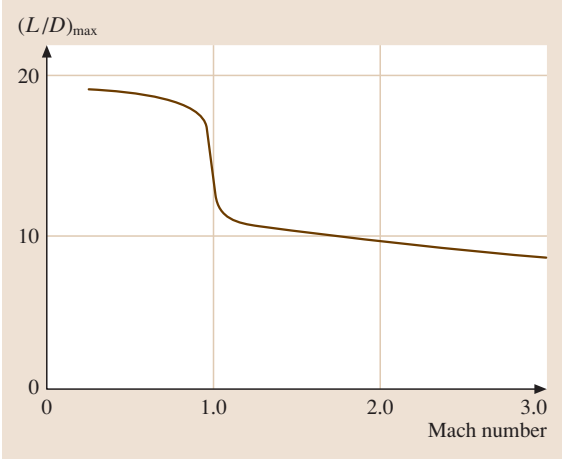

Fig. 13.175 Mach number effects on the maximum lift-to-drag ratio

to those of subsonic speed designs, but the significant parameters show a different trend at supersonic speeds. The pressure on the wing upper and lower surface tend to reduce as the Mach number is increased supersonically, roughly by the factor $1/\sqrt{\mathrm{Ma}^2-1}$, so that the lift curve slope, which increases at high subsonic speeds, decreases beyond Mach 1.0, as shown in Fig. 13.173. The maximum lift capability supersonically is described in terms of a maximum usable lift coefficient, which results from detached shock waves and unsteady flow at high angles of attack. The drag curves at supersonic speeds are basically parabolic in shape, but with very high values of parasite drag coefficient because of the added element of supersonic wave drag, as shown in Fig. 13.174, and very high drag levels at operating lift coefficients due to the wave drag element that increases with lift coefficient. The presence of wave drag at supersonic speeds has a significant impact on the maximum lift-to-drag ratio $(L/D)_{\max}$ referred to in Fig. 13.166. Because of this added drag element, the $(L/D)_{\max}$ values at supersonic speeds are usually less than half of the values at subsonic speeds, for any specific configuration.

For jet transports, the $(L/D)_{\max}$ values subsonically are just under 20, while the best supersonic transport values are less than 10, as shown in Fig. 13.175.

13.4.7 Airplane General Arrangements

Airplanes are often described by their general arrangement. Figure 13.176 shows various aircraft types classified by number of wings, location of the wings on the fuselage, and number of engines.

Aircraft Component Nomenclature

The various components of an airplane have unique names. Figure 13.177 indicates the names of the various components of a modern commercial transport aircraft.

Some specific geometric characteristics are defined in Table 13.22 and shown schematically in Fig. 13.178.

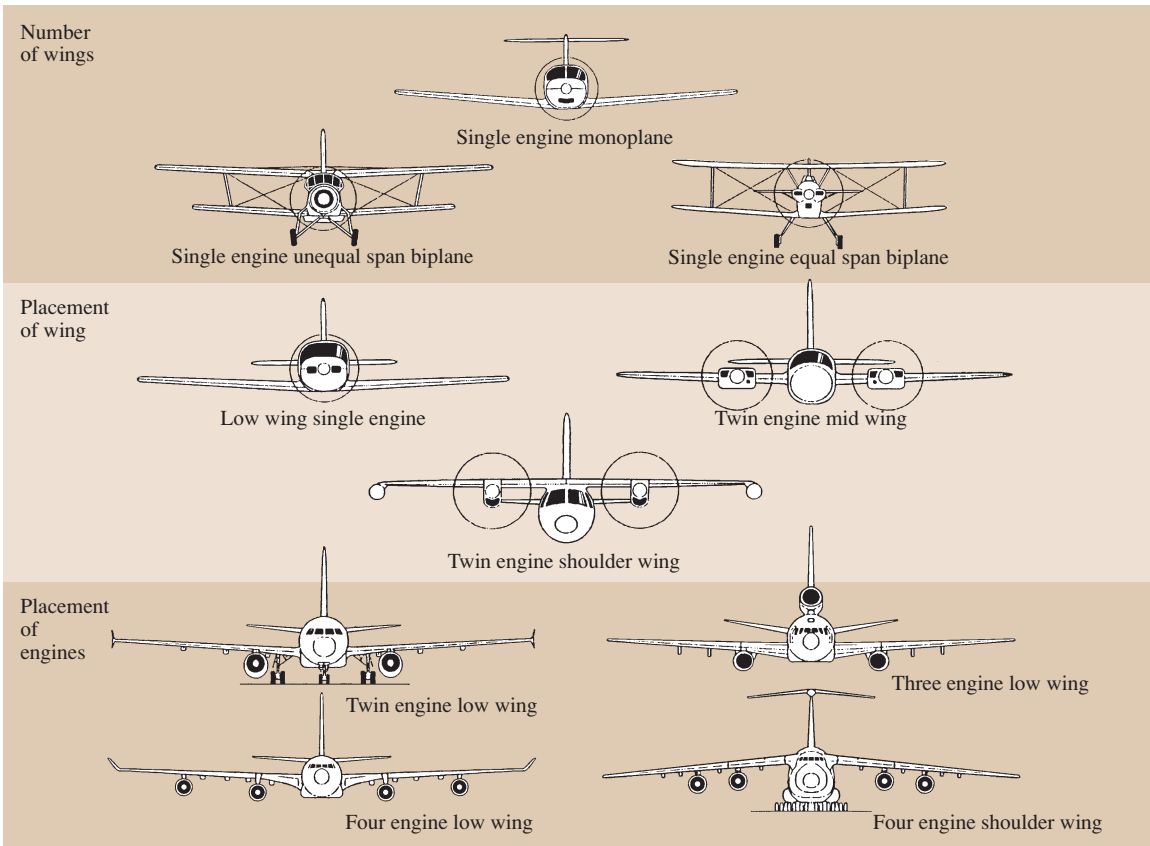

Fig. 13.176 Aircraft general arrangements

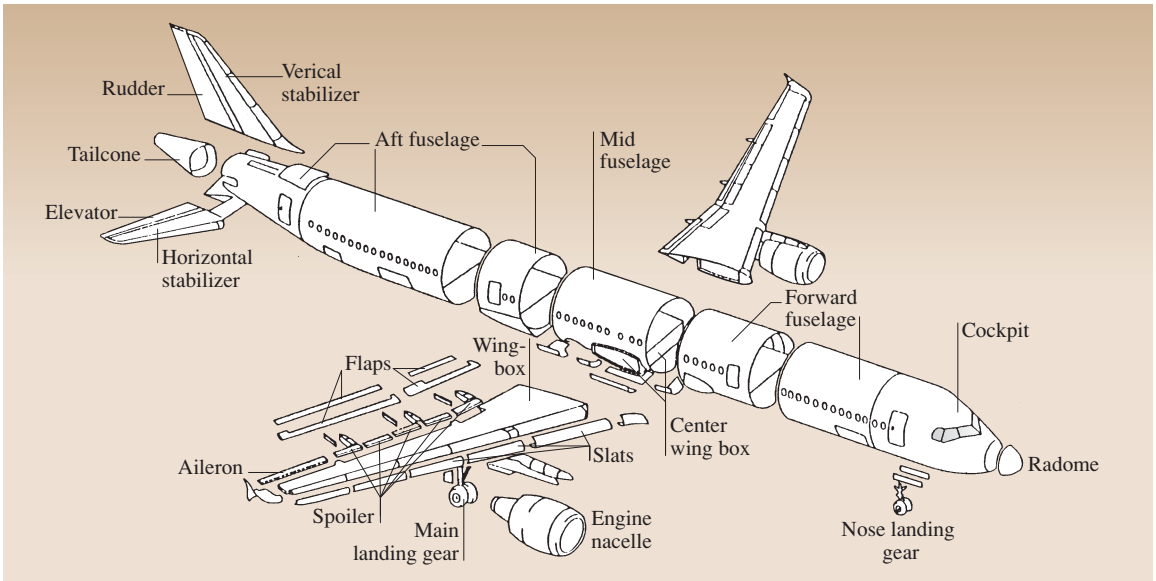

Fig. 13.177 Airplane component nomenclature

Wing Geometric Characteristics

The wing geometric characteristics include the wing area, aspect ratio, taper ratio, airfoil sections, thickness distribution, sweepback angle aerodynamic twist, and dihedral angle. Other important elements that are incorporated in the geometric definition of the wing are high-lift system devices, and lateral control system components.

Table 13.22 Airplane geometric definitions

b	Wing span
$b/2$	Wing semispan
S	Wing area
b_H	Horizontal tail span
S_H	Horizontal tail area
l_H	Horizontal tail length
S_V	Vertical tail area
l_V	Vertical tail length
c	Wing mean aerodynamic chord
c_H	Horizontal tail mean aerodynamic chord
c_V	Vertical tail mean aerodynamic chord
l_{oa}	Overall length
l_{fus}	Fuselage length
h	Height
V_H	Horizontal tail volume
V_V	Vertical tail volume

Wing Area. The wing area is usually taken to be the total planform area of the wing from the fuselage centerline to the wing tip, including the area encompassed by the fuselage, as shown in Fig. 13.178.

Aspect Ratio. The wing aspect ratio (AR) is defined as the square of the wing span b divided by the wing area S

$$\mathrm{AR} = \frac{b^2}{S} .$$

Aspect ratio selection is basically a compromise between aerodynamic efficiency, in the form of high cruise L/D and wing structural weight associated with the bending moments due to air loads for a given wing area.

Taper Ratio. The taper ratio λ is defined as the ratio of the chord at the tip of the wing to the chord at the airplane centerline, called the root chord

$$\lambda = \frac{c_t}{c_r} .$$

Taper ratio is also a compromise between aerodynamic considerations, primarily span load distribution, important for cruise efficiency, stall characteristics, and bending moments due to air loads and structural considerations, associated primarily with the bending moments.

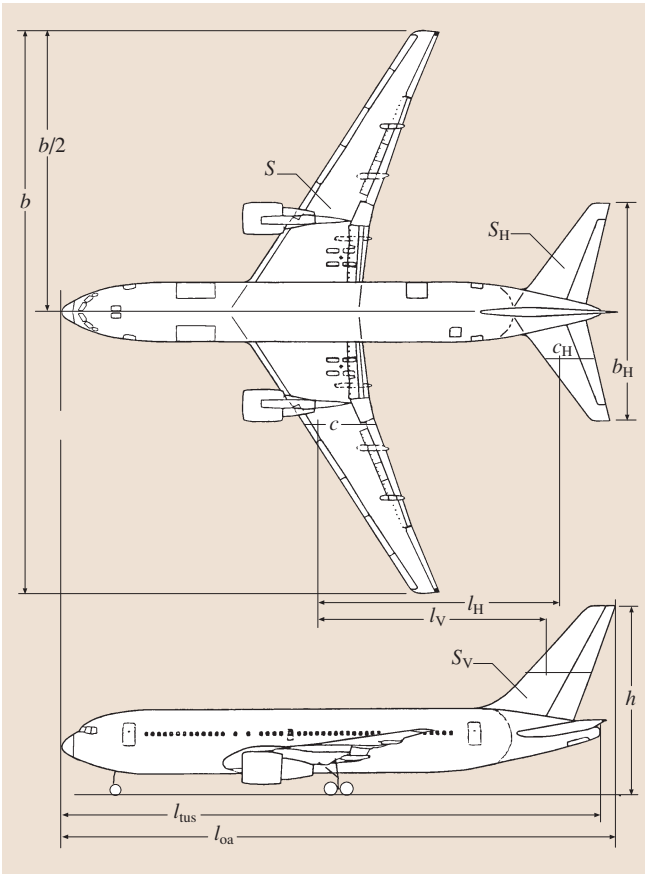

Fig. 13.178 Airplane geometric characteristics

Airfoil Sections. Wing airfoil sections are the cross-sectional shapes of the wing in planes parallel to the airplane center line and normal to the wing reference plan. The wing airfoil sections provide the wing lift, by creating suctions on the wing upper surface and pressures on the wing lower surface. The wing airfoil geometry determines the detailed pressure distribution on the wing upper and lower surfaces, which in turn may have a significant influence on some of the important aerodynamic characteristics of the wing. Airfoil geometric parameters are defined in Fig. 13.179.

Mean Aerodynamic Chord. An important wing geometric parameter is the mean aerodynamic chord (m.a.c.). The m.a.c. is the chord of an imaginary wing, with constant chord, which has the same aerodynamic characteristics as the actual wing. The m.a.c. may be defined graphically, as shown in Fig. 13.180.

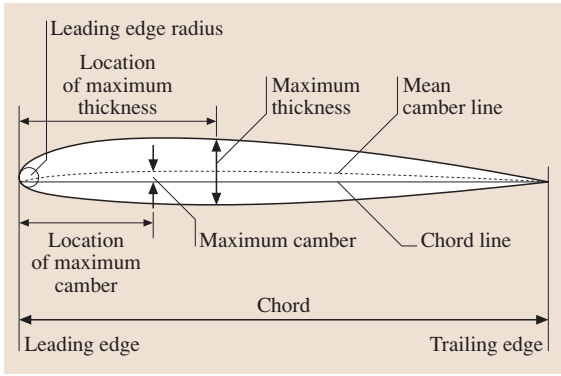

Fig. 13.179 Airfoil section geometric parameters

The wing span b is $b = \sqrt{\mathrm{AR} \cdot S}$, where AR is the wing aspect ratio and S is the reference wing area.

The root chord length is $C_{\mathrm{root}} = \frac{2S}{b(1+\lambda)}$, where λ is the wing taper ratio.

The tip chord length is $C_{\mathrm{tip}} = \lambda C_{\mathrm{root}}$.

For trapezoidal planforms, the wing m.a.c. length is

$$\overline{C} = \left(\frac{2}{3}\right) C_{\mathrm{root}} \frac{1+\lambda+\lambda^2}{1+\lambda} .$$

The distance from the centerline to the m.a.c. location is

$$\overline{Y} = \left(\frac{b}{6}\right) \frac{1+2\lambda}{1+\lambda} .$$

Thickness Distribution. Another wing geometric characteristic is the variation of the airfoil thickness ratio across the span of each wing panel. Of course the simplest wing geometry, still found on many small personal/utility airplanes, is a constant-chord constant-thickness-ratio configuration. More sophisticated personal/utility aircraft, as well as commuters, regional

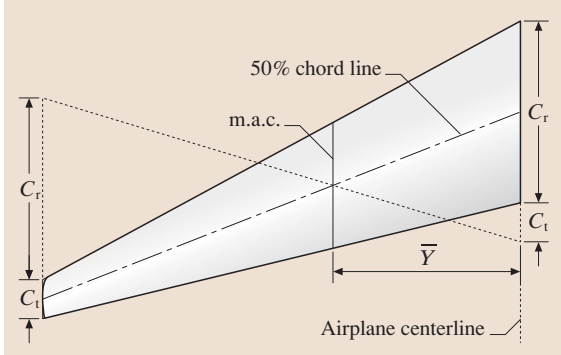

Fig. 13.180 Wing m.a.c. determination

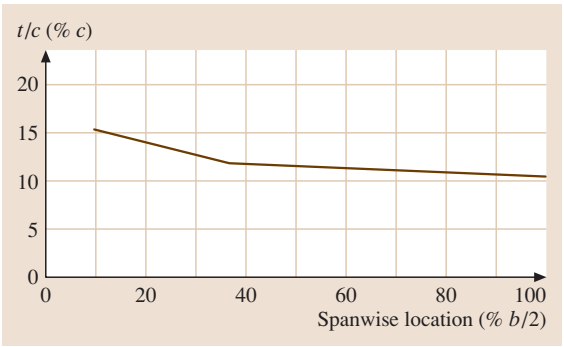

Fig. 13.181 Typical wing thickness distribution for a jet transport

turboprops, business jets, and jet transports have wing designs which vary the airfoil section thickness ratio (t/c) across the span, primarily to obtain greater depth for the airfoil sections at the wing root. This greater depth provides for a more efficient structural beam to resist the bending moments due to wing air loads. For straight-wing propeller-driven aircraft, the wing is usually defined by two airfoil sections, one at the wing root, and one at the wing tip, connected by straight-line elements through the constant percentage chord points.

For business jets and jet transports which cruise at high subsonic speed the wing is usually defined by three or more airfoil sections, one at the side of the fuselage, one at the tip, and one or more at intermediate spanwise locations. The purpose of the additional defining airfoils is to produce wing upper-surface pressure distributions that maintain insofar as possible uniformly swept lines of constant pressure, or isobars at cruise conditions, so that the entire wing reaches its M_{DIV} at the same point. A typical wing thickness distribution for a commercial jet transport is shown in Fig. 13.181.

Sweepback Angle. Two very important wing geometric parameters, especially for airplanes that cruise at high subsonic speeds, are the wing sweepback angle and the average thickness. Wing sweepback or sweep angle is defined in the plan view as the angle between a line perpendicular to the airplane center line and the constant 25% chord line of the wing airfoil sections, as shown in Fig. 13.182. Nearly all high-subsonic-speed aircraft have wings with some amount of sweep, because sweep increases the wing drag divergence Mach number M_{DIV} for a given streamwise airfoil thickness.

Geometric Twist. Nearly all wing designs incorporate some degree of geometric twist, that is, a change in the orientation of the airfoil section chord lines from root to tip, with the tip airfoils having less of an angle of incidence than the root, as shown in Fig. 13.180. This geometric twist is used to avoid initial stalling at the wing tip as the airplane $C_{L_{max}}$ is reached. Typical values of wing twist vary from 3° for personal/utility, commuters, and regional turboprops, to as much as 7° for business jets and jet transports. Supersonic military fighter/attack aircraft usually have little or no twist, and depend on other means to provide satisfactory stall characteristics.

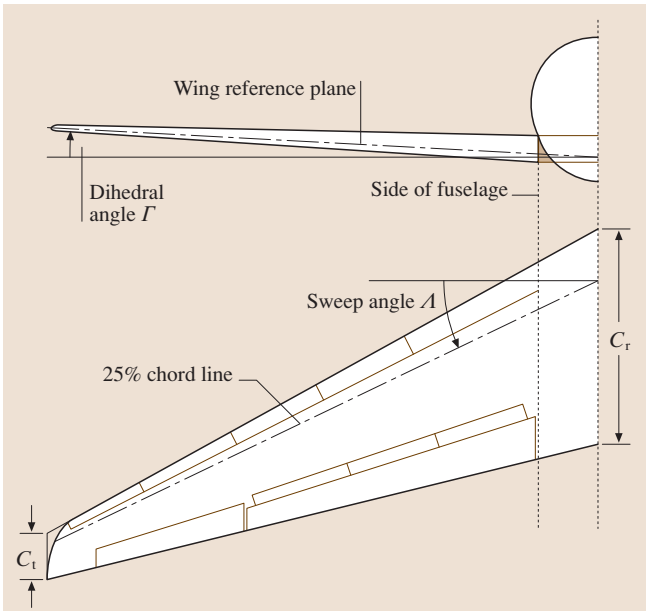

Fig. 13.182 Wing planform parameters

Dihedral Angle. The dihedral angle is defined in the front view of the airplane as the angle between the horizontal and a line midway between the upper and lower surfaces of the wing, as shown in Fig. 13.182. The dihedral angle primarily affects the lateral stability characteristics of the airplane. If the wing tips are higher than the wing root, the wing is said to have positive dihedral, which produces effective lateral stability. For low-wing airplanes with low horizontal tails, nearly all of the lateral stability comes from the wing dihedral angle, which is usually set around 5° for these types. For low-wing airplanes with high-mounted horizontal tails (tee tails), a significant amount of lateral stability is generated by the intersection between the horizontal and vertical tail sections, so that the wing dihedral angle for these types is usually down to around 2°. For

high-wing airplanes, especially those with tee-tail arrangements, there is sufficient lateral stability generated by the wing–fuselage intersection and the horizontal tail–vertical tail intersection that the wing dihedral angle is set at negative angles ranging from −2° to −5°.

Spar Locations. The front and rear spars, along with the upper and lower wing skins, are the major elements of the wing structural *box*, which resists the applied wing loads in bending and torsion. The distance between the wing spars is important structurally, but also has a significant impact on the space available for high-lift and lateral control devices, and on the volume available for internal wing fuel tankage. Typical locations for the front spar are 16–22% of local chord, while typical rear spar locations range from 60% to 75% of local chord.

High-Lift Systems. Nearly all modern aircraft incorporate devices that fit within the wing to increase the maximum lift coefficient in the take-off and landing configuration. These devices are collectively called the high-lift system. High-lift devices fall into two categories: trailing-edge devices located at the rear portion of the wing, and leading-edge devices located at the forward portion of the wing. Trailing-edge devices include single, double, and triple slotted flaps, as shown in Fig. 13.182. Single slotted flaps are standard for personal/utility airplanes. Single slotted flap chords are usually in the range of 25–30% of chord, and have a maximum deflection of 35°. For commuters, regional turboprops, business jets, and jet transports, more powerful double slotted trailing-edge flaps are usually employed. Double slotted flap chords are in the range of 30–35% chord with maximum deflections of 45−50°. Some jet transports with design mission specifications that call for extremely low landing approach speeds and short landing distances have utilized triple slotted trailing-edge flaps to achieve very high $C_{L_{max}}$ values in the landing configuration. Flap chords up to 40% may be used in triple slotted flap designs, with maximum deflections of the aft flap segment of up to 55°. The effectiveness of trailing-edge flaps may be enhanced by selecting a large percentage of chord dimension for the flap, and utilizing as much flap span as possible, considering the need for lateral control ailerons on the outboard wing trailing edge.

Significant increases in $C_{L_{max}}$ can also be achieved through the application of leading-edge high-lift devices. The simplest leading-edge device is the plain leading-edge flap, used on a number of military fighter/attack aircraft. Some jet transports have used leading-edge Krueger flaps. A more effective, but more complicated, leading-edge device is the slat, which is used on all modern jet transports. The maximum effectiveness of leading-edge flaps and slats is usually

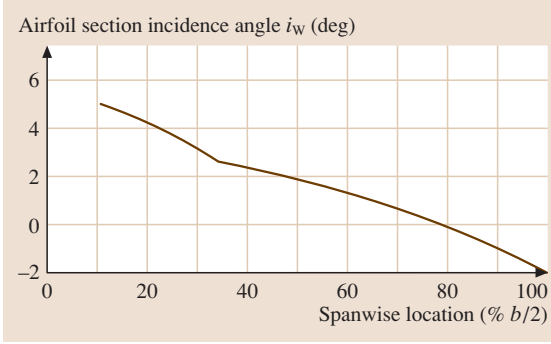

Fig. 13.183 Typical wing twist distribution for a jet transport

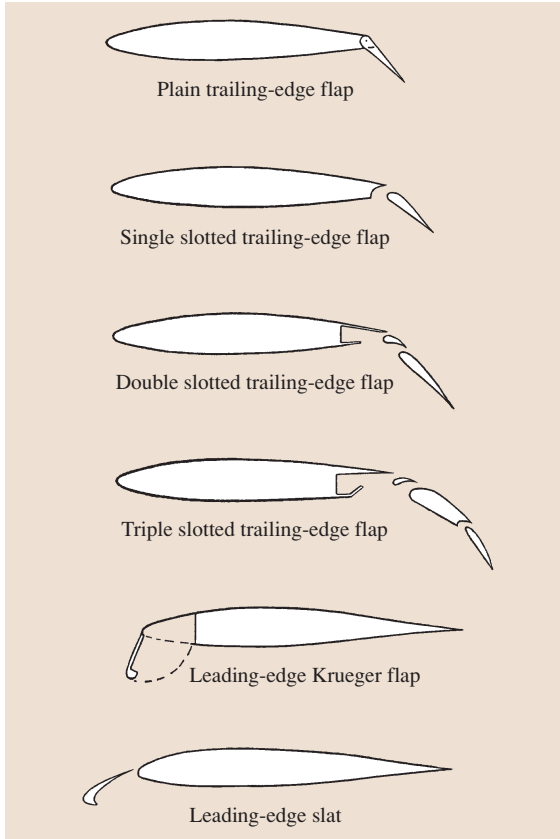

Fig. 13.184 Typical high-lift devices

achieved with flap and slat chords of 12–15%, and deflections ranging from 20° for slats to 30° for plain leading-edge flaps to 60° for Krueger flaps. Leading-edge flaps and slats must extend for the full span of the wing to be effective in increasing $C_{L_{max}}$. Typical high-lift devices are shown in Fig. 13.184.

Lateral Control Devices. An additional consideration for the preliminary wing design is the provision for lateral control devices which produce rolling moments about the airplane's x-axis. The most common lateral control devices are ailerons, essentially a plain trailing-edge flap, and spoilers, basically a portion of the wing upper surface, hinged at its leading edge, which reduces the lift in the affected area of the wing when the spoiler is deflected. When deflected asymmetrically, spoilers can produce significant rolling moments, especially if they are located ahead of deflected trailing-edge flaps. Spoilers have additional uses when deflected symmetrically as drag-producing devices to allow the airplane to slow down in level flight, or to increase the rate of descent at the end of cruise. Spoilers are also used symmetrically to reduce the airplane's lift during landing ground roll, which improves braking effectiveness.

For personal/utility, commuters, and regional turboprops, the usual lateral control device is the aileron, with aileron spans ranging from 55% to 90% of the wing semispan. For business jets and jet transports, spoilers are generally used in conjunction with ailerons. Furthermore, since ailerons located on the outer part of the wing trailing edge tend to twist the wing as they are deflected to produce rolling moments at high dynamic pressure, or high q conditions, thereby reducing there effectiveness, most jet transports utilize smaller ailerons located further inboard in addition to the outboard ailerons for high-q lateral control and trim.

Inboard Trailing-Edge Extensions. Wing inboard trailing-edge extensions are often used on business jets and jet transports with wing sweep angles greater then 30°. The need for an inboard trailing-edge extension arises from the required main landing gear leg upper pivot point location, which would be very near the wing trailing edge on a trapezoidal planform. By incorporating an inboard trailing-edge extension, a suitable structural arrangement may be designed to provide the necessary gear pivot location. This situation is shown in Fig. 13.185.

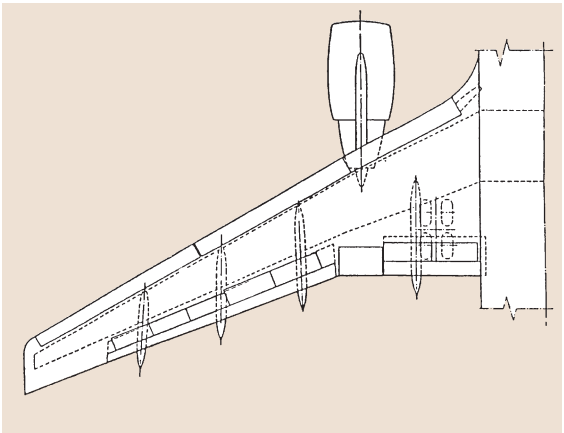

Fig. 13.185 Inboard wing trailing-edge extension

Fuselage Geometry

Primary requirements for the fuselage are to provide accommodation for the crew station, passengers, other payload to be carried in the fuselage, and for some designs, accommodating the engine/propulsion system as well. For single-engine propeller-driven airplanes, the fuselage accommodates the engine/propeller installation forward, the pilot and passenger cabin next, followed by the aft fuselage, which serves mainly as a convenient structure for locating the horizontal and vertical tail well aft of the wing. For larger transport airplanes, the fuselage is made up of three distinct sections: (1) the nose section, (2) a constant-section passenger compartment, and (3) the afterbody or tail cone.

The nose section on larger airplanes usually contains the crew station, with crew seats, control yoke

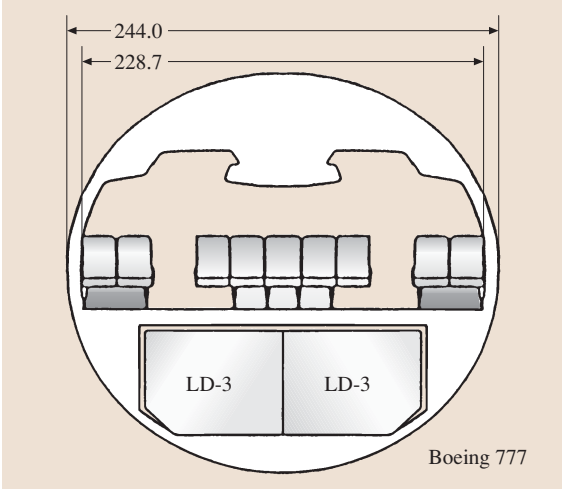

Fig. 13.186 Twin-aisle transport fuselage cross section

and wheel, or control stick, rudder pedals, instrument panel, glare shield, plus a variety of levers, knobs, and switches to operate various aircraft systems. Specific requirements for pilot field of view and downward vision from the defined pilot design eye position are contained in the federal air regulations (FARs) and the military specifications (Mil Specs). The constant-section passenger compartment for larger airplanes is usually pressurized, and circular or near-circular in cross section, because of the structural weight efficiency of this shape for pressure vessels. For larger-capacity long-range jet transports, two aisles are provided for greater passenger mobility, and for ease of entry and exit from multiple adjacent seats. These larger circular cross sections provide significant space below the passenger deck to carry large amounts of revenue cargo, either in special containers or stacked on flat pallets. A typical cross section for a twin-aisle transport is shown in Fig. 13.186.

The length of the passenger compartment must be sufficient to accommodate the required number of passengers, allow for galley space, lavatories, coat rooms, plus passenger entrance doors, and emergency exits.

There are specific requirements in the FARs for emergency exits to be used in survivable accidents. The aft fuselage or afterbody is influenced by conflicting requirements of aerodynamic performance and structural weight. The afterbody should be long enough to avoid severe curvature and separation drag, while being as short as possible to avoid limiting the airplane pitch attitude on the ground during normal take-offs, as well as avoiding excessive weight from a long afterbody.

Empennage Geometry

For conventional aft-tail configurations, the horizontal and vertical tail arrangement, called the empennage, is the major element in providing both static aerodynamic stability in pitch and yaw, as well as providing aerodynamic control moments in pitch and yaw. For unconventional configurations such as *flying wings* or forward horizontal tail *canards*, static aerodynamic stability and control are provided by other means.

The aft horizontal tail is the major contributor to static aerodynamic stability in pitch. This is quite logical, since static longitudinal stability involves the generation of aerodynamic restoring moments which are dependent on an aerodynamic force from the horizontal tail (proportional to the horizontal tail area) and a moment arm (proportional to the distance from the airplane center of gravity to the horizontal tail m.a.c.). The horizontal tail also provides the aerodynamic control moments to allow the pilot to achieve equilibrium in pitch at any desired lift coefficient, allowing the control of airspeed in steady unaccelerated flight, and the curvature of the flight path in accelerated flight. Longitudinal control is usually provided through the hinged, moveable, aft portion of the horizontal tail called the elevator, although some designs move the entire horizontal tail about a fixed pivot point. This arrangement is called an all-moveable horizontal, or a stabilator.

Landing Gear

Most modern airplanes use a tricycle landing gear configuration that is one with two main wheels aft of the c.g. and one forward. Except for small airplanes with low cruise speed, landing gears are usually retracted for climb and cruise flight. The landing gear wheels and tires must be adequate to handle a variety of taxi, take-off, and landing loads prescribed by the FARs, as well as spreading the reaction loads from the gear sufficiently so as not to overstress the runway pavement. The landing gear also has to house the brakes.

Propulsion Systems

Propulsion systems for modern airplanes are of one of the following types:

- Piston engine-propeller
- Turbine engine-propeller
- Turbojet engine
- Turbofan engine
- Turbofan engine with afterburner

Small personal utility or acrobatic airplanes are usually powered by piston engine-propeller combinations, while larger personal utility and smaller commuter airplanes are usually powered by turboprop propulsion. Business jets and larger jet transports are powered by turbofans. High-performance military airplanes are usually powered by low-bypass turbofans equipped with afterburners. The key parameter for the propulsion system is the *specific fuel consumption* c, i. e., the amount of fuel burned per hour, per unit of output of the propulsion system.

For piston engines and turboprops, it is expressed as

$$c = \frac{\text{lb}}{\text{bhp/h}} .$$

For turbojets and turbofans, it is expressed as

$$c = \frac{\text{lb}}{\text{lb/h}} .$$

13.4.8 Weights

The weight of an airplane, especially its empty weight, is a vital parameter in the performance and economics of the design. The following paragraphs provide information on the various aspects of aircraft weight.

Weight Definitions

Figure 13.187 shows a simple bar chart illustrating the elements of the weight buildup to the maximum take-off weight W_{to} required for a specific design mission. Also noted to the right of the bar chart are some important structural weight definitions that are related to the weight buildup, for a typical commercial jet transport. Other aircraft types have similar structural weight definitions.

Note that the operating weight empty involves both the manufacturer's weight empty (MWE), plus the operator's items, which include the flight crew, cabin crew, food, galley service items, drinkable water, cargo containers and pallets, plus life vests, life rafts, emergency transmitters, and the unusable fuel trapped in the fuel system and unavailable for use by the engines. When all the payload is loaded, that is, all available passenger seats filled at the *standard* passenger + baggage weight and all the available revenue cargo volume is filled at some selected cargo density, the aircraft has reached its space limit payload (SLPL), which usually coincides with another key weight definition, the maximum zero-fuel weight (MZFW), the maximum design weight for the aircraft with no fuel on board. Loading on the fuel required for the mission, the mission fuel, plus the required reserves, brings the aircraft to the W_{to}, the maximum take-off gross weight required to perform the specified design mission. The design maximum landing weight (MLW) for most smaller aircraft, such as private propeller-driven aircraft and short-range commuters is usually the same as the MTOGW. However, for larger, long-range aircraft, where the mission fuel is a large percentage of the MTOGW, a somewhat lower MLW is selected to minimize the structural weight impact of designing all the structure to withstand the loads associated with landing at MTOGW. For this design choice, a fuel dump system, which allows fuel to be jettisoned overboard in an emergency following a high-gross-weight take-off, allows the aircraft to reduce its weight to the MLW without having to burn off large amounts of mission fuel. A summary of the airplane weight definitions is given in Table 13.23.

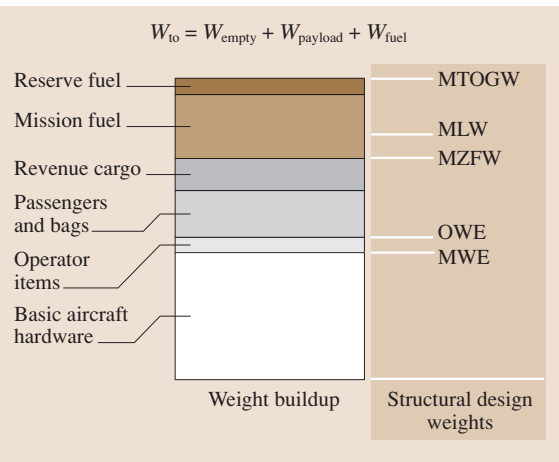

Fig. 13.187 Typical weight buildup – jet transport

Weight Fractions

The maximum take-off weight required for a specific design mission (W_{to}) may be written as

$$W_{to} = W_{empty} + W_{payload} + W_{fuel}$$

or

$$\frac{W_{empty}}{W_{to}} + \frac{W_{payload}}{W_{to}} + \frac{W_{fuel}}{W_{to}} = 1 ,$$

where

$$\frac{W_{empty}}{W_{to}} = \text{weight empty fraction} ,$$
$$\frac{W_{payload}}{W_{to}} = \text{payload fraction} ,$$
$$\frac{W_{fuel}}{W_{to}} = \text{fuel fraction} .$$

and:

W_{empty} = operating weight empty (OWE), the basic aircraft hardware plus other items required to allow the aircraft to perform the design mission;

$W_{payload}$ = passengers + bags + revenue cargo (commercial) or bombs, missiles, cargo (military);

W_{fuel} = total fuel onboard for the mission, that is, fuel burned + reserve fuel.

Weight Estimation and Control

In order to begin design work on a specific aircraft project, there is a need to establish the weight of the various components and systems that make up the aircraft

Table 13.23 Airplane weight definitions

Weight	Symbol	Definition
Manufacturer's weight empty	MWE	Airplane weight at the end of the manufacturing process.
Operating weight empty	OWE	Airplane weight ready for operation. Includes flight crew, cabin crew, food, galley service items, potable water, cargo containers and pallets, life vests, life rafts, emergency transmitter, lavatory fluids, and unusable fuel.
Maximum zero-fuel weight	MZFW	Airplane weight with maximum design payload on board, but no fuel. Design payload includes all passengers and their baggage, plus the maximun design cargo weight.
Maximun landing weight	MLW	Airplane weight defined as the maximum for which the airplane meets all of the structural design requirements for landing. It is usually somewhat higher than the MZFW.
Maximum take-off gross weight	MTOGW	Airplane weight defined as the maximum for which the airplane meets all of the structural design and performance requirements for takeoff. Includes the maximum design payloads plus the fuel required to fly the design mission plus the required reserve fuel.

empty weight. This process, usually conducted by aircraft weight engineers, initially involves much reliance on empirical data from actual aircraft, correlated with appropriate physical parameters. This data is assembled into a group weight statement, a list of weights of the major elements that make up the MWE. Examples are shown in Table 13.24.

As the design work progresses, the group weights are updated as various parts of the aircraft are specifically defined. Major effort is required to ensure that the initial target weight for the entire aircraft is not exceeded during the design and manufacturing phase of the project.

Balance Diagram and C.G. Limits

The airplane balance diagram is used to ensure that the airplane center of gravity (c.g.) is in the proper location for all of the probable loading conditions considering OWE c.g. location, fuel loading and usage, passenger loading, and cargo loading. The OWE c.g. is usually set by designers based on experience for a specific airplane design. Then the extreme excursions of the c.g. due to the most probable adverse loading conditions that move the c.g. forward and aft are examined by calculation to establish forward and aft limits for c.g. travel. The results of these calculations are plotted on a chart of airplane gross weight versus c.g. location so that appropriate c.g. limits can be established. Stability and control and structural design criteria must be met at these c.g. limits.

13.4.9 Aircraft Performance

Aircraft performance is the part of the subject of flight mechanics that deals with parameters such as speed, rate of climb, range, fuel consumption, and runway length requirements.

Level-Flight Performance

The simplest performance condition is steady level-flight cruise, when all forces are in equilibrium as the aircraft moves at a constant speed and altitude. From Fig. 13.162, equilibrium requires that

$$\text{lift } L = \text{weight } W = C_L \frac{\rho}{2} V^2 S \,,$$

$$C_L = \frac{W}{(\rho V^2/2)S}$$

and

$$\text{thrust } T = \text{drag } D = C_D \frac{\rho}{2} V^2 S \quad \text{subsonic flight} \,.$$

For any given weight, C_L may be found and substituted into the induced drag term. ΔC_{D_C}, the empirical compressibility drag coefficient, is dependent on C_L and the Mach number.

Several fundamental airplane characteristics can be derived from the drag equation. One major objective of airplane design is to minimize the drag for any required lift. At any altitude and speed, the ratio of drag to lift depends only on the ratio of C_D to C_L. At low Mach

numbers, $\Delta C_{D_C} = 0$ and

$$C_D = C_{D_p} + \frac{C_L^2}{\pi AR e} .$$

For minimum drag, C_D/C_L is a minimum. Now

$$\frac{C_D}{C_L} = \frac{C_{D_p}}{C_L} + \frac{C_L}{\pi AR e} .$$

At the value of C_L for which C_D/C_L is a minimum, $d(C_D/C_L)/dC_L = 0$. Then

$$\frac{d(C_D/C_L)}{dC_L} = -\frac{C_{D_p}}{C_L^2} + \frac{1}{\pi AR e} = 0 .$$

And for $L/D =$ maximum,

$$C_{D_p} = \frac{C_L^2}{\pi AR e} .$$

Thus, for minimum drag, the lift coefficient is the value for which drag due to lift is equal to parasite drag. For this condition

$$C_{L_{(L/D)max}} = \sqrt{C_{D_p} \pi AR e} .$$

The value of L/D is

$$\frac{L}{D} = \frac{C_L}{C_D} = \frac{C_L}{C_{D_p} + C_L^2/(\pi AR e)} ,$$

for $L/D =$ maximum

$$C_L = \sqrt{C_{D_p} \pi AR e}$$

and

$$C_{D_p} = \frac{C_L^2}{\pi AR e} .$$

Thus,

$$\left(\frac{L}{D}\right)_{max} = \frac{\sqrt{C_{D_p} \pi AR e}}{2C_{D_p}}$$

To obtain this minimum drag in flight, we must fly at the speed corresponding to the C_L given above. This speed is designated as $V_{(L/D)max}$. Then

$$V_{(L/D)max} = \sqrt{\frac{2W}{\sqrt{C_{Dp} \pi AR e} \rho S}} .$$

Propeller-driven airplanes achieve their best range at the lift coefficient and corresponding speed for $(L/D)_{max}$.

It is customary to study the performance of propeller-driven airplanes in terms of power, since they operate with engines that produce power rather than thrust. Thrust horsepower required for level flight is drag times distance covered per unit time, so

$$550 \, thp_{req} = DV = C_{D_p} \frac{\rho}{2} V^3 S + \frac{C_L^2}{\pi AR e} \frac{\rho}{2} V^3 S .$$

Then $V = \sqrt{2W/C_L \rho S}$ and we obtain

$$thp_{req} = \frac{1}{550} \sqrt{\frac{2W^3}{\rho S}} \left(\frac{C_{D_r}}{C_L^{3/2}} + \frac{C_L^{1/2}}{\pi AR e} \right) .$$

The constant 550 is carried to keep the units in horsepower and the other units in the corresponding English system units. The minimum power will be obtained when the term in parenthesis is a minimum. Taking the derivative of that term with respect to C_L, equating it to zero, and defining $C_{L_{mp}}$ as the lift coefficient for minimum power required leads to

$$-\frac{3}{2} \frac{C_{D_r}}{C_{L_{mp}}^{5/2}} + \frac{1}{2} \frac{1}{\pi AR e C_{L_{mp}}^{1/2}} = 0 .$$

Therefore

$$C_{L_{mp}}^2 = 3\pi C_{D_p} AR e ,$$

and

$$C_{L_{mp}} = \sqrt{3\pi C_{D_p} AR e} = \sqrt{3C_{L_{(L/D)max}}} .$$

Substituting in the induced drag coefficient portion of the equation gives

$$C_{D_{imp}} = \frac{3\pi C_{D_p} AR e}{\pi AR e} = 3C_{D_p} .$$

At the minimum-power condition, the induced drag coefficient is three times as large as the parasite drag coefficient. This contrasts with the minimum drag condition, for which they are equal. Since, for a given total lift, the speed varies inversely as the square root of the lift coefficient, the speed for minimum power is lower than the speed for minimum drag by the ratio $1/(3)^{1/4} = 0.76$. Taking the inverse, the minimum drag speed is 1.32 times the minimum-power speed.

Climb and Descent Performance

Figure 13.162 illustrates the force on an airplane in steady-state constant-speed climb. The thrust is shown acting parallel to the flight path direction. In general, this is not quite true, but in conventional aircraft the effects of an inclination of the thrust vector are small enough to be neglected.

Equating forces perpendicular and parallel to the flight path

$$L = W \cos \gamma ,$$
$$T = D + W \sin \gamma .$$

Then

$$\sin \gamma = \frac{T - D}{W} = \frac{T}{W} - \frac{D}{W} = \frac{T}{W} - \frac{D}{L} ,$$

γ is the flight path angle or angle of climb. We may assume that γ is sufficiently small so that $\cos \gamma$ is approximately equal to 1.0. Then $L = W$.

$$\text{rate of climb RC} = V \sin \gamma = \frac{V(T - D)}{W}$$

For propeller-driven aircraft, it is convenient to use power rather than thrust and drag. If RC is to be determined in feet per minute, the usual units, then with V

in feet per second,

$$\begin{aligned}\text{RC(ft/min)} &= 60\left(\frac{TV - DV}{W}\right)\\ &= \frac{\text{thp}_{\text{avail}} - \text{thp}_{\text{req}}}{W}(33\,000)\\ &= \frac{\text{thp}_{\text{excess}}}{W}(33\,000)\,,\end{aligned}$$

where $\text{thp}_{\text{excess}}$ is the thrust horsepower available for climbing; W is in pounds.

The preceding equations are based on an airplane climbing at constant true airspeed. In practical operations, climbing flight is done at constant indicated airspeed or constant Mach number. This provides the pilot with a simple guide to the proper climb speed, whereas a constant true speed would mean an ever-changing indicator reading as the altitude increases. A constant indicated speed essentially corresponds to a constant calibrated airspeed. At low Mach numbers, this is the same as a constant equivalent airspeed, since the compressibility correction to airspeed is very small.

With a constant equivalent airspeed, the airplane continually accelerates as the altitude increases. The equilibrium equation along the flight path must then include an inertial term. Thus

$$T = D + W\sin\gamma + \frac{W}{g}\frac{\mathrm{d}V}{\mathrm{d}t}\,.$$

Since

$$\frac{\mathrm{d}V}{\mathrm{d}t} = \frac{\mathrm{d}V}{\mathrm{d}h}\frac{\mathrm{d}h}{\mathrm{d}t} \text{ and } \frac{\mathrm{d}h}{\mathrm{d}t} = V\sin\gamma$$

we can write

$$\sin\gamma = \frac{(T-D)/W}{1+(V/g)(\mathrm{d}V/\mathrm{d}h)} = \frac{T-D}{W}\,\text{(K.E. factor)}\,.$$

This equation differs from the previous rate-of-climb equation at constant true speed by the kinetic-energy correction factor $[1+(V/g)(\mathrm{d}V/\mathrm{d}h)]^{-1}$. Approximate values of the term $(V/g)(\mathrm{d}V/\mathrm{d}h)$ are given as functions of Mach number in Table 13.25 for various types of climb paths. Note that, for constant-Mach-number climb below the isothermal atmosphere, the correction increases the rate of climb. In this region, constant Mach number means decreasing velocity as altitude increases because the speed of sound is decreasing. The airplane is losing kinetic energy and trading it for increased rate of climb. When applicable, the kinetic-energy correction factor is applied to gradient-of-climb and rate-of-climb calculations.

The foregoing equations include a surprisingly large amount of useful information. First, the federal air regulations (FARs) specify minimum permissible performance for commercial aircraft in terms of minimum climb gradients, primarily after failure of one engine. A gradient is the tangent of an angle. For small to moderate flight path angles, the sine of the angle is essentially equal to the tangent, so

$$\begin{aligned}\text{gradient } \gamma &= \tan\gamma = \sin\gamma\\ &= \frac{T-D}{W}\,\text{(K.E. factor)}\\ &= \left(\frac{T}{W} - \frac{D}{W}\right)\text{(K.E. factor)}\,.\end{aligned}$$

Thus the gradient depends on the thrust-to-weight ratio minus the inverse of the lift-to-drag ratio.

There are three conditions that are related to an airplane's climb performance. The first is the gradient of climb, important for clearing obstacles close to the ground. The second is the rate of climb, important for

Table 13.25 Kinetic-energy correction factors for climb

Climb operation	Altitude (ft)	$\frac{V}{g}\frac{\mathrm{d}V}{\mathrm{d}h}$ (approx.)
Constant true speed	All	0
Constant v_E	Above 36 150	0.7Ma^2
Constant v_E	Below 36 150	0.567Ma^2
Constant Ma	Above 36 150	0
Constant Ma	Below 36 150	-0.133Ma^2

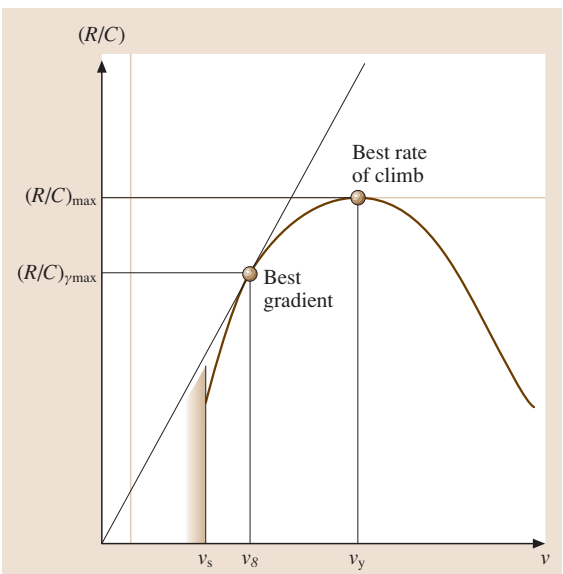

Fig. 13.188 Climb speed diagram

reaching cruise altitude as soon as possible. The third is the best economy of climb, climbing at a higher speed than the best rate of climb speed, but covering more distance in the climb for a given amount of fuel burned. These climb speeds are shown in Fig. 13.188.

Other important performance characteristics can be found from the climb gradient and rate-of-climb equations. If the thrust is zero, then the flight path gradient is the inverse of the L/D ratio, and the rate of descent or sink speed is given by the expression

$$\text{rate of descent} = V/(L/D) .$$

For gliders and sailplanes, these equations are used to develop charts such as the one shown in Fig. 13.189, which provide the essential performance data for these aircraft.

Range

The total range capability of an airplane consists of the climb, cruise, and descent segments. The cruise range is equal to the summation of the range increments obtained by multiplying the miles flown per pound of fuel used (mi/lb) at selected average weights by the appropriate incremental fuel quantity. The value of the miles per pound is called the specific range and is defined as follows.

For jet or turbofan aircraft,

$$\frac{\text{mi}}{\text{lb}} = \frac{\text{miles flown per hour}}{\text{fuel flow (lb/h)}} = \frac{V}{cT} = \frac{V}{cD} ,$$

where c is the specific fuel consumption (SFC) in pounds of fuel per pound of thrust per hour (lb/(lb/h)).

The SFC used in the performance equations is the installed specific fuel consumption. *Installed* means that all adverse effects on SFC associated with the engine installation are included. A typical markup on engine specification SFC for jet and turbofan transports is 3% (i. e., installed SFC equals 1.03 times bare engine SFC). In some cases, for which the engine data are based on zero inlet and nozzle losses, the markup may be twice that amount.

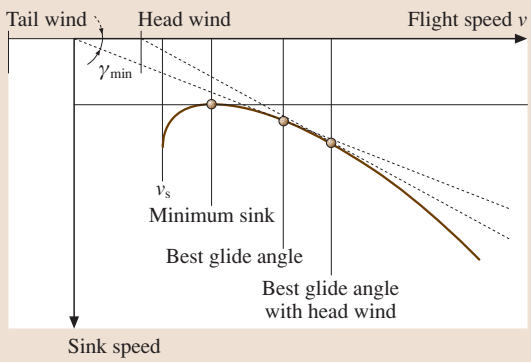

Fig. 13.189 Glider performance chart

Also,

$$D = \frac{W}{L/D} = \frac{D}{L} W$$

and thus

$$\text{mi/lb} = \frac{V}{c(D/L)W} = \frac{V}{c}\frac{L}{D}\frac{1}{W} \text{ (jet)} .$$

The term $(V/c)(L/D)$ is called the range factor and is a measure of the aerodynamic and propulsive system range efficiency. If V is in knots, the range in miles per pound will be in nautical miles per pound of fuel.

For a propeller-driven airplane,

$$\frac{\text{mi}}{\text{lb}} = \frac{V}{c\text{bhp}} ,$$

where c is the specific fuel consumption in pounds of fuel per horsepower per hour (lb/(bhp/h)). Then the range in nautical miles per pound of fuel is

$$\frac{\text{mi}}{\text{lb}} = \frac{V(\text{kn})}{c(\text{thp}/\eta)} = \frac{\eta}{c}\left(\frac{V(550)}{DV \times 1.69}\right) = 325\frac{\eta}{c}\frac{1}{D} = 325\frac{\eta}{c}\frac{L}{D}\frac{1}{W} \text{ (propeller)} .$$

For propeller-driven airplanes, specific range depends only on propeller efficiency, SFC, and L/D; speed is not a factor. Since propeller efficiency and SFC are essentially constant in cruise, range is determined by L/D.

The specific range equation for jet airplanes can also be written as

$$\text{mi/lb} = a\frac{\text{Ma}}{c}\frac{L}{D}\frac{1}{W} ,$$

where a is the speed of sound and Ma is the cruise Mach number. The expression $(\text{Ma}L/D)$ is a measure of the specific range capability due to the aerodynamic characteristics of jet powered airplanes. Curves of $(\text{Ma}L/D)$ versus lift coefficient at various Mach numbers show that jet range is increased by high speed as well as high L/D up to the point where the adverse compressibility drag effect on L/D overpowers the beneficial effect of higher speed. This situation can be summarized on a chart such as that in Fig. 13.190, which shows that,

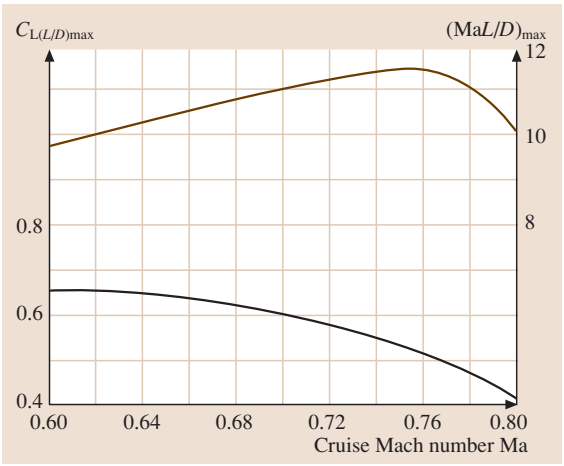

Fig. 13.190 $(MaL/D)_{max}$ and $C_{L(L/D)max}$ for maximum range, jet airplanes

if the SFC is constant with Mach number, the maximum mi/lb value for a jet airplane occurs at a Mach number and lift coefficient where the maximum value of (MaL/D) at each Mach number reaches its peak. However, the turbofan SFC increases slowly with Mach number, so that the optimum range will be obtained at a slightly lower Mach number than taht indicated by Fig. 13.190.

The total cruise range is given by

$$\text{range} = \int_{w_f}^{w_i} \frac{\text{mi}}{\text{lb}}\,\mathrm{d}W\,.$$

If average values of η, c, and L/D can be chosen, the cruise range may be found analytically. For jets,

$$\begin{aligned} R(\text{n. miles}) &= \int_{w_f}^{w_i} \frac{\text{mi}}{\text{lb}}\,\mathrm{d}W \\ &= \int_{w_f}^{w_i} \frac{V}{c}\frac{L}{D}\frac{\mathrm{d}W}{W} \\ &= \frac{V}{c}\frac{L}{D}\log_e\frac{W_i}{W_f}\,. \end{aligned}$$

For propeller-driven planes,

$$\begin{aligned} R(\text{n. miles}) &= \int_{w_f}^{w_i} 325\frac{\eta}{c}\frac{L}{D}\frac{\mathrm{d}W}{W} \\ &= 325\frac{\eta}{c}\frac{L}{D}\ln\frac{W_i}{W_f} \quad \text{(Breguet formula)}\,, \end{aligned}$$

where η, c, and L/D are assumed constant throughout the flight or, more realistically, are taken as effective averages; V is in knots; and c is in lb/(lb/h) or lb/(bhp/h), as appropriate. The range formula for propeller-driven aircraft is called the Breguet formula, after its originator. The analogous jet formula is often similarly labeled.

The total range includes the cruise range plus the distance covered in climb and descent. For long flights, where the cruise portion is dominant, the lower mi/lb in climb due to the higher power being used, and the higher mi/lb in descent due to lower power being used, may be assumed to cancel, allowing the range to be estimated directly from the Breguet range equation, using the appropriate parameters chosen at an average weight. For short flights, where climb is a large portion of the total trip, this approximation may result in a significant error.

A summary of the payload–range characteristics of an airplane is shown in Fig. 13.191. The payload–range curve is one of the most important performance curves for a commercial transport or business jet. It establishes the envelope which shows how far the airplane can carry a given payload, or how much payload it can carry over a given range.

The payload–range curve applies to a specific airplane–engine combination (MWE, OWE, interior seating arrangement, fuel-tank configuration, MTOGW), operating under specific flight rules (cruise Mach number, altitude, altitude steps, alternate distance). The maximum payload is usually the volume or space limit payload (full passengers + bags and full cargo containers or pallets at some standard cargo density, i. e., 10 lb/ft^3) or the maximum zero-fuel weight limit payload, based on the structural limit of maximum zero-fuel weight. When operating on the maximum

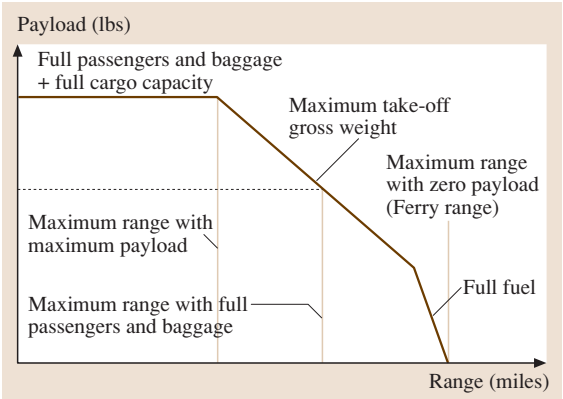

Fig. 13.191 Payload–range curve

take-off weight limit, it is necessary to trade payload for fuel if greater range is desired. Operating on the fuel capacity limit line requires large reductions in payload to achieve small increases in range, due to modest improvements in cruise efficiency achieved by reductions in cruise weight. The key points on the payload range curve are calculated using the Breguet range equation for jet aircraft

$$\text{Range (n. miles)} = \left(\frac{V}{c}\right)\left(\frac{L}{D}\right)\ln\frac{W_\text{i}}{W_\text{f}}\,.$$

For a specific design, on a particular cruise operation, V, C, and L/D are usually taken as constants, W_initial and W_final are derived from known weights, i. e., OEW, payload, reserve fuel, maximum take-off weight, maximum fuel capacity. From this equation, it can be seen that maximum range is achieved by cruising at a point where the quantity VL/D is a maximum.

Some key ideas about payload range curves are as follows:

- Weight-limited payload = MZFW − OWE.
- Space-limited payload is slightly lower.
- Passengers + bags range is usually set by MTOGW.
- Greater passengers + bags range can be achieved by increasing MTOGW (allows more fuel to be carried).
- If passenger + bags range is limited by maximum fuel capacity, greater range can be achieved only through increased fuel capacity.

Endurance

The endurance problem is similar to the range problem except that we are trying to determine how long the aircraft will fly rather than how far it will fly. The quantity analogous to specific range is specific endurance, the hours flown per unit quantity of fuel. In the usual units, specific endurance is measured in hours per pound of fuel.

To maximize endurance, fuel flow per unit time must be minimized. Since the specific fuel consumption is nearly constant, the drag must be minimized for jet aircraft, while thrust horsepower must be as small as possible for propeller-driven aircraft. The endurance t_e for turbojet or turbofan aircraft is

$$t_\text{e} = \int_{w_\text{f}}^{w_\text{i}} \text{h/lb fuel}\,\mathrm{d}W = \int_{w_\text{f}}^{w_\text{i}} \frac{1}{Dc}\,\mathrm{d}W$$

$$= \int_{w_\text{f}}^{w_\text{i}} \frac{1}{[W/(L/D)]c}\,\mathrm{d}W$$

$$= \int_{w_\text{f}}^{w_\text{i}} \frac{1}{c}\frac{L}{D}\frac{\mathrm{d}W}{W} = \frac{1}{c}\frac{L}{D}\ln\frac{W_\text{i}}{W_\text{f}}\,.$$

Again, c and L/D are assumed to be constant throughout the flight, or taken as average values. Note the similarity between this equation and the jet range equation.

Endurance is simply range divided by speed. For the greatest endurance, the aircraft should obviously fly at the speed for minimum drag. This, of course, assumes that c is a constant with speed, a good assumption for jets but not quite true for turbofans. In addition, at very low engine thrust levels, c tends to increase as the thrust is decreased. This may also influence the speed for best endurance.

For propeller-driven aircraft, endurance is

$$t_\text{e} = \int_{w_\text{f}}^{w_\text{i}} \frac{1}{\text{thp}\,c/\eta}\,\mathrm{d}W = \int_{w_\text{f}}^{w_\text{i}} \frac{\eta}{c}\left(\frac{550}{DV\times 1.69}\right)\mathrm{d}W$$

$$= \int_{w_\text{f}}^{w_\text{i}} 325\frac{\eta}{c}\frac{L}{DV}\frac{1}{W}\,\mathrm{d}W\,,$$

where V is in knots and c is in pounds of fuel per brake horsepower per hour. We cannot assume that L/DV is a constant. L/DV is the ratio of lift to thrust power required, and we have shown that thp_req is a nonlinear function of weight. At any given lift coefficient, power required varies with $W^{3/2}$. However, it has been shown that, if V is expressed as $\sqrt{2W/C_\text{L}\sigma\rho_\text{s}S}$, t_e is given by

$$t_\text{e}(\text{h}) = 37.9\left(\frac{\eta}{c}\right)\frac{C_\text{L}^{3/2}}{C_\text{D}}\sqrt{\frac{\sigma S}{W_\text{i}}}\left[\left(\frac{W_\text{i}}{W_\text{f}}\right)^{1/2} - 1\right].$$

Here we see that, for best endurance, a propeller-driven airplane should be flown at the flight condition for maximum $C_\text{L}^{3/2}/C_\text{D}$. It is a maximum when the lift coefficient is $\sqrt{3}$ times the value for maximum lift-to-drag ratio. Since low speed as well as a particular lift coefficient is desirable for minimum power required, best endurance occurs at a high density (i. e., low altitude). Therefore, propeller aircraft endurance is best at low altitudes.

Take-Off Performance

The take-off performance problem is basically an acceleration to the required speed plus a transition to climb

at a 35 ft height for civil turbine-powered transports, or a 50 ft height for piston-engine general aviation or military airplanes. The required runway length is defined as the distance from the start of take-off to the point where these *obstacle* heights are reached. The take-off field length required by FARs for jet transport operation is the greater of:

1. The all-engine take-off distance ×1.15
2. The take-off distance with an engine failure at the *most critical point* in the take-off

The most critical point is where the distance to stop on the runway is equal to the distance to continue the take-off with one engine failed to a height of 35 ft. This situation is called the balanced field length concept. The most critical point in a given take-off, where the *accelerate–stop* distance is equal to the *accelerate–continue* distance is found by plotting the accelerate–stop distance and accelerate–continue distance versus the engine failure speed, as shown in Fig. 13.192.

For propeller-driven transports, the FAR balanced field length concept is the same, but the speed at 35 ft is $1.15V_S$ for four or more engines, and $1.2V_S$ for two or three engines.

For single and multi-engine normal, utility, and acrobatic aircraft under 12 500 lb maximum gross weight, FAR 23 specifies only the all-engine take-off distance to a height of 50 ft with a speed equal to or greater than $1.3V_S$ at 50 ft. For FAR 23 commuter-category aircraft, the balanced field length concept is applied and the criteria for take-off are basically the same as for FAR 25, except that the take-off distance is defined to a 50 ft height, and the speed at 50 ft must be at least $1.3V_S$.

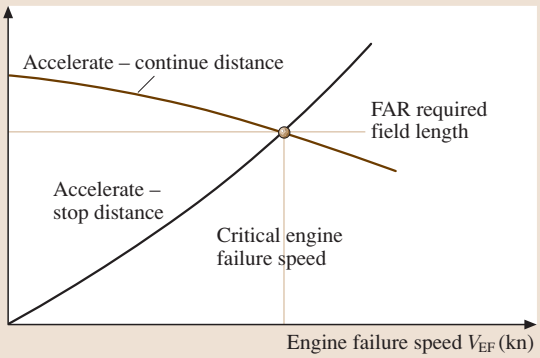

Fig. 13.192 Determination of FAR balanced field length with engine failure

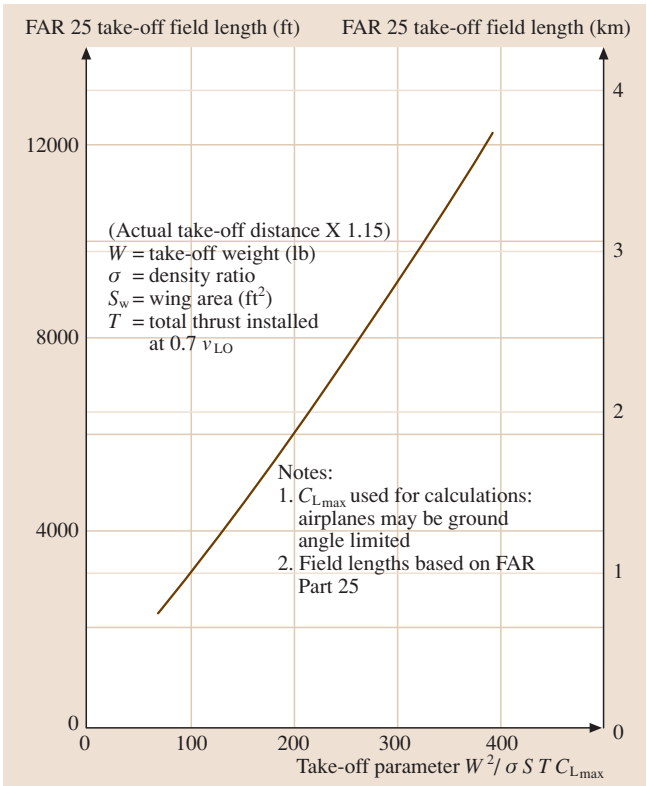

Fig. 13.193 FAR 25 all-engines-operating take-off field length to a 35 ft height

Analysis and flight test suggest that the distance to liftoff is a function of several airplane factors, namely

$$d_{LO} = f\left(\frac{W^2}{\sigma S C_{L_{max}} T}\right),$$

where $\sigma = \rho/\rho_s$ and T is the thrust at $0.7V_{LO}$. Since the ground run distance to lift-off is about 80% of the total distance to the 35 ft height, it has been shown that this parameter works very well in correlating the required runway length results for many aircraft. Figure 13.193 shows the FAR all-engines-operating take-off field length to a 35 ft height d_{35} for jet or turbofan aircraft as a function of $W^2/\sigma S C_{L_{max}} T_{0.7V_{LO}}$. This chart applies to normal take-off without engine failure and includes a 15% increase above the actual performance in accordance with the air transport requirements of FAR 25.

The actual distance is the distance determined from Fig. 13.193 divided by 1.15. Figure 13.194 shows the FAR one-engine-inoperative take-off field length for two-, three-, and four-engine transports.

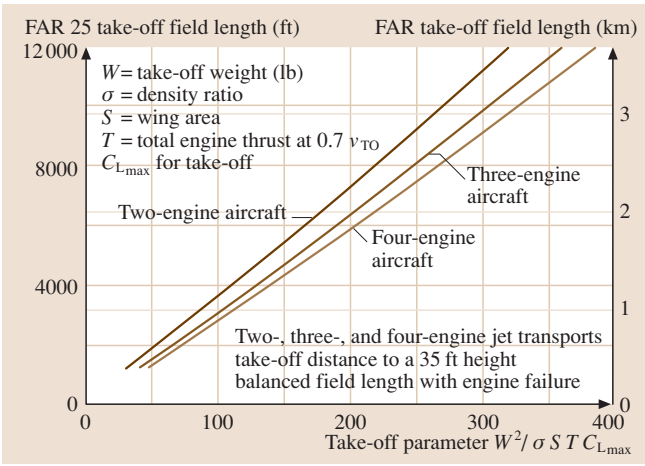

Fig. 13.194 FAR 25 one-engine-inoperative take-off field length

For propeller-driven aircraft, a comparable analysis shows that take-off distance is a function of $W^2/\sigma S C_{L_{max}} P$, where P is the total brake horsepower. This is a less accurate approximation, since the effectiveness of the power depends on the propeller efficiency during take-off. Use of this parameter assumes that all propellers are designed to attain a similar level of efficiency in take-off.

Landing Performance

Landing distances consist basically of two segments: the air run from a height of 50 ft to the surface accompanied by a slight deceleration and flare, and the ground deceleration from the touchdown speed to a stop. Landing runway lengths are required by FAR 25 for commercial aircraft to be demonstrated by flight tests. The air distance d_{air} can be approximated by a steady-state glide distance d_{GL} plus an air deceleration distance d_{decel} at constant altitude, as shown in Fig. 13.195.

V_{50} is the speed at the 50 ft height. In accordance with FAR 25, V_{50} must be at least $1.3V_S$. In practice, it is taken as equal to $1.3V_S$. V_L is the landing or touchdown

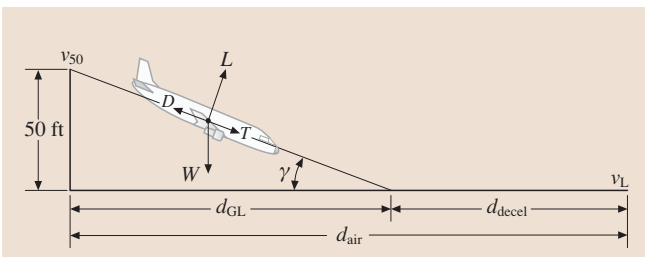

Fig. 13.195 Landing air distance

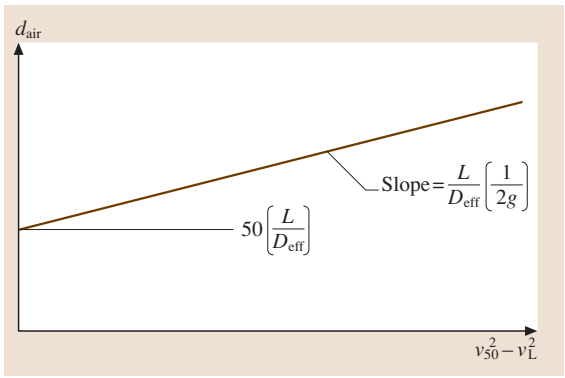

Fig. 13.196 Landing air run determination

speed and is usually about $1.25V_S$. The glide distance is

$$d_{GL} = 50\left(\frac{L}{D_{eff}}\right),$$

where $D_{eff} = D - T$,

$$d_{decel} = \frac{V_{50}^2}{2a} - \frac{V_L^2}{2a} = \frac{\frac{1}{2}\left(\frac{W}{g}\right)V_{50}^2 - \frac{1}{2}\left(\frac{W}{g}\right)V_L^2}{D_{eff}}.$$

Since lift is essentially equal to the weight,

$$d_{air} = 50\frac{L}{D_{eff}} + \frac{1}{2g}\left(V_{50}^2 - V_L^2\right)\frac{L}{D_{eff}}$$
$$= \frac{L}{D_{eff}}\left[50 + \frac{1}{2g}\left(V_{50}^2 - V_L^2\right)\right].$$

L/D_{eff} is the effective L/D ratio during the air run. It can be determined from flight test air runs by plotting flight test air run distances versus $(V_{50}^2 - V_L^2)$, as illustrated in Fig. 13.196.

The ground deceleration distance is

$$d_G = \frac{V_L^2}{2a} = \frac{V_L^2}{2[R/(W/g)]},$$

where

R = effective average resistance or total stopping force
$= \mu(W - L) + D$,
μ = braking coefficient of friction (Table 13.26),
D = drag, including drag of flaps, slats, landing gear, and spoilers.

Note that both d_{air}, air distance, and d_G, ground stopping distance, are directly proportional to V_{50}^2 and/or V_L^2. Both V_{50}^2 and V_L^2 are fixed percentages above V_S for safety reasons. Thus landing distance is linear in V_S^2 except for the glide distance from 50 ft, which depends only on the L/D in the landing configuration.

Table 13.26 Runway friction coefficients

Surface	μ typical values	
	Rolling (brakes off)	Brakes on
Dry concrete/asphalt	0.03–0.05	0.3–0.5
Wet concrete/asphalt	0.05	0.15–0.3
Icy concrete/asphalt	0.02	0.06–0.10

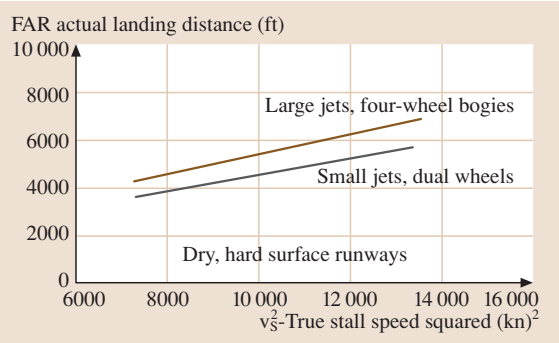

Fig. 13.197 FAR 25 demonstrated landing distance

Thus, for similar airplanes with similar L/D values and equivalent braking systems (i. e., similar μ), landing distances can be of the form

$$d_{\text{land}} = A + BV_S^2 ,$$

where $A = 50(L/D)_{\text{eff}}$.

The FAR 121 scheduled landing field length is defined as the actual FAR 25 demonstrated distance from a 50 ft height to a full stop on a dry, hard surface runway, increased by a factor of 1/0.60, i.e., a 67% increase. Curves of landing field length versus V_S^2 based on flight tests (Fig. 13.197) are linear, but vary between airplanes due to the effective L/D in the air run, the effective coefficient of friction, and the drag in the ground deceleration. It should be noted that the FAR dry runway tests do not allow the use of engine thrust reversers. FAR dry runway distances must be increased by 15% for operation on wet runways.

13.4.10 Stability and Control

The subject of airplane stability and control deals with the ability of an airplane to fly straight with wings level without pilot input (stability) and the ability of the pilot to produce moments about the various airplane axes (control). *Static stability* refers to the initial tendency of the airplane to return or move away from its equilibrium position following a disturbance. *Dynamic stability* is concerned with the entire history of the airplane motion, in particular whether the motion subsides or diverges. In the following discussion, the airplane will usually be treated as a rigid body, a reasonable assumption for the majority of conditions studied. However, at high dynamic pressures many of the structural elements deflect under aerodynamic loads, which further complicates stability and control analysis. The study of the behavior of the structural elements under load and the interaction with aerodynamic load is called *aeroelasticity*. Aeroelastic effects usually tend to reduce static stability. In extreme cases, this interaction may lead to dangerous undamped structural oscillations called *jitter*. The rigid-body motions of an airplane may be divided into two classifications: longitudinal and lateral motions. *Longitudinal motions* occur in the plane of symmetry, whereas *Lateral motions* displace the plane of symmetry. For normal symmetric airplanes, with small displacements from equilibrium, these two types of motions are independent of each other.

Static Longitudinal Stability

Static aerodynamic stability in pitch, more commonly known as static longitudinal stability, is most easily achieved through the use of an aft-mounted horizontal tail. In concept, static longitudinal stability may be defined as the tendency of the airplane to return to its original flight condition without pilot input, when disturbed from steady, unaccelerated flight. While not an absolute requirement for sustained, controlled flight, static longitudinal stability has been found to be a desir-

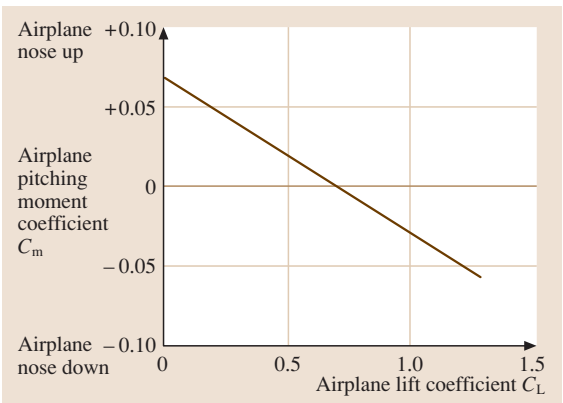

Fig. 13.198 Airplane pitching moment curve

able characteristic for ease of flight, that the variation of airplane pitching moment coefficient C_m with airplane lift coefficient C_L has a negative slope, as shown on the pitching moment diagram in Fig. 13.198.

It should be noted that the pitching moment coefficient is defined with respect to the airplane center of gravity (c.g.) location, expressed as a percentage of the wing mean aerodynamic chord (m.a.c.) aft of the leading edge. For example, with a c.g. location expressed as 25% m.a.c., the c.g. is located at a distance of 25% of the m.a.c. length aft of the leading edge of the m.a.c. Using the sign convention noted earlier, the negative slope of the pitching moment curve means that, for an airplane in equilibrium (pitching moment equal to zero) in steady, un accelerated flight at a given lift coefficient, any disturbance which increases the airplane lift coefficient will result in a negative, or airplane nose down (AND), pitching moment coefficient.

Effect of C.G. Location. It can be shown by analysis of the equation for the airplane pitching moment coefficient versus lift coefficient that the airplane c.g. location has a powerful effect on static longitudinal stability. The results of this analysis show that for every 1% of m.a.c. that the c.g. is moved forward, the slope of the pitching moment curve, dC_m/dC_L about that c.g. will become more negative by 0.01. This point is illustrated for a typical airplane configuration in Fig. 13.199. In this figure, the pitching moment curve with the c.g. located at 25% m.a.c. shows a negative (stable) slope of −0.05. If the c.g. is moved forward to 20% m.a.c., the pitching moment curve about this c.g. location shows a negative (stable) slope of −0.10, indicating that a 5% forward movement in c.g. location results in a pitching moment curve that is more negative by 0.05. Similarly, if the c.g. is moved aft, the pitching moment curve will have a less stable (negative) slope about that c.g. location. In Fig. 13.199, if the c.g. location is moved aft to 30% m.a.c., then the slope of the pitching moment curve about this c.g. location is zero.

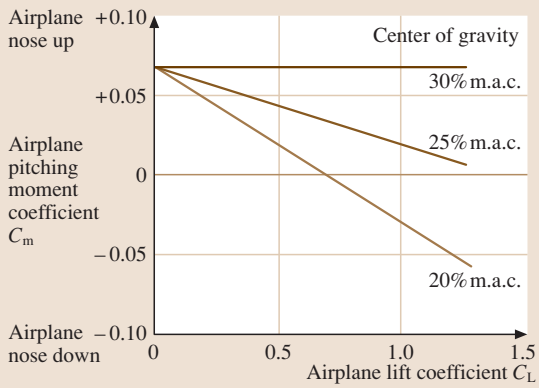

Fig. 13.199 Effect of c.g. location on airplane pitching moments

This situation illustrates another important concept in the discussion of static longitudinal stability, that of aerodynamic center.

Aerodynamic Center. From basic aerodynamics, the aerodynamic center location for any configuration is defined as the center of constant pitching moments, that is, the c.g. location where the pitching moment coefficient remains constant as the lift coefficient varies. In the illustration of Fig. 13.199, the aerodynamic center for the configuration shown is at 30% m.a.c., since for this c.g. location the pitching moment coefficient, C_m, is constant as the lift coefficient varies. For any aircraft configuration, the criterion for achieving static longitudinal stability is that the aircraft c.g. must be located forward of the airplane aerodynamic center (a.c.). This criterion applies to all types of configurations, conventional aft-tail arrangements as well as canards, three-surface layouts, and even flying wings. However, as we shall see, this stability criterion is most easily met using a conventional aft-mounted horizontal tail. Again referring to Fig. 13.199, with the c.g. located at 25% m.a.c. and the a.c. located at 30% m.a.c., this configuration meets the criterion for static longitudinal stability, and with dC_m/dC_L equal to −0.05 is said to be stable by 5% m.a.c. With the c.g. located at 20% m.a.c. and the a.c. at 30% m.a.c., dC_m/dC_L is −0.10 and the configuration is said to be stable by 10% m.a.c. Expressed in equation form

$$dC_m/dC_L = X_{c.g.} - X_{a.c.},$$

where X is expressed in terms of a percentage of the m.a.c.

Aerodynamic Center Buildup. The aerodynamic center location for a complete airplane configuration is determined by the contribution of the various elements of the configuration in pitch. The contributions of these elements can be calculated with reasonable accuracy, but are usually verified by wind-tunnel model tests very early in the preliminary design phase. The major contributors to the complete configuration aerodynamic center are the wing, fuselage, engine nacelles, and the horizontal tail. A typical wind-tunnel model buildup to determine the contributions of these elements to the

complete configuration a.c. is shown in Fig. 13.200. These data are all referred to a c.g. location of 25% m.a.c. By measuring the slope of the pitching moment curve about this c.g., one can obtain the a.c. location for any configuration made up of the major elements that contribute to the a.c. location as

$$X_{\text{a.c.}} = 0.25 - (\mathrm{d}C_\mathrm{m}/\mathrm{d}C_\mathrm{L})\,.$$

Figure 13.200 summarizes the a.c. locations for the various partial configurations, leading up to the complete configuration a.c. Also shown is the contribution of the various elements to the complete airplane a.c.

The wing alone a.c. is at 22.6% m.a.c. The wing plus fuselage a.c. is at 16.3% m.a.c., indicating that the fuselage has a destabilizing or unstable contribution of 0.063 or 6.3% m.a.c. The wing plus fuselage plus engine nacelles have an a.c. location of 11.0% m.a.c., indicating that the nacelles have an unstable contribution of 5.3% m.a.c. to the a.c. location. The addition of the horizontal and vertical tails to the model results in an a.c. location for the complete configuration of 42.7% m.a.c. Since the vertical tail has no aerodynamic contribution in pitch, the horizontal tail provides a strong stabilizing contribution of 31.7% m.a.c. Some generalizations may be made from the data. First, the wing-only a.c. is usually around 25% m.a.c., not surprising since the a.c. for nearly all airfoil sections which make up the wing is within 1% m.a.c. or so of the 25% m.a.c. point. Wing sweep may also move the wing alone a.c. a percent point or two, usually aft. Secondly, fuselages are destabilizing contributors, tending to move the a.c. location forward. The larger the fuselage is relative to the wing, the more destabilizing will be its contribution to the complete airplane a.c. Forward-mounted nacelles, like the ones shown on the model in Fig. 13.200, are also destabilizing, although aft fuselage-mounted nacelles are usually stabilizing. Finally, the aft horizontal tail is a major stabilizing contributor to the complete airplane a.c. location. It can be shown that the horizontal tail contribution to static longitudinal stability is dependent on the distance between the 25% chord point on the wing m.a.c. and the 25% m.a.c. point on the horizontal tail, called the horizontal tail length l_H, and the horizontal tail area S_H. This is quite logical since static longitudinal stability involves the generation of aerodynamic restoring moments which are dependent on an aerodynamic force from the horizontal tail (proportional to the horizontal tail area) and a moment arm (proportional to the horizontal tail length).

Longitudinal Control

In addition to providing a major contribution to static longitudinal stability, the horizontal tail is also a source of longitudinal control moments. These control moments are used by the pilot to achieve equilibrium in pitch ($C_\mathrm{m} = 0$) at any desired lift coefficient, allowing control of airspeed in unaccelerated flight, and the curvature of the flight path in accelerated flight. A typical pitching moment diagram illustrating the control moment required to balance the pitching moment at another lift coefficient is shown in Fig. 13.201.

This airplane is stable about its c.g. with a $\mathrm{d}C_\mathrm{m}/\mathrm{d}C_\mathrm{L}$ equal to -0.10, and is in equilibrium ($C_\mathrm{m} = 0$) at a lift coefficient $C_\mathrm{L} = 0.5$. This means that the airplane will fly steadily at a speed corresponding to this lift coefficient, and its static longitudinal stability will resist any disturbances tending to deviate from this speed. If the pilot desires to slow the airplane

down, and fly at a $C_L = 1.0$, he must be equipped with some type of control that can overcome the airplane nose-down moment coefficient of -0.05 at a $C_L = 1.0$, as shown in Fig. 13.201, in order to establish equilibrium at $C_L = 1.0$. Obviously, the more stable the airplane, the more control power that must be provided to change the equilibrium lift coefficient. Thus the designer must achieve a proper balance between the amount of static longitudinal stability provided and the amount of control power available. Longitudinal control power is usually provided through the hinged, moveable aft portion of the horizontal tail (elevators), although in some designs the control power is provided by moving the entire horizontal tail about a fixed pivot point (all-moveable horizontal tail or stabilator).

Longitudinal control capability for a specific configuration may be shown on a pitching moment diagram

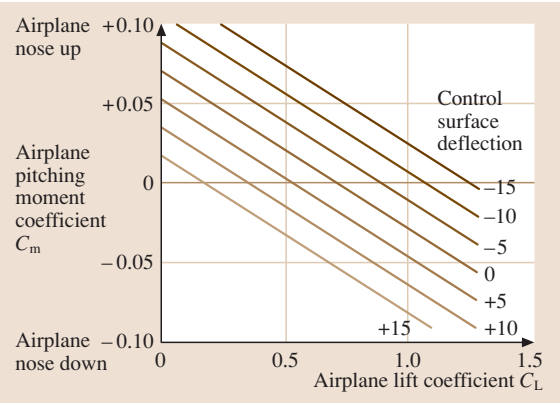

Fig. 13.202 Pitching moment diagram – effect of control deflections

(Fig. 13.202), in which the pitching moment curves with various control surface deflections show the control deflection required to obtain equilibrium at various lift coefficients. Notice that a negative (trailing-edge-up) control deflection produces a positive (airplane-nose-up) pitching moment.

Static Directional Stability

Static directional stability for an airplane is defined as its tendency to develop restoring moments when disturbed from its equilibrium sideslip angle, normally zero. The static directional stability of an airplane is assessed from a chart of yawing moment coefficient, C_n, versus sideslip angle β as shown in Fig. 13.203. Using the sign convention of Figs. 13.155 and 13.157, a positive value of $dC_n/d\beta$ is required for static directional stability; i. e., a positive (airplane-nose-left) sideslip produces a positive (airplane-nose-right) yawing moment.

Similar to the longitudinal case, the static directional stability of an airplane may be determined by adding up the contributions of the various elements of the configuration in sideslip. Analysis has shown that the main contributors to the airplane static directional stability are the fuselage and the vertical tail. The wing, a major element in longitudinal stability, has a negligible effect on the directional stability. This is due to the fact that an angle of sideslip produces very small cross-wind forces on the wing, whereas an angle of attack can produce very large lift forces. The fuselage is a major contributor to static directional stability, and its contribution is always unstable (destabilizing). The stabilizing contributor to static directional stability is the vertical tail, in reality a low-aspect-ratio wing attached to the aft fuselage. The contribution of the major ele-

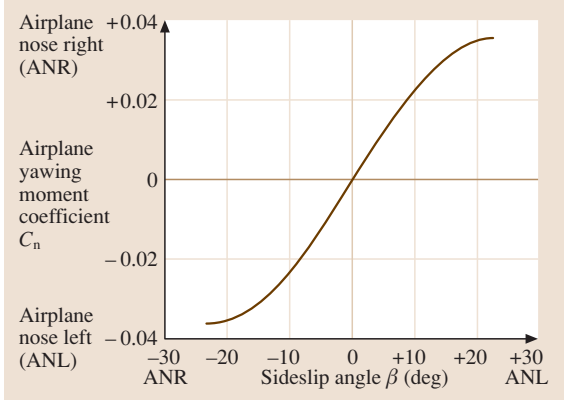

Fig. 13.203 Typical directional stability diagram

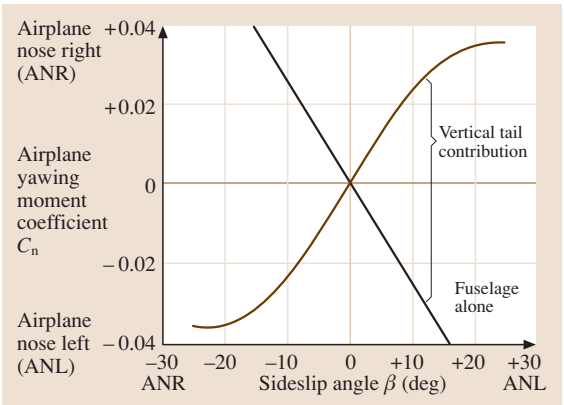

Fig. 13.204 Directional stability buildup

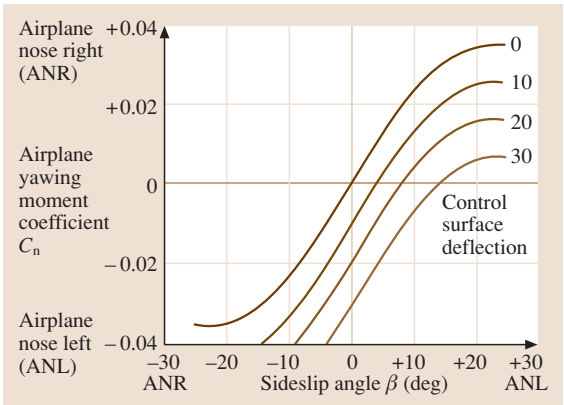

Fig. 13.205 Directional stability diagram – effect of control deflections

ments is shown in Fig. 13.204. When a sideslip angle develops due to a disturbance, the vertical tail experiences an increase in its angle of attack, and produces a restoring moment. The loss in directional stability at high sideslip angles, the *roundover* of the directional stability curve, is due to the vertical tail reaching its maximum lift capability, and stalling as the sideslip angle is increased. This roundover is not desirable and is often offset by the addition of a dorsal fin located at the intersection of the vertical tail leading edge and the fuselage. The magnitude of the restoring moment generated by the vertical tail depends on the distance from the airplane c.g. to the 25% m.a.c. point on the vertical tail, called the vertical tail length l_v and the vertical tail area S_v. For convenience l_v is usually taken from the 25% m.a.c. point on the wing, rather than the c.g.

Directional Control

The vertical tail also provides the means for directional control. The predominant means is through a hinged, moveable aft portion of the vertical tail (rudder), although some advanced military aircraft use all-moveable verticals. As shown in Fig. 13.205, directional control is used to obtain equilibrium ($C_n = 0$) in steady sideslips. This figure shows that 30° of left rudder produces about 14° of positive sideslip.

Another requirement for directional control is to offset the asymmetric thrust moment which develops on a multi-engine airplane when one engine becomes inoperative. In this situation, the aerodynamic moment from the vertical tail at or near-zero sideslip with the control surface deflected must balance the thrust moment caused by the loss of one engine. This situation is most critical at low speeds during take-off. The minimum speed for which it is possible to maintain directional equilibrium ($C_n = 0$) during take-off with one engine inoperative is called the minimum control speed V_{mc}, which may be obtained graphically by the intersection of the yawing moment due to the inoperative engine and the yawing moment due to full directional control, as shown in Fig. 13.206.

A summary of typical pilot control systems for airplanes is shown in Table 13.27.

Longitudinal Dynamics

In order to understand the requirements for static stability and control, it is necessary to study the dynamic

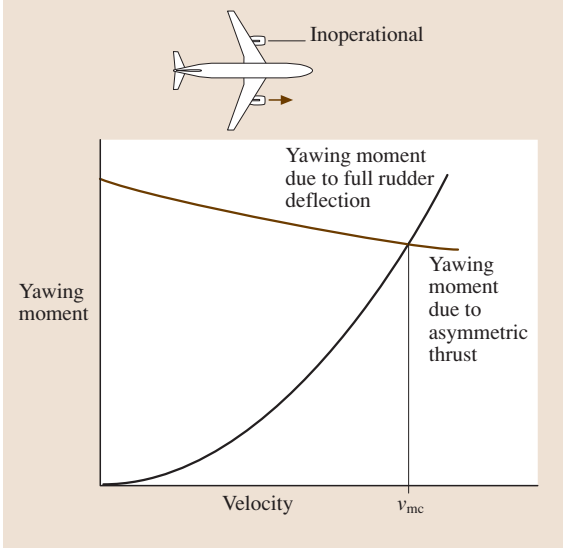

Fig. 13.206 Determination of ground minimum control speed

Table 13.27 Typical pilot control systems

Control about	Cockpit controller	Control direction	Airplane response

Vertical axis	Pedal right Pedal left	Yaw	Nose right Nose left

characteristics of the airplane, investigating the types of motion that characterize the response of the airplane to a disturbance from some equilibrium flight condition and the nature of the transient motions of the airplane to the movement of its controls. Dynamic systems in general have four different modes of motion when responding to a disturbance from an equilibrium condition. These modes are oscillatory or periodic, damped or undamped, as shown in Fig. 13.207.

The characteristic modes for nearly all airplanes are two oscillations, one of long period with poor damping, called the *phugoid*, and one of short period with heavy damping, called the *short period*. The *phugoid* oscillation is one in which there is a large-amplitude variation in airspeed, pitch angle, and altitude The short period is a heavily damped oscillation in which the angle of attack varies at nearly constant speed.

Lateral Dynamics

There are two types of lateral dynamic motions. The first is called the *spiral mode*, which involves variations in bank angle and sideslip. This mode is usually a pure divergence, starting with a slow spiral in the direction of the disturbance, which if uncorrected, will develop into a high-speed spiral dive. The second motion is called the *Dutch roll*, because of its similarity to the well-known ice skating figure. This is an oscillatory motion involving variations in roll and yaw angles that for straight-wing propeller-driven airplanes is usually damped. However for swept-wing airplanes, the Dutch roll oscillation is often lightly damped or mildly divergent, requiring the installation of a supplemental *yaw damper* system to provide satisfactory damping.

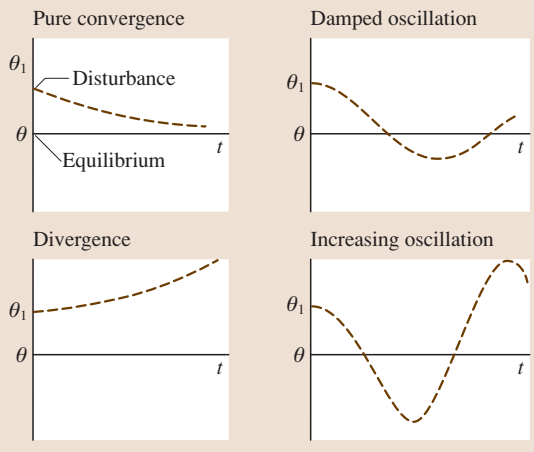

Fig. 13.207 Typical modes of motion

Maneuverability and Turning

The airplane flight path is controlled by varying the magnitude of the lift vector and by varying the output of the power plant. The magnitude of the lift vector is directly related to the lift coefficient through the angle of attack. The pilot can vary the angle of attack by controlling the pitching moment contributed by the control surfaces so that the pitching moment for the complete airplane is zero at the desired lift coefficient. From a steady unaccelerated level-flight condition, a maneuver in the plane of symmetry is initiated by a pilot control input to produce a positive nose-up pitching moment. This nose-up pitching moment will be balanced at some higher lift coefficient by the airplane's static

Load factors in level flight turns

75	5.464
90	∞

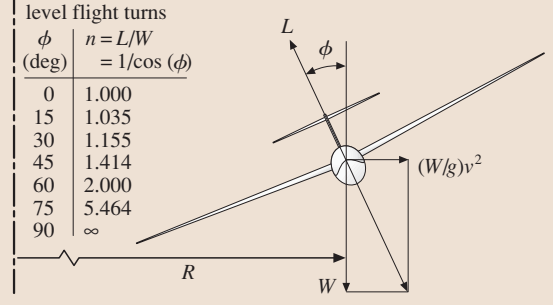

Fig. 13.208 Forces and load factors in level flight turns

longitudinal stability. If the longitudinal control input is made fairly rapidly, the speed will not have time to reduce to the speed required for equilibrium, and the lift will exceed the weight. With lift greater than weight, the airplane will experience a vertical acceleration. The maneuver just described is called an *abrupt pull-up* and may be the start of more complicated maneuvers. For a level-flight turn, referring to Fig. 13.208, the horizontal component of the lift vector accelerates the airplane laterally and curves the flight path. In a turn of radius R, the lateral force $L\sin\phi$, where ϕ is the angle of bank, must balance the centrifugal force on the airplane. Thus

$$L\sin\phi = \frac{(W/g)V^2}{R} \,. \tag{13.5}$$

For a level-flight turn, the weight W must be equal to the vertical component of lift $L\cos\phi$. Substituting in (13.5), we obtain

$$L\sin\phi = \frac{[(L\cos\phi)/g]V^2}{R} \,,$$

$$\tan\phi = \frac{V^2}{gR} \,. \tag{13.6}$$

Equation (13.6) specifies the angle of bank required for any speed and radius of turn. Conversely, the radius of turn is given by

$$R = \frac{V^2}{g\tan\phi} \,.$$

Also, since for a level-flight turn

$$W = L\cos\phi \,,$$

it follows that the lift for such a turn must be given by $L = W/\cos\phi$ and

$$\frac{L}{W} = \frac{1}{\cos\phi} = n \,.$$

As we shall see later, the quantity $n = L/W$ is an important parameter defined as the *load factor*.

13.4.11 Loads

Aircraft structures must be designed to withstand the most serious of the infinite number of possible combinations of external loads that may act on it in flight and when landing. Experience, accumulated over many years of design, analysis, and research, has led to the formulation of a very rational set of procedures that determine the design loads and define the airspeeds for which the design loads are imposed. For civil aircraft, these requirements and procedures are described in the federal air regulations (FAR) part 23 and part 25 *Airworthiness Standards, Airplanes*. For military aircraft, these requirements and procedures are described in MIL-A-8660, *Airplane Strength and Rigidity, General Specification For* and MIL-A-8661, *Airplane Strength and Rigidity, Flight Loads*. The requirements are, in most cases, nearly identical in both the civil and military documents. The information that follows will be based on FAR 23 and 25, with information from MIL-A-8660 and MIL-A-8661 added where significant differences exist:

- Flight conditions (FAR 25.331–25.459):
  - Maneuver load generated by intentional pilot application of controls
  - Gust load generated by sudden change in angle of attack due to encountering a *gust*
- Landing conditions (FAR 25.473–25.511):
  - Level landing
  - Tail-down landing
  - One-wheel landing
  - Side load conditions
  - Braked roll conditions
  - Yawing conditions

Air Loads

Flight Load Factor. An important concept in the analysis of air loads imposed under various flight conditions is the flight load factor n, which is defined as follows

$$n = \frac{\text{aerodynamic force} \perp \text{longitudinal axis}}{\text{aircraft weight}} \,.$$

For an aircraft in steady, level flight, the aerodynamic force perpendicular to the longitudinal axis is given by the lift, which is equal to the weight. Since the weight is due to the force of gravity, the aircraft is said to be in 1 g flight. If the lift is four times the weight, the aircraft is subjected to 4 g's. In a simpler form,

$$n = \frac{\text{lift}}{\text{weight}} \,.$$

V–n Diagrams. The analysis of the critical design air loads for an aircraft employs a chart known as the V–n diagram. These charts show flight load factors as a function of equivalent airspeed and represent the maximum load factors expected in service, based on the requirements of the applicable specifications. These load factors are called *limit* load factors. The airplane structure must withstand these loads without damage.

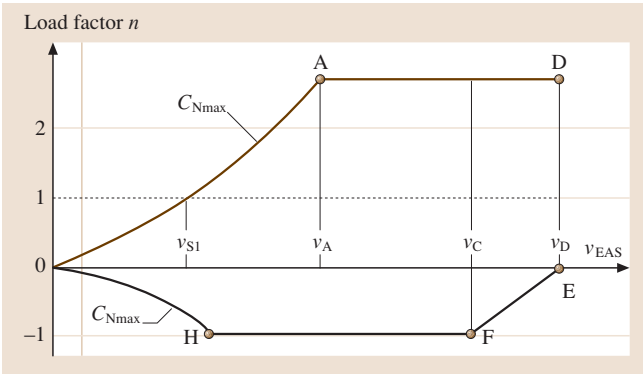

Fig. 13.209 *V–n* diagram: maneuvering envelope

These limit loads are multiplied by a safety factor of 1.5 to define *ultimate* or failure loads. There are two types of *V–n* diagrams; one to define maneuver load factors, and one to define gust load factors.

V–n Diagram: Maneuver Envelope FAR 23.333 and FAR 25.333. The *V–n* diagram showing the maximum maneuver load factors that must be used for structural design (Fig. 13.209) is an envelope defined by various lines and points which have a specific relationship to the design load factors. A brief explanation of the key portions of the maneuvering envelope is given below.

Line 0–A. This line describes the load factor that results when the aircraft is maneuvered to its maximum normal force coefficient $C_{N_{max}}$ in the clean or cruise configuration. Since this is the maximum normal force that can be generated by the aerodynamic characteristics of the configuration, it is the maximum load factor that can be generated by the pilot. The equation of this line is $n = C_{N_{max}} qS/W$.

Point A. This is the intersection of the pull up to $C_{N_{max}}$ with the maximum positive maneuver load factor specified in the requirements for the particular type of aircraft being designed. It should be noted that point A is not selected by the designer, but is determined uniquely by the aircraft parameters and the maneuver limit load factor for the type.

Line A–D. This is the maximum positive maneuver load factor for the type. The design limit load factors for various aircraft types were determined many years ago from flight tests of a number of airplanes of various types, each subjected to a number of typical maneuvers. These tests were made with an accelerometer placed at or near the airplane center of gravity, which recorded the imposed accelerations. Experience has indicated that these load factors resulted in highly satisfactory designs.

Table 13.28 Maximum maneuver load factors

Aircraft type	Max positive	Max negative
Normal	3.8	1.52
Acrobatic	6.0	3.00
Commuter	3.8	1.52
Utility	4.4	1.76

Line 0–H. This line describes the load factor generated when the airplane is maneuvered to its maximum negative $C_{N_{max}}$ value. Since wing design is focused on using airfoils that have high values of positive $C_{N_{max}}$, the maximum values of negative $C_{N_{max}}$ are usually about 0.7 times the positive $C_{N_{max}}$ values.

Line H–F. This line describes the maximum negative maneuver load factor, again determined from flight tests as noted above.

The maximum maneuver load factors vary with aircraft type (Table 13.28). For FAR 23 aircraft, the maximum positive and negative maneuver load factors are listed in Table 13.29.

For FAR 25 aircraft, the maximum positive maneuver load factor varies with design gross weight. The maximum value is 3.8 up to a gross weight of 4100 lb. At higher gross weights, the maximum value varies according to the relation up to a gross weight of 50 000 lb where the maximum becomes a constant value of 2.5. The maximum negative maneuver load factor for FAR part 25 aircraft is −1.0. Corresponding maneuver load factors for military aircraft are shown in Table 13.29.

V–n Diagram: Gust Envelope FAR 23.333 and FAR 25.333. In addition to the load factors imposed by intentional maneuvers controlled by the pilot, appreciable increases in effective angle of attack result from entering a *gust*, or current of air having a velocity component normal to the line of flight. The resulting increase in load factor depends primarily on the vertical velocity of the gust, and especially for business jets and jet transports, it may exceed the maximum due to intentional maneuvers. These load factors are summarized on a *V–n* gust envelope diagram (Fig. 13.210).

The load factors produced by gusts vary directly with equivalent airspeed, and are computed using the

Table 13.29 Design maneuver load factors for military airplanes

Aircraft type	Basic flight design weight		All weights	Max. design weight		Max. ordnance weight	
	Max.	Min. at V_H	Min. at V_H	Max.	Min. at V_H	Max.	Min. at V_H

Utility	4.00	−2.00	0	2.50	−1.00		
Tactical bomber	4.00	−2.00	0	2.50	−1.00		
Strategic bomber	3.00	−1.00	0	2.00	0		
Assault transport	3.00	−1.00	0	2.00	0		
Conventional transport	2.50	−1.00	0	2.00	0		

gust load factor equation given in FAR 23.341 and FAR 25.343.

The equation is

$$n = 1 + \frac{K_g U_{gE} V_E a}{498(W/S)},$$

where

$$K_g = \frac{0.88\mu_g}{5.3 + \mu_g} = \text{gust alleviation factor},$$

$$\mu_g = \frac{2(W/S)}{\rho \overline{C}_{ag}} = \text{airplane mass ratio},$$

U_{gE} = equivalent gust velocity (ft/s),

ρ = density of the air (slug/ft^3),

W/S = wing loading (lb/ft^2),

$\overline{C}$ = mean geometric chord (ft),

g = acceleration due to gravity (ft/s^2),

V_E = aircraft equivalent airspeed (kts),

a = slope of the airplane normal force curve per radian.

The V–n diagram for the gust envelope is shown in Fig. 13.210.

The designer must assume a symmetrical vertical gust of:

- 66 fps at V_B from sea level (S.L.) to 20 000 ft, decreasing to 38 fps at 50 000 ft
- 50 fps at V_C from S.L. to 20 000 ft, decreasing to 25 fps at 50 000 ft
- 25 fps at V_D from S.L. to 20 000 ft, decreasing to 12.5 fps at 50 000 ft

The key points of the gust envelope are as follows.

Line 0–B′. As in the maneuver envelope, this line describes the maximum load factor that can be generated by a gust which causes the airplane to reach its $C_{N_{max}}$.

Point B′. This point is the intersection of the load factor for $C_{N_{max}}$ and the load factor for a 66 fps gust. This point determines V_B, the design speed for maximum gust intensity.

Point C′. This point is the intersection of the load factor due to a 50 fps gust and the design cruising speed V_C.

Point D′. This point is the intersection of the load factor due to a 25 fps gust and the design dive speed, V_D.

Points E′, F′, and G′. These points are the corresponding intersections for negative gusts at the designated speeds.

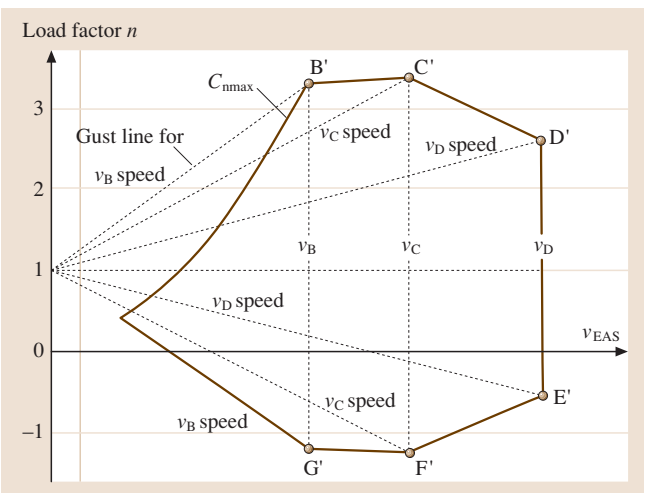

Fig. 13.210 V–n diagram: gust envelope

The maneuver and gust envelopes are superimposed to determine the highest load factors for design at all speeds within the flight envelope and the entire aircraft structure analyzed for these load factors.

In addition to these major air loads imposed on the airplane by intentional maneuvers and gusts, there are other conditions associated with abrupt control inputs in pitch, roll, and yaw that must be accounted for in the structural design.

Design Airspeeds

The airspeeds associated with the V–n diagram except for V_A and V_B are chosen by the designer, but must meet certain definitions and criteria contained in the FARs. The following list is a simplified summary:

Design airspeeds – EAS:

V_S – Stalling speed or minimum steady flight speed;
V_A – Maneuver speed or full control deflection speed;
V_B – Design speed for maximum gust intensity;
V_{FE} – Design flap-extended speed;
V_{LE} – Design landing-gear-extended speed;
V_{LO} – Design landing-gear-operating speed (if different from V_{LE});
V_C – Design cruising speed ($\geq V_B + 43$ kts);
V_{MO} – Maximum operating limit speed (*Barber Pole* speed);
V_{FC} – Maximum speed at which flight characteristics requirements must be met;
V_D – Design dive speed, $\geq V_C/0.80$, or speed reached in 7.5° dive for 20 s from V_C, followed by $1.5g$ recovery.

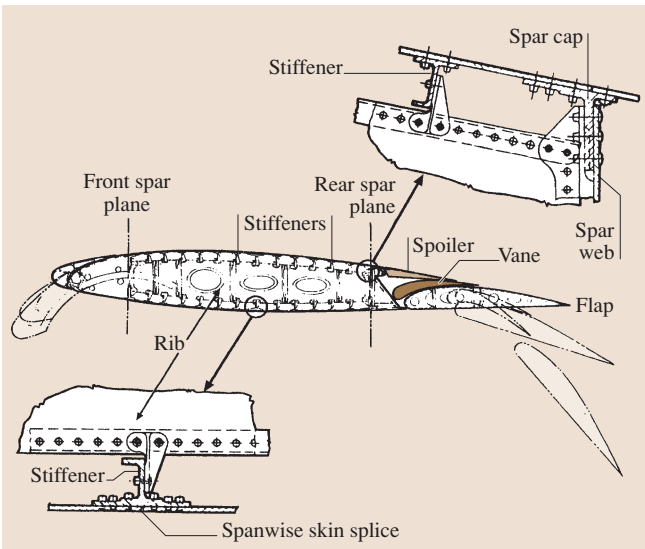

Fig. 13.211 Wing box structural elements

The military speed definitions are basically the same, although MIL-A-8660B combines V_C and V_{MO} into a maximum level flight speed V_H, and replaces V_D with the *limit speed* V_L.

For subsonic airplanes, the design airspeeds are usually constant for the entire flight envelope. For high-subsonic and supersonic airplanes, the design airspeeds are varied throughout the flight envelope, since equivalent airspeeds that are appropriate at sea level and lower altitudes are beyond the performance capabilities of the airplane at higher altitudes. Therefore, the design airspeeds for these types are usually defined in terms of Mach number at higher altitudes; for example, the maximum operating limit speed is defined by a V_{MO}/Ma_{MO} line that is a function of altitude. As noted earlier, the design cruise speed (Mach number) need not be higher than the maximum speed in level flight at that altitude with maximum cruise power. This provision usually sets Ma_C. V_{MO} is usually set at or slightly above (0.01 or 0.02 Mach number) Ma_C, providing a margin on the order of 0.08 Mach number between the best long-range cruise Mach number and Ma_{MO}. The design dive Mach number is usually about 0.05 Mach number higher than Ma_{MO}.

Ground Loads

There are a range of take-off and landing conditions that must be considered in the structural design of the airplane. These conditions are described in detail in the appropriate sections of the federal aviation regulations. These loads may be classified as vertical loads due to descent rates at touchdown and taxiing over rough surfaces, longitudinal loads caused by wheel spin-up loads on landing, braking loads, and rolling friction loads, and lateral loads caused by landing with some sideslip angle, cross-wind taxiing, and turning on the ground.

13.4.12 Airplane Structure

The structure of an aircraft must withstand the applied aerodynamic and ground reaction loads encountered in normal operation, as well as those that may be encountered very rarely. The essential character of aircraft structure is light weight, because weight plays such an important role in the performance and economics of the

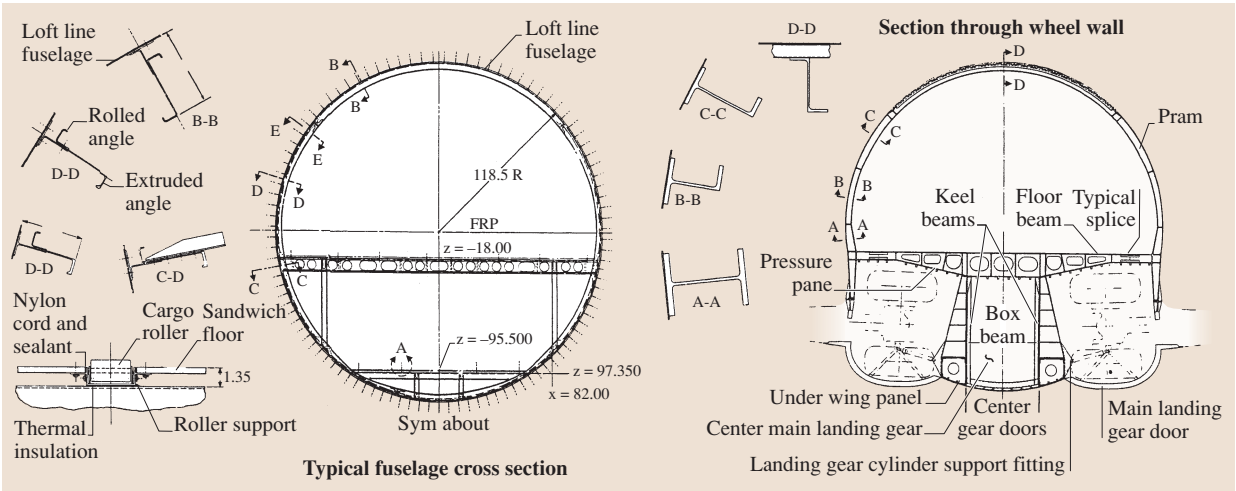

Fig. 13.212 Fuselage structural elements

airplane. This critical significance of structural weight is the major difference between aircraft structural design and other types of structural design.

Aircraft structural design has always sought to meet the applied load requirements with a minimum acceptable margin of safety and the least weight. However, the potentially disastrous effect of an aircraft structural failure requires that the structure must be designed for long life either with safe life criteria or fail-safe design. Safe life means that the stresses in a component are so low that fatigue failure is not possible over the anticipated life of the airplane, or at least until some

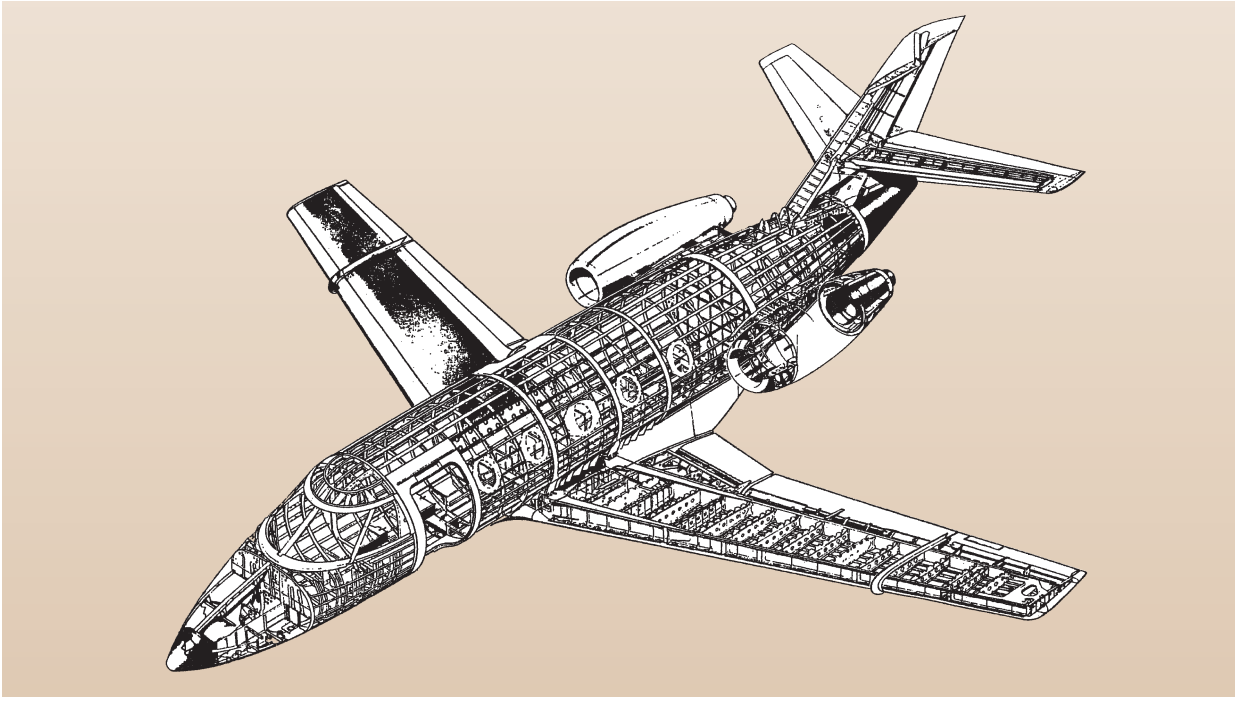

Fig. 13.213 Complete airplane structure overview

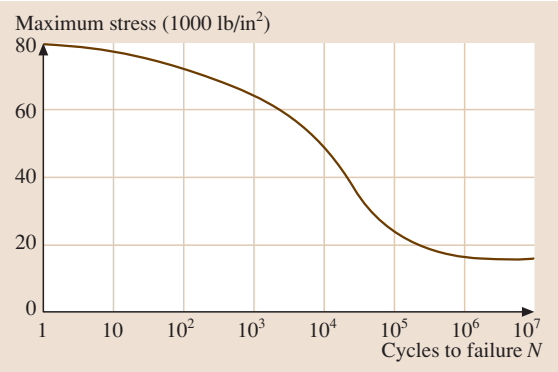

Fig. 13.214 Fatigue test results

period has passed after which a part replacement is required. Fail-safe means that the structure has alternate load paths so that no single failure of a part will be hazardous to the airplane. This is accomplished by designing the structure so that no one part carries most of the maximum load. Therefore, if one part fails, the remainder of the structure can still carry most of the maximum load. Since the maximum load is rarely encountered, and the structure has a safety factor of 1.5, the structure remains safe until the failure is found and repaired.

Structural Design

Aircraft structures are composed of three basic types of structural elements: stiffened shells, stiffened plates, and beams. The terms stiffened shells and stiffened plates refer to the fact that, under compressive loading, the thin skins of the shells and plates generally buckle before reaching the compressive failure stress of the material. To avoid this condition, stiffeners are attached to the thin skins. Stiffeners not only carry their own load, but by preventing early buckling of the skin, they increase the stress that can be supported in compression before buckling occurs. The primary wing structural element, the wing *box*, is essentially a hollow beam, consisting of the upper and lower wing skins, ribs, wing skin stiffeners, spar caps, and spar webs, as shown in Fig. 13.211.

The wing skins transfer the external air loads to the wing box structure. The fuselage structure (Fig. 13.212) consists of frames which maintain the cross-sectional shape, to which are attached various longitudinal stiffeners called stringers or longerons. Loads on the fuselage floor are supported by floor beams, with other beam elements to accommodate cutouts in the fuselage shell. Horizontal and vertical tail structure is very similar to the wing structure, employing skins, ribs, stiffeners, spars, spar caps, and spar webs.

An overview of the complete structure for a large transport airplane is shown in Fig. 13.213.

Another important aspect of structural design is the need to design for long fatigue life. Metals suffer a gradual deterioration under repeated application and removal of loads. Modern commercial transports may fly for many thousands of hours and take-off and landing cycles, so that often fatigue life, rather than strength requirements, dominate the structural design. The number of load cycles a material can tolerate depends on the stress level. The lower the stress level, the greater number of cycles the part can withstand. The results of a typical fatigue test (Fig. 13.214) show the tremendous improvement in fatigue life that can be obtained by limiting a material to cyclic stress levels that are well below the ultimate strength.

If fatigue is critical, a less strong material with better fatigue resistance may result in a lighter structure. Excessive stress levels conducive to early fatigue failure may arise not only from an overall high stress level, but also from stress concentrations at local points in the structure. Fittings and joints, which serve to carry loads from one structural component to another, may, if not designed very carefully, introduce increased local stresses leading to fatigue failure long before any problem occurs in the basic structure. A major part of the design of aircraft structure is the avoidance of stress concentrations by careful detail design. One approach is to lower the stress level approaching a hole or fitting

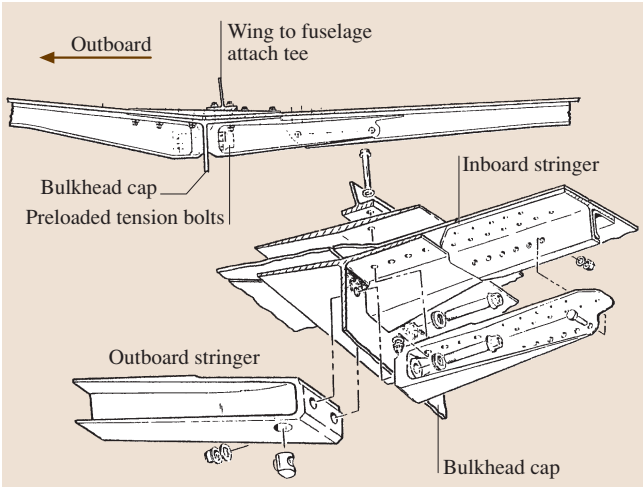

Fig. 13.215 Wing–fuselage joint fitting

by adding an extra sheet or thickness of metal called a *doubler* to the inside surface of a wing skin around an access hole or to the fuselage skin around a window. Special attention is given to fitting design (Fig. 13.215). In spite of the care taken in detailed structural design, a vital part of aircraft maintenance is the continuing search on a scheduled basis for structural cracks.

Structural Analysis

In the design and analysis of real aircraft structure, usually a large assemblage composed of various structural elements such as stiffened shells, stiffened plates, and beams, the overall geometry becomes extremely complex, and cannot be represented by a single mathematical expression. In addition, these built-up structures are characterized as having material and structural discontinuities such as cutouts, thickness variations in the members, as well as discontinuities in loading and support structure. It is apparent that classical methods can no longer be used, particularly those which require the formulation and solution of governing differential equations. For complex structures, the preferred method of analysis is called the finite element stiffness method. With the advent of high-speed large-storage-capacity digital computers, finite element matrix methods have become the most widely used tools in the analysis of complex structures.

Structural Materials

Modern aircraft are constructed from a variety of materials, chosen based on considerations such as density, mechanical properties, corrosion resistance, ease of fabrication, and cost. The most used materials are the light metals, aluminum alloys, and titanium, although for some applications where high strength is required, steel alloys are used. Structural composite materials are being used more because of their low density and good mechanical properties. Composites generally consist of a plastic matrix of epoxy resin, reinforced by many high-strength fibers of carbon, Kevlar, glass, or boron. The distribution of materials used in aircraft construction has been changing over the years as material science researchers have developed more attractive products. Figure 13.216 shows a comparison of the structural materials distribution between the Boeing 747 of 1969 and the Boeing 777 of 1994. In the 25 years between the design of these two transport aircraft, the most notable difference in materials use is the large

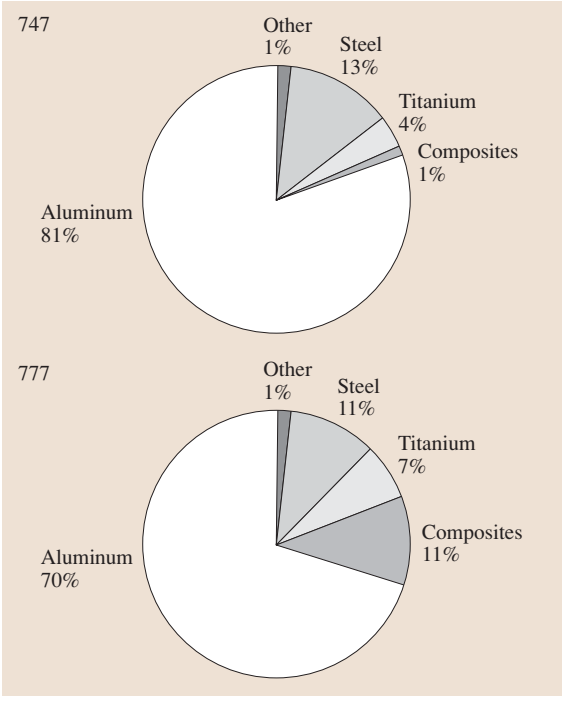

Fig. 13.216 Comparison of structural materials distribution – commercial transports

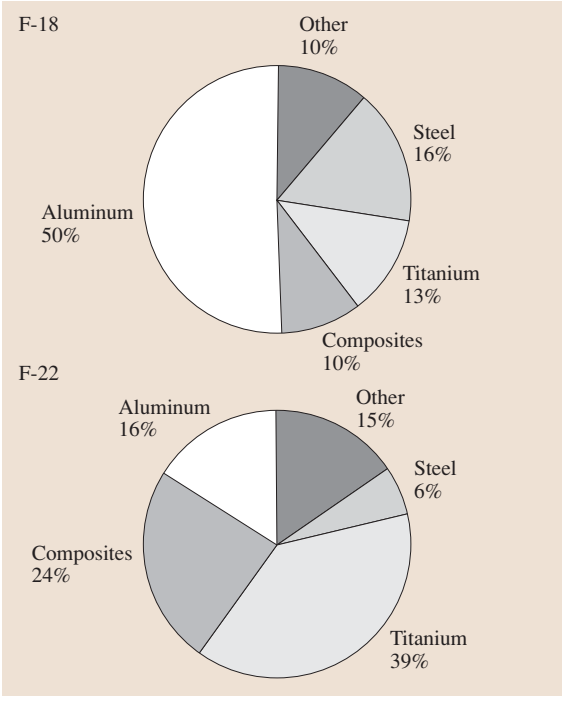

Fig. 13.217 Comparison of structural materials distribution – military fighters

Table 13.30 Summary of typical maintenance checks for transport airplanes

	B 737	B 747	A 300	A 320	Time required	Man-hour
A-Check	350 h	650 h	350 h	350 h	Overnight	20–130
B-Check	5.5 months	1800 h	1000 h	–	One day	200–1000
C-Check	15 months	18 months	18 months	15 months	A few days	600–1400
D-Check	22000 h	31000 h	25000 h	–	≈ 6 weeks	50000
	25000 loading	72 months	12500 loading	–		
	108 months	–	108 months	102 months		

increase in composites and titanium, and a significant reduction in the use of aluminum.

An even more startling change in structural materials distribution has taken place in military aircraft design. Figure 13.217 shows the distribution of structural materials in the McDonnell Douglas F-18 of 1978 and the Lockheed Martin F-22 of 2003. The most startling difference in the materials use between these two aircraft is the large reduction in the use of aluminum alloy and steel in the F-22 and the large increase in the use of titanium and composites.

In addition to the introduction of newer, nontraditional materials, several new processes for producing parts from these new materials have been introduced, which reduce the number of parts required and also reduce the amount of labor required to produce each part. Examples of these new processes are *resin transfer molding* (RTM) for producing composite parts, and *hot isostatic pressing* (HIP) for producing large high-quality castings.

13.4.13 Airplane Maintenance Checks

As noted earlier, in order to insure safe operations, especially for commercial transport aircraft, regular formal maintenance checks are made of the airplanes systems and structure. These checks range from the very simple *preflight* check of the aircraft conducted by the flight crew prior to each flight, to the extensive, detailed maintenance inspection checks conducted by technical specialists at major maintenance facilities. A summary of the various types of maintenance checks that are conducted by the airline operators is presented in Table 13.30.

14. Construction Machinery

Eugeniusz Budny, Mirosław Chłosta, Henning Jürgen Meyer, Mirosław J. Skibniewski

In this chapter the most common classes of machinery found on construction sites will be presented. For the purpose of this chapter the authors focus on construction machinery and equipment applications in the building and public utility sectors of the construction industry. The classes of machinery and equipment for earth, concreting, assembly, and finishing works described in this chapter are used not only in these two construction industries, but also in road, bridge, and railway building; pile, tunnel, and water foundation; the opening of mines; the building of natural gas and petroleum pipelines; sewerage systems; cooling towers for the power industry; and other industrial building structures.

One should note that specialized equipment ensuring the efficiency, high quality, and safety of work during the realization of structures is used in almost all these kinds of construction. Even a brief description of this equipment would require a separate publication. For example, in road building alone 63 types of machines (see the draft International Standard ISO/FDIS 22242) are used. In the final part of this chapter the state of automation and robotization of construction machinery is presented.

14.1 Basics

14.1.1 Role of Machines in Construction Work Execution

Construction work is to a large extent hard and labor intensive and often poses a health hazard. This is due to the fact that building production involves handling large masses of materials and that some of the materials, such as lime, paints, industrial chemical products, and asbestos, are detrimental to human health. In addition, most construction works are carried out in the open.

The mechanization of construction started with hard physical work and labor-consuming effort, such as earth works and the horizontal and vertical transport of materials, only later embracing finishing works.

Construction work mechanization is inseparably linked with the technologies used in construction and so one can distinguish work mechanization by the different branches of construction (e.g., housing, public utility building, civil engineering, industrial building, and power facility building) or by particular kinds of work, e.g., earth work, assembly, and finishing work.

The transition from craft methods to a more economically effective form of industrial building, using a wide range of prefabricated units, gave an impetus to the development of more efficient machines for the assembly of such units as well as machinery and equipment for concrete works.

The mechanization of construction is a worldwide phenomenon and determines the development of this industry.

Through construction mechanization one can achieve the following goals:

- Speed up the rate of work in comparison with manual methods and so shorten the construction cycle.
- Reduce labor consumption, increase production capacity, and reduce work costs.
- Make work in construction less arduous and so more attractive.
- Improve work safety (construction is the most hazardous field of human activity).

Particularly rapid advances in construction mechanization were made after World War II in response to the urgent need to increase construction production capacity to provide the population with housing and improve standard of living. This was done by developing the construction machine building industry and new technologies consisting of the assembly of building structures from prefabricated units. Construction mechanization covered the following kinds of work: earth work, vertical and horizontal materials transport, materials handling, assembly, and finishing work (including external and internal plastering, painting, terrazzo and wooden floor sanding, and element fixing).

Mechanization is the primary factor contributing to an increase in productivity and it should be economically worthwhile, which is achieved through the intensive use of modern machines in good working order.

Definitions

Construction machine: a device whose function is to increase or replace human or animal physical force in carrying out construction processes.

In the field of construction machinery one can distinguish two general classes of machines: technological machines (for processing raw materials and/or semifinished products) and transport machines (for changing the location of building elements and materials).

Construction work technology: a method for carrying out construction work.

Mechanization of construction: activities covering the application of machines, equipment, and mechanized tools to carry out manufacturing processes in construction.

14.1.2 Development of Construction Machinery – Historical Outline

The available historical data indicate that cranes form the oldest class of construction machines invented by humans. Cranes were known in Greece as early as the

5th century BC. They were used for transporting structural elements vertically and horizontally and putting them in specified places, among other tasks, in the construction of magnificent temples. Greek cranes incorporated structural components such as toothed and worm gears, pulley blocks, rope drums, supports, and power units in the form of levers mounted directly on the hoisting winch's shaft, or various treadmills.

Figure 14.1 shows a derrick commonly used in both ancient Greece and Rome, with a mast in the form of the letter "A". The hoisted block is grabbed by a crampon. The winch is turned by means of two levers and the mast's inclination is adjusted by guy-ropes.

As late as the second half of the 19th century, i. e., until the industrial revolution, cranes were driven by people or, less commonly, by animals. Treadmills, including treadwheels with steps to be climbed, or pole windlasses were used as the driving devices [14.1] (Fig. 14.2).

Historically, the next class of construction machines to be invented was pile-drivers. These were needed to build structures (including temples) on weak ground and bridges. The first pile-drivers were very similar in their design to cranes. A simple medieval pile-driver consisted of a tripod, a rope sheave, and a rope with a hook on which a heavy stone block was hung. The dropped block would drive a pile into the ground. Devices working on the double-arm lever principle and a hoisting winch were employed to pull out such piles.

Towards the end of the 19th century pile-drivers with a guided drop weight began to be used. Later floating pile-drivers powered by a paddle waterwheel were introduced. Also the pulling up of the pile hammer was improved: the work of several people hoisting the pile hammer to its upper position by simply pulling the rope was replaced by a treadwheel or a treadmill.

The next class of construction machines developed were dredgers [14.2], which were used to build waterways and deepen ports and canals. The first record of the design of a gouge-dipper dredger dates from 1420, presented by Venetian Giovanni Fontana (Fig. 14.3).

The Fontana dredger was installed on a pontoon and its working tool was a dipper moving in a chute with a sharp metal tip. First the lowered dipper was inserted into the ground under its deadweight and then the winning was detached by the gouge-dipper as the latter was pressed into the ground. The winning was brought to the surface by pulling the dipper up in the chute.

The gouge-dipper dredger was the precursor of a whole family of dredgers. Later scraper dredgers,

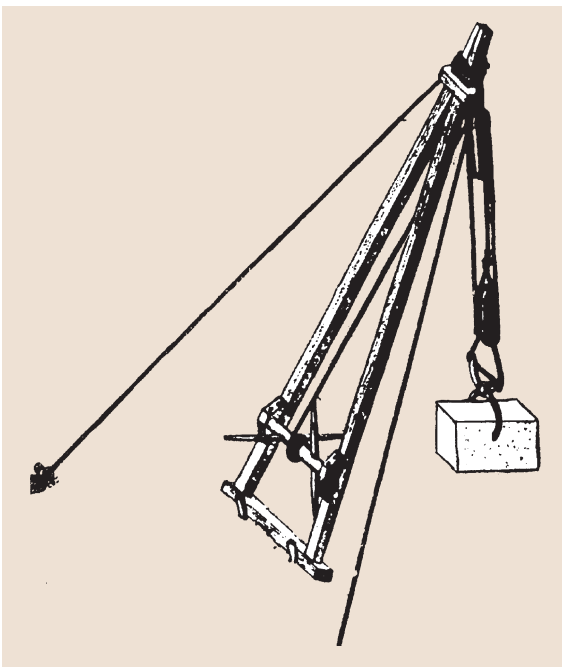

Fig. 14.1 Derrick used in ancient Greece and Rome

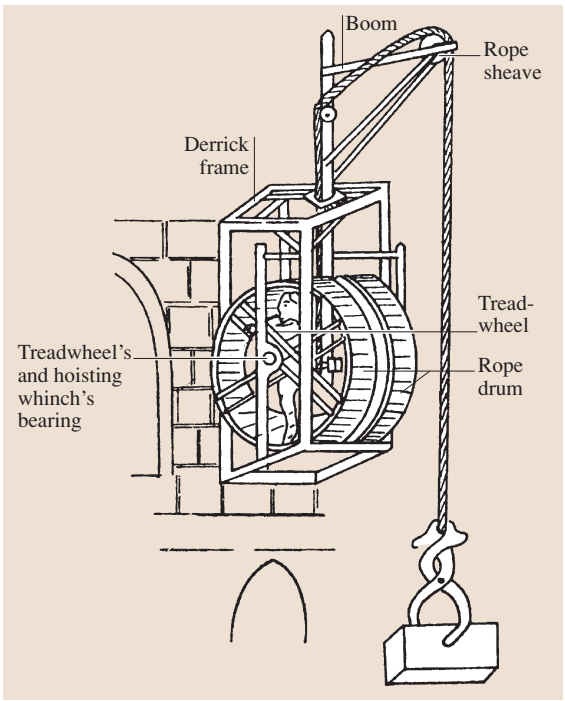

Fig. 14.2 Treadwheel-type boom derrick placed on erected building's wall

clamshell dredgers, dipper dredgers, dipper-scraper dredgers, wheel dredgers, and carding dredgers were designed.

The working mechanisms were driven via hoisting winches by treadwheels, pole windlasses or treadmills powered by men. The exception was a horse-driven 16 m^3/h-capacity dredger with a 0.66 m^3-capacity dipper, built in the USA around 1820.

The development of dipper dredgers gave French designers the idea of putting similar machines to work on land, and so excavators came into being [14.2]. The first excavator designs, although unrealized, appeared in the first half of the 17th century [14.2].

The beginnings of the development of construction mechanization and a breakthrough in construction machine building are associated with the industrial revolution in the UK in the middle of the 18th century.

The most important device in the industrial revolution was the steam engine, improved by Thomas Newcomb (1683–1729) and James Watt (1736–1819). As a result of the Industrial Revolution and its spread to other countries, rapid population growth combined with the expansion of large cities and the development of road, water, and sea transport occurred. The massive and rapid construction of railway lines, roads, canals, and ports involved large-scale earth works. Construction machines, initially powered by steam engines and later combustion engines and electric motors, appeared. The first construction machines in which power drives were employed were dredgers, most commonly bucket-ladder dredgers, used for extracting the winning from the bottom of rivers and canals and for building ports. They were first built in the UK and then in the USA, Russia, and France, and worked in conjunction with loading bridges, transport-tow vessels, and rail transport for carrying off the winning.

The development of the railway system boosted demand for related construction works, track, and rolling stock. Embankments, tunnels, and bridges were built, and tracks were also laid.

In the development of construction machinery one can distinguish the following landmarks:

- The development of the first steam-powered earth-moving machine in 1776. This was a dipper dredger used for dredging the canals in the port of Sunderland.
- The building of the first steam bucket-ladder dredger by Samuel Bentham in 1802 for work in the port of Portsmouth (UK).
- The construction of a floating bucket-ladder dredger, called the *Amphibious Digger*, by Oliver Evans – the pioneer constructor of steam engines in America – for dredging the river and port of Philadelphia in the years 1800–1804.
- The invention of the steel cable by Albert in Germany in 1834, the use of which greatly contributed to the development of cranes.
- The building of the first single-bucket excavator, called the *American Steam Excavator* or the *Yankee Geologist*, by William Smith Otis in the USA in 1836 (Fig. 14.4). Otis's machine has been a symbol of construction mechanization to this day. The proof of its originality and technical excellence is the fact that it set the direction of the development of excavators for 140 years. Otis's first machines were used in the construction of the Baltimore–Ohio railroad.

Otis's excavator with a 1.15 m^3-capacity bucket replaced the work of 80 diggers. Its high economic efficiency significantly contributed to the development of the excavator, grab-dredger, and crane building industry.

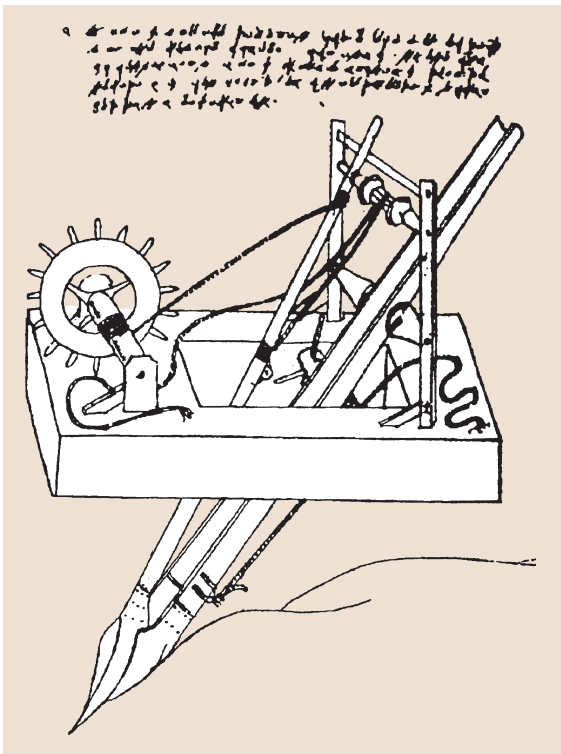

Fig. 14.3 Giovanni Fontana's gouge-dipper dredger

The total production of excavators and dredgers in the USA in 1880 reached 1000 units per annum, and a considerable number of them were exported:

- In 1850 Briton William Fairbairn (UK) developed an arch crane jib made from two riveted plates and then steam-driven cranes.
- In 1861 in Germany Nicolaus August Otto developed a four-stroke, spark-ignition combustion engine.
- In 1874 the company the Aveling & Porter (UK) developed the first steam-driven wheeled crane, called *Little Tom*. In the same year a gantry crane with a truss bridge girder was constructed in north Germany.
- Bucket-ladder dredgers, loading bridges, locomotives, and steam-powered transport-tow vessels were built in France for the construction of the Suez Canal in the years 1865–1869.
- The construction of the Manchester–Liverpool Canal in the UK in the years 1887–1898. Fifty-eight British-made (Ruston, Smith, Whiteker, and Wilson) single-bucket excavators, 18 Priestman clamshell excavators, and many bucket-ladder excavators and dredgers were used to carry out earthwork amounting to 38 million m^3.
- In 1897 Rudolf Diesel built the first compression-ignition engine.
- The development of bucket ladder excavators in France, Germany, and the USA in the second half of the 19th century.
- In 1890 the Osgood Company (USA) built the first electrically driven railway excavator.
- Around 1900 the first traveling tower cranes with a hoisting capacity of 0.25–5.5 Mg were built in Germany and France.
- The building of the Panama Canal under the control of the USA in the years 1904–1914. About 100 railway single-bucket excavators were with a bucket capacity of 2–2.9 m^3 each were used on the building site. They were American-made machines supplied mainly by the Bucyrus Steam Shovel and Dredge Co. (South Milwaukee) and the Osgood Dredge Co. (Troy, NY).

Besides these excavators many other steam-driven machines, such as dredgers and narrow-gauge railways for transporting the output, were used in the construction of the canal.

The 20th century brought rapid development of construction machines. Steam engines were replaced by combustion engines and electric motors, which were

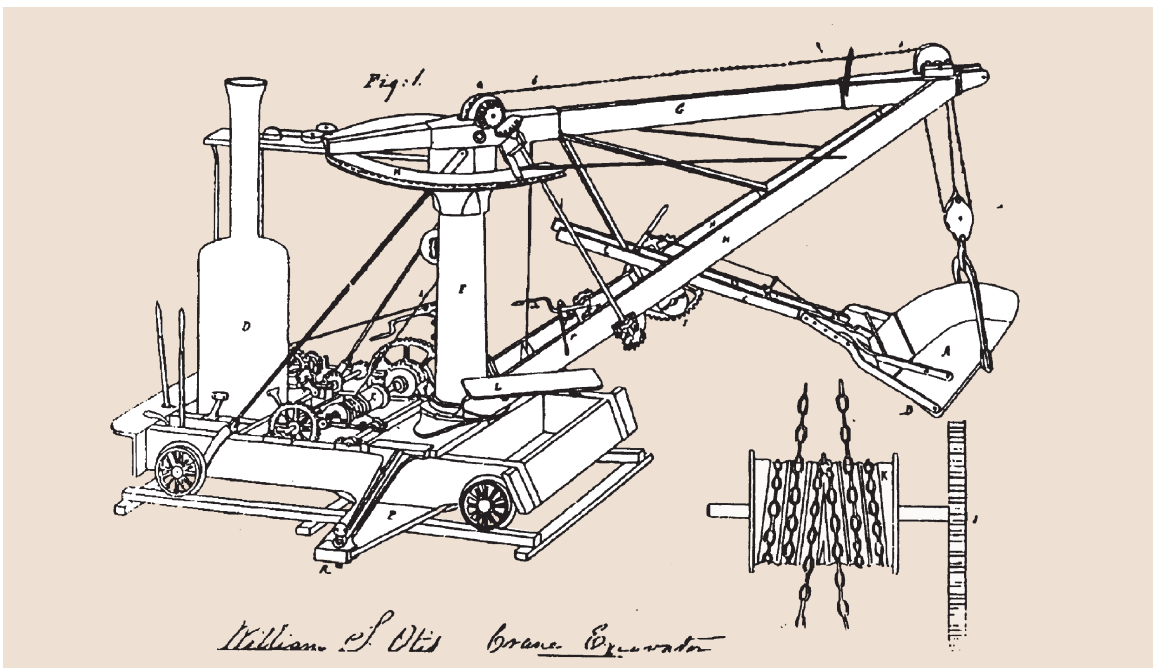

Fig. 14.4 Patent drawing of excavator signed by W. S. Otis on 24 February 1839

easier to operate. High-strength structural materials, hydraulic and pneumatic drives, and control systems incorporating electronics, computer technology, and microprocessors were introduced. As a result of these innovations the performance of construction machines improved and their range of application was extended.

American companies have contributed greatly to the development of construction machinery. For example, Powling and Harnischfeger was one of the first companies to manufacture crawler cranes at the end of World War I and Bucyrus-Erie was the first company in the world to present in 1946 a traveling hydrocrane with a telescopic jib. Several classes of modern construction machines will be described in the next sections of this chapter.

14.1.3 Classification of Construction Machinery

The various construction machines can be divided into two classes. One class comprises specialized machinery exclusively for construction-assembly work while the other includes general-purpose machinery used in various industries. This means that one should distinguish between the terms: *construction machinery* and *machinery used in construction*.

In many cases, however, this distinction is not clear cut. This is so, for example, in the case of motor transport means (trucks, semitrailers, trailers, and tractors), wheeled cranes used for reloading different materials, and power shovels, bulldozers, and front loaders used also in surface mining and in loose-material reloading yards. Another example is the use of helicopters for the assembly of tower structures.

In the literature on this subject one can come across various methods of classifying construction machinery, usually according to the kinds of construction work for which it is used, its function or design.

The classification found in [14.3] can be regarded as the most reliable classification of construction machinery and equipment. This document is not yet an international standard but may become one in the future.

In this report, construction machinery and equipment are divided according to the kinds of work for which they are used into the following seven classes:

1. Earthmoving machinery and equipment
2. Foundation engineering and soil compaction machinery and equipment
3. Machinery and equipment for manufacturing, transporting, and processing concrete and mortar and for reinforcement and formwork
4. Lifting and access machinery and equipment (scaffolds and work platforms)
5. Specialized machinery and equipment used in building construction (e.g., machinery for roadworks and pipe-laying)
6. Equipment for installation, finishing work, and maintenance
7. General-use machinery and equipment used in construction processes

The above classes are divided into subclasses and then into types. Readers interested in the detailed classification are referred to the report itself.

14.2 Earthmoving, Road Construction, and Farming Equipment

It is decisive for human action to use tools, devices, and machines. For a long time man has been making use of machines for construction and agriculture. The huge buildings of antiquity could never have appeared without the application of construction machinery. However, agricultural machinery – especially those according to the EU machinery directive [14.4] – did not emerge until the 18th and 19th century, with the UK and the USA being the first to make use of them [14.5]. A particular problem to be addressed for agricultural machinery was the necessity to be mobile, and today it is still mobility which is one of the most important functions of earthmoving, road construction, and agricultural machines. This is the feature which distinguishes them from stationary machines such as machine tools. Therefore, they are summarized as *mobile working machines*. Due to their requirement for mobility, the following issues are important for this kind of machine and their construction:

- The machine must be connected to an energy source.
- Energy is needed for running the device or the drive.
- The machine can move actively (automotive) or passively (pulled).
- It must be equipped with a (wheel or chain) chassis to supply the tools with energy.
- It must be possible to integrate all components of the machinery system (drive, sensors, actors, etc.) into the vehicle.

Another important feature of earthmoving, construction, and agricultural machinery is the fact that they are designed to fulfil specialized working functions and to be part of complex processes in the area of construction or agriculture.

14.2.1 Soil Science and Driving Mechanics

Soil Composition

Regarding mobile working machines, the soil is of special importance in two regards:

- Mobile working machines move on the soil. Every vehicle requires ground to move on. Depending on the type of chassis used, the drive force must be introduced into the ground in some form, which means that the soil has to take up the driving power; otherwise the wheels or chains would spin. In a broader sense, even roads made of asphalt or concrete must be regarded as soil, representing artificial, manmade hard soils (rocks) that provide a good driving surface.
- Soil is the main resource for plant production and, indirectly, for animal production, thus serving man's demands. Regarding its important role, soil cannot be replaced by any other resource. Soil fertility is mainly dependent on the activity of soil bacteria, fungi, algae, and other microbes. Mobile working machines, especially agricultural machines, are closely linked to this resource, as they are utilized for plant and animal production. The same is true for forestry machines and municipal machines. Earthmoving machines, which are also mobile working machines, also work mainly on soil.

A more detailed description of soil follows, in terms of both its physical and biological features.

Soil consists of various components:

- Solids
- Liquids (water)
- Gas (air)

This distribution of solid, air, and water can be represented as a three-phase system. Soils are classified depending on their aim and application. So, in the area of earthmoving, for rock production, the decisive criteria are different from those in the area of agriculture, which concentrates on soil fertility. An example of agricultural soil classification is the *World Soil Classification* initialized by the Food and Agriculture Organization (FAO) [14.6]. Rock may be classified according to the ISO standard 14689-1 entitled *Geo-technical Investigation and Testing – Identification and Classification of Rock* [14.7]. Apart from these international classification systems there are various national ones [14.8].

Chassis Types

The chassis can be regarded as an interface between the mobile working machine and the ground; two main groups can be distinguished (Fig. 14.5):

- Wheel chassis
- Tracklaying or crawler chassis

In addition to these two groups, there are special-purpose chassis types such as walking chassis to move machines, e.g., in open-cast mining. The driving resistance can be calculated by multiplying the force due to

gravity by the tractive resistance. The most important difference between a wheel chassis and a tracklaying chassis is that a chain tread has a higher driving resistance than a wheel chassis. This has a positive effect on force transmission between the wheel and the soil, reducing soil pressure. However, a wheel chassis permits higher driving speeds than a tracklaying chassis, which turns out to be advantageous, and, with their simpler construction, they can also be used for vehicle suspension.

Wheel Chassis

Force transmission between the wheel and the soil is very complex, being determined by various parameters:

- Penetration into the soil (i. e., soil load-bearing capacity and structure)
- The variety and construction of wheel
- Load and its distribution over area
- Air pressure
- Suspension
- Tyre profile

The roll resistance force value determines the distance between the two vertically acting forces weight and vertical acting force in the case of the driven wheel, and also the angle between the weight and vertical acting force with the pulled wheel (Fig. 14.6).

When the wheel is driven and, additionally, when the traction forces F_T have to be transmitted, e.g., by pulling a trailer or a plough, the propulsion torque is in balance with the soil force.

Figure 14.6 shows the forces acting on a pulled wheel in a simplified way. The driving torque is determined as follows:

$$M = F_T r + F_G f \,, \qquad (14.1)$$

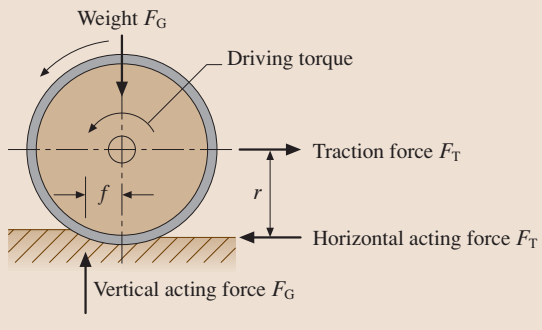

Fig. 14.6 Simplified forces model for a rigid wheel (after [14.9])

where M is the driving torque, F_T is the driving power, F_G is the weight, and r is the effective roll radius. The tractive resistance ρ of a four-wheel tractor is 0.13–0.18 on sand. On concrete or asphalt the tractive resistance is 0.015 [14.9].

Figure 14.7 shows the relation between the wheel perimeter force and the slip. The wheel perimeter force depends on the roll resistance and the driving power.

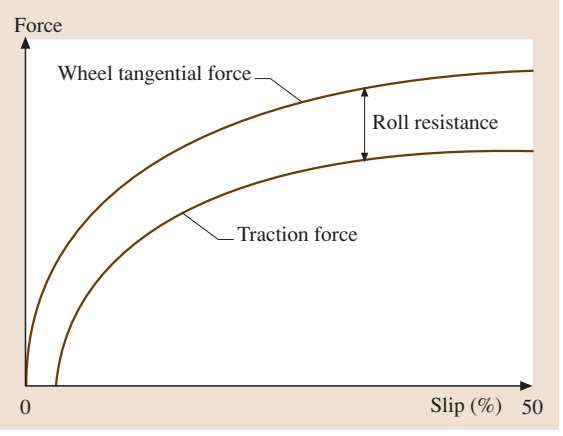

Fig. 14.7 Roll resistance force F_R and wheel traction force F_T depending on the slip σ [14.9]

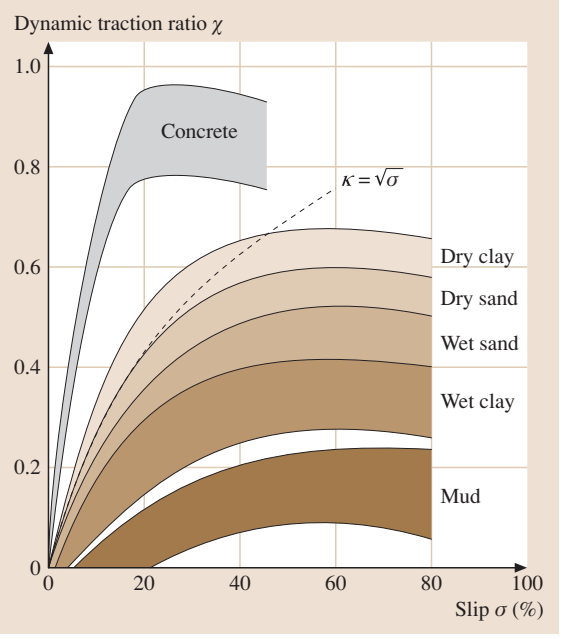

Fig. 14.8 Dynamic traction ration with different soil types (after [14.10])

There is always slip because the roll resistance force F_R has to be overcome to move the vehicle. Indeed, the slip is always small and positive (Fig. 14.7) and, in general, driving is not possible without slip.

The dynamic traction ratio expresses the ratio between the maximum traction force and the wheel load (including the wheel's own weight)

$$\kappa = \frac{F_T}{F_G} . \qquad (14.2)$$

The dynamic traction ratio is determined by measurement. Above all, it depends on the slip σ, as shown in Fig. 14.8. As is shown by this curve, the softer the soil, the lower the propulsion that the wheel can transmit. We can also see that the wheels tend to spin faster and more easily for a flat curve profile. Approximately the following formula describes the behavior up to slip of 30%

$$\kappa \approx \sqrt{\sigma} . \qquad (14.3)$$

The curves shown in Fig. 14.8 are influenced by three features:

- Tyres and stud deformations
- Soil deformations
- Gliding on the contact surface

14.2.2 Tyres

Tyre Structure

Figure 14.9 shows the general structure of a tyre. The tyre consists of a casing and a contact surface. The casing is also laterally covered by rubber material. The wire-wound core keeps the tyre inside the rim's bead. Nowadays, drive wheel tyres are equipped with a hose in most cases, as the driving power transmission would otherwise be restricted.

Consisting of several tissue layers, the casing provides the tyre with stability. According to the casing's construction, different tyre construction varieties can be divided into the following groups:

- Biased ply construction (Fig. 14.9b): The tissue layers run from one bead to the other with 45° staggering. This construction variety is relatively easy, making the tyres cheaper.
- Radial ply construction (Fig. 14.9c): In this tyre type, also called belted tyres, the tissue layers run radially from bead to bead. Around this inner layer, on the contact surface, there is an additional contact surface consisting of several tissue layers (the belt). Thus, the contact surface gains greater stability. Due to the soft casing, the tyre exhibits much greater spring deflection and thus a larger footprint than that produced by a diagonal tyre. Additionally, there is:
  - Better force transmission
  - Reduced soil pressure
  - Reduced roll resistance
  - Softer spring deflection of the tractor
  - Extended life of the contact surface

Force Transmission Between Tyre and Soil

Various forces are transmitted from the tyre to the soil. As already mentioned above, the material properties of the soil considerably affect the driving mechanics.

The highest pressure transmitted by the tyre to the soil, and thus the greatest degree of compaction, is always found at the center of the contact surface. However, the dimensions of this contact surface depends on the deformability of the ground. This means that the footprint increases with a softer soil, i. e., the contact surface pressure decreases. In any case, the integral of the pressure stays the same (Fig. 14.10).

The soil pressure arising from the machine's weight considerably influences the soil fertility, thus being of special importance for agricultural machines. It

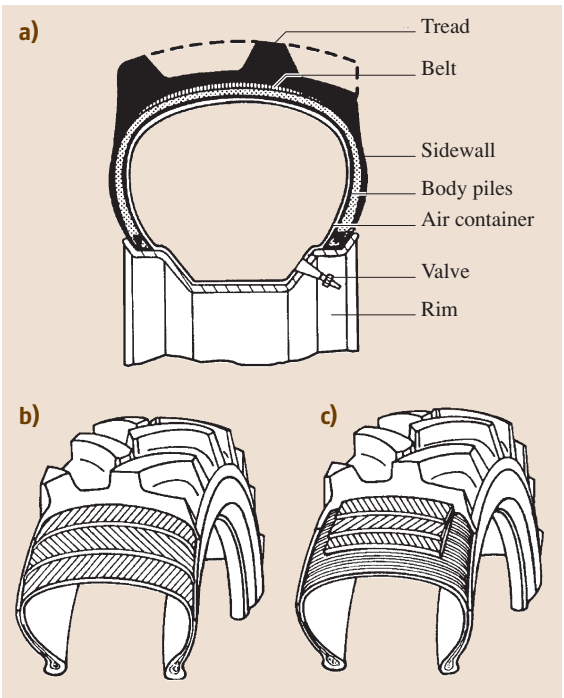

Fig. 14.9a–c Cross section through a tractor tyre with rim (after [14.10], description in text)

is important to minimize the negative impact of increased soil pressure by choosing an appropriate set of tyres. Due to internal friction in the soil, the pressure continuously decreases with distance from the footprint. However, the isobars, i. e., the lines of equal pressure, reach deeper into the soil with increasing load (Fig. 14.11). When the subsoiler does not work efficiently enough, detrimental soil compaction may occur.

The contact surface pressure is a decisive feature regarding the growth of new plants and soil ventilation. For solid ground, the following empirical rule apples: due to the casing's rigidity, the contact surface pressure on the footprint is about 0.03–0.04 MPa higher than the inner tyre pressure with radial tyres, and 0.05 MPa higher with diagonal tyres. For solid ground, this pressure is almost the same across the footprint because the deformation of the tyre is much greater than that of the soil [14.9].

In the case of earthmoving and road construction machinery, preserving soil fertility is less important. It is much more important to concentrate on features such as load-bearing capacity, insensitivity to stones, and good traction capacity. In the case of compaction rollers, it is precisely compaction which is important. In any case, it is necessary to consider these effects and their relations with the corresponding application.

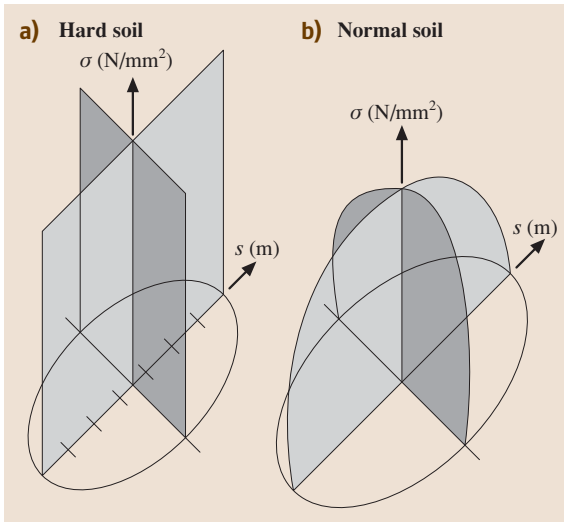

Fig. 14.10a,b Qualitative description of the pressure tension fields in the soil below the tyre (after [14.11])

Chain Chassis

Apart from tyre chassis, earthmoving and road construction machines mainly use a chain or caterpillar chassis. A caterpillar track consists of individual links arranged in front of the machine following the driving direction, thus serving as a lane for the machine. The chain has to simultaneously take up all forces resulting from traction and the load of the machine itself as well as possible lateral forces caused by steering movements. Similar to the tyre–soil system, the dynamic traction ratio between the chain and the soil depends on a number of parameters. Usually, the chain–soil system permits the transmission of large traction forces. Due to its footprint, which is larger than that of a wheel chassis,

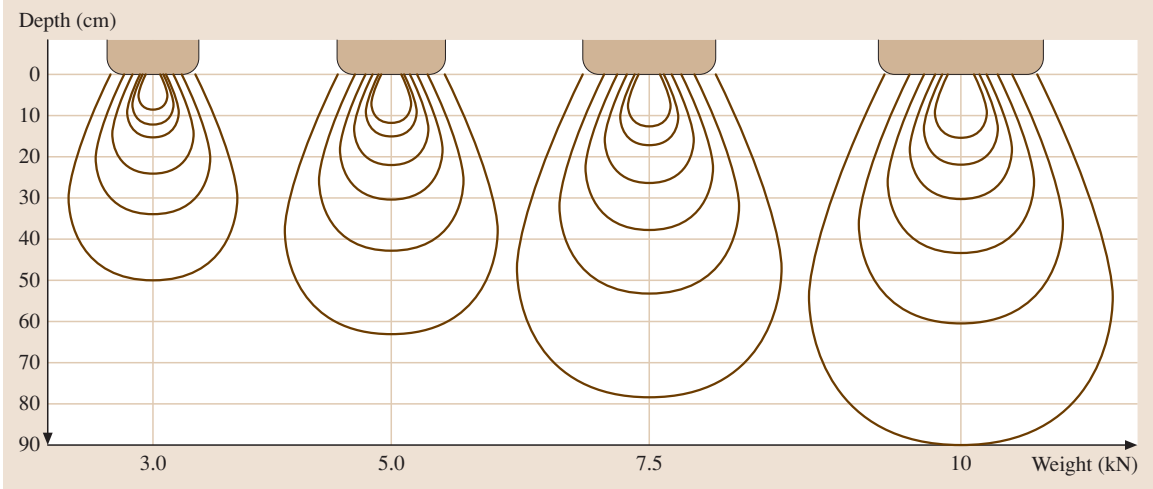

Fig. 14.11 Influence of the tyre load on the soil pressure (air pressure 0.082 MPa in all cases) [14.9]

the soil pressure is lower. Another feature of the chain chassis is its good stability, which is of considerable importance for hydraulic excavators.

Rubber belt tracks combine the advantages of both systems. They are applied in mini-excavators and road pavers. In the area of agriculture, rubber belt tracks are used in tractors equipped with high engine powers designed to work on the soil. Rubber belt tracks suffer from less vibrations compared with steel chains, while almost the same driving speeds are possible as with standard tractors. Moreover, they cause less damage to the road surface [14.12].

Figure 14.12 shows the general construction of a chain track. It consists of the chain, the base plate, the track rollers, the support rolls, the driving wheel, the guide wheel, the tensioning device, and the track frame. A chain chassis consists of at least two chain tracks. The guide wheel usually has only one guide profile and, using the chain tensioning device, can be shifted in order to tighten the chain. The smaller track rollers on the bottom serve to support the machine against the chain. The track rollers are designed to transmit even lateral forces emerging from steering movements or slope forces. There are various arrangements for the tractive turas. Whereas the conventional variety is preferred for hydraulic excavators and cold milling machines, large dozers are mainly equipped with the delta arrangement. Advantages of the latter include that the drive is protected against pollution and that driving performance is better.

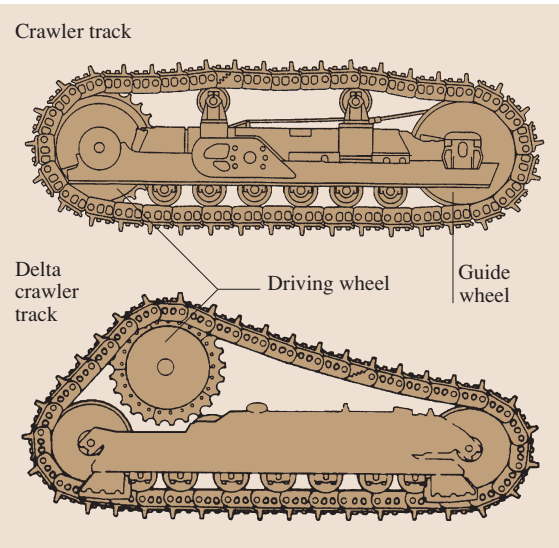

Fig. 14.12 General construction of a chain track

Steerings

The vehicle's chassis and the planned application are decisive for the choice of the steering system to be utilized. The steering considerably influences a machine's steering stability, driving security, stability, and manoeuvrability. In the case of tracklaying vehicles, the only useful steering method is skid steering. With a wheel chassis, vehicle steering is achieved by applying different driving speeds to the left and right chain tracks. A wheel chassis uses axle pivot steering of one or both axles, articulated steering or a combination of articulated and axle pivot steering. Whereas tractors mainly use axle pivot steering, earthmoving machines are equipped with the steering varieties shown in Fig. 14.13. The articulated steering variety is applied mainly in wheel loaders and is characterized by a two-part machine frame. An articulated chassis connects both frame elements, facilitating hydraulic displacement of the elements around the vertical axle. The steering angles are 40–50° to both sides. Given an additional movement around the vehicle's lateral axle, this articulation results in a center pendulum pivot steering system. Such an articulation replaces a pendulum axle. The characteristic features of the articulated steering are:

- Very good manoeuvrability
- The rear wheels are running in the same track as the front wheels
- Slim machine construction is possible
- When turning the wheels, the center of gravity is displaced, reducing the maximum load capacity

Axle pivot steering is an alternative to articulated steering. In most cases, tractors are equipped with axle pivot steering, on one or both axles. Various types are used in the case of all-wheel drive:

- Driving curves: Here, the wheels are turned so as to move the machine around the intersection point of the verticals or the prolonged axle. To achieve this, it is only necessary to steer one axle; in most cases, the front axle is used for steering.
- Four-wheel crab steering: The wheels are turned so as to move the vehicle laterally in a line parallel to its longitudinal axis.
- Circular driving: The wheels are turned so as to turn the machine on the spot.
- Diagonal driving: All four wheels are turned by 90° so as to move the vehicle diagonally to the vehicle's longitudinal axis.

The characteristic features of a vehicle equipped with axle pivot steering are:

- With axle pivot steering of the front axle, there are four tracks. which causes the driving resistance to increase on yielding soil.
- It is not possible to *free* the vehicle with only. one turn of the wheels as is possible with articulated steering.
- Good manoeuvrability is possible for all-wheel-driven vehicles.
- Good stability.
- Steering and turning the wheels requires space.
- Four-wheel crabbing facilitates lateral displacement of the machine.

Apart from these general types, there are also combinations of articulated steering and axle pivot steering.

14.2.3 Earthmoving Machinery

Earthmoving designates all modifications of the Earth's crust regarding position, form, and density. Among others, this might include:

- Excavate soil
- Digging ditches and soil excavations
- Raw material extraction
- Soil transport
- Material installation, e.g., for road and embankment construction
- Material compaction

Along with structural and civil engineering, earthmoving is another branch of construction, being applied in different cases.

Wheel Loaders

Wheel loaders or shovel dozers are extremely mobile machines with universal application possibilities. Their main task is to remove soil, as well as to load, transport, and locate material [14.13]. The working level is the same as the driving level, or even slightly below in some cases. Wheel loaders can be classified into:

- Front-end loaders
- Swing loaders
- Overhead loaders
- Telescopic loaders
- Skid steer loaders

The chassis and the steering variety used (articulated or axle pivot steering) are other criteria that can be used to distinguish between types of wheel loaders.

The most important variety of the wheel loaders listed above is the front-end loader. Here, the working device is mounted on the front part of the machine frame. It consists of a multiple bar linkage powered by hydraulic cylinders. This hoisting gear is usually equipped with a loader shovel. When loading soil, the shovel is lifted to the surface level. Keeping this position, the whole machine has to drive into the material. Thus, apart from the driving resistance, the machine also has to compensate the shovel's penetration into the material and filling resistance. When the shovel is filled, the hydraulic cylinders are placed into the transport position. Wheel loaders are mainly driven by diesel engines. Generally, a wheel loader has to be equipped with drives for the working devices, the steering units, and the chassis. Depending on the machine's power class, various drive varieties are used:

- *Wheel loaders of maximum* 59 kW. These wheel loaders mainly use hydrostatic drives. The efficiency factor, which is worse than that of mechanical drives, is compensated by lower costs and broader application. In general, the resulting maximum speed is 25 km/h and, in most cases, steering is by axle pivot.

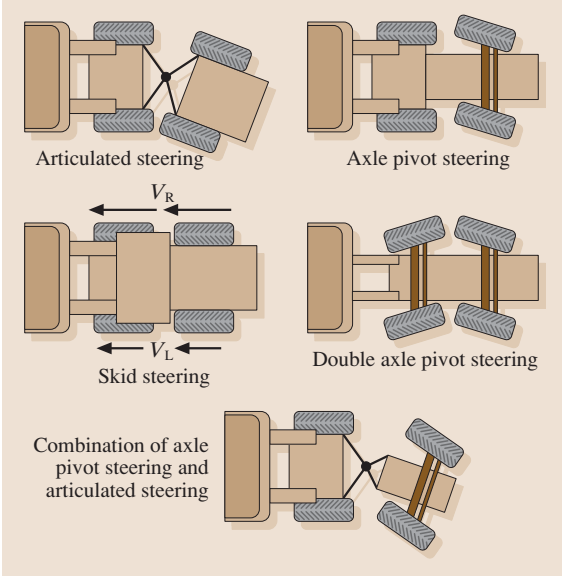

Fig. 14.13 Steering types

- *Wheel loaders of max.* 110 kW. The drive of these wheel loaders is realized by a power shift transmission and a torque converter. Some machines also use hydrostatic drives. Either articulated or axle pivot steering is applied. Maximum driving speed is about 40 km/h.
- *Wheel loaders of more than* 110 kW. Large wheel loaders are always equipped with power shift transmission, a torque converter, and articulated steering. Their maximum driving speed is 35–45 km/h. These machines often have a general operating license for general traffic.

Apart from driving power, there must be sufficient power for the working devices. Usually, the lifting force and the lifting speed of the working devices are adjusted, aiming to minimize the time period necessary for one loading process. Additionally, the lifting force is restricted to ensure stability of the machine. The working hydraulics usually consists of an open system with pilot control, which is used to supply the drives for steering and loading movements with an extra pump. Figure 14.14 shows an example of a hydrostatic drive of a wheel loader's working hydraulics.

The shovel's lifting and breaking off forces are mainly determined by the hydraulic cylinders and the kinematics applied. Figure 14.15 shows the kinematics used today. Modern machines are very often equipped with Z-kinematics due to the huge breaking off force effected by the good transmission of the shovel-tip cylinder mechanism. During the lifting process, Z-kinematics moves the shovel forwards and backwards while lowering the shovel. Parallel carrying is worse than with P-kinematics. The torque parallel (TP)-kinematic represents a compromise between both types of kinematics.

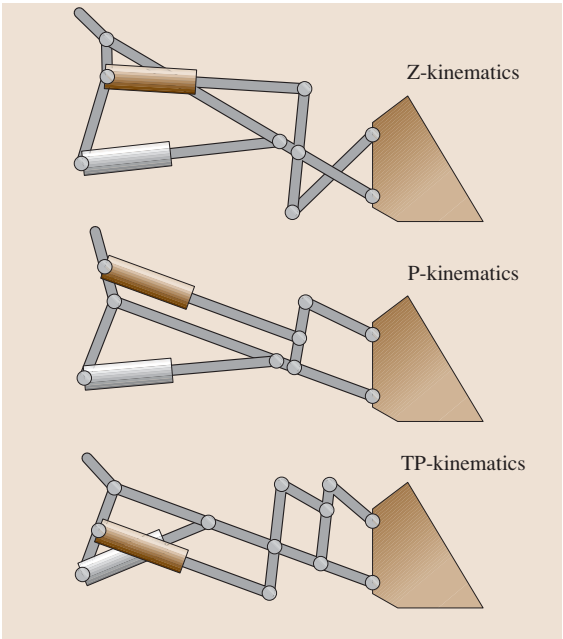

Fig. 14.15 Kinematics of a wheel loaders' working devices

Regarding the driver's working place, wheel loaders are similar to tractors. As a rule, these machines are equipped with a driver cabin today, not only for safety

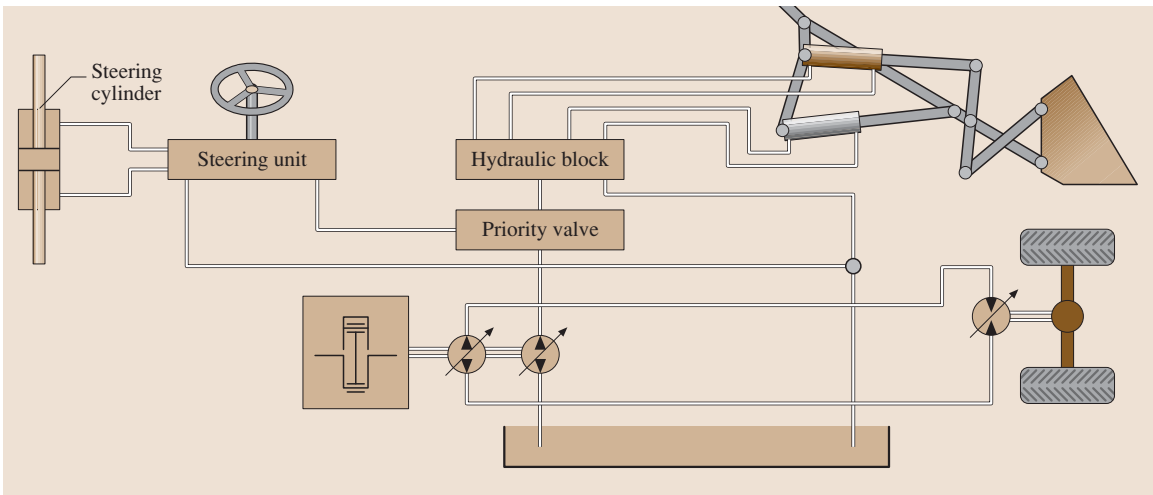

Fig. 14.14 Simplified hydraulic plan of a wheel loader

but also for driver comfort. Usually, the driver spends several hours operating the machine without a break. Therefore it is necessary to minimize stress and strain on the driver. The requirements for the driver's working place:

- Good view over the working device and the load during the whole working cycle
- Complete visibility without disturbances
- Huge door opening angle
- Safe and easy access to machine
- Air-conditioned cabin
- Adjustable driver's seat
- Ergonomic arrangement of the instruments
- Good vibration damping and reduction

The control system is also very similar to that of tractors. A controller area network (CAN) bus system is used for communication between the engine, operating device, and other machine components [14.14] (Fig. 14.16). The electronic components must be adjusted to rough machine usage, i. e., they must be well protected against vibrations, water, and dust. Nowadays, there are even microcontrollers that facilitate automated movement processes as well as supervising individual system states in order to prevent accidents.

Excavators

Excavators are loaders equipped with one or more buckets. A machine equipped with one bucket can only work discontinuously, i. e., carrying out intermittent process steps. In contrast to these *one-bucket excavators*, machines equipped with several buckets can work continuously.

Below we give a more detailed description of the so-called *one-bucket excavator* or cable dredger. This is an extremely large group, extending from special-purpose machines to universally applicable devices, so-called universal excavators.

The application area of the *one-bucket excavator* (or simply *excavator*) is extraction and handling of any kinds of goods. For this purpose, they use excavator spoons as well as digging and loading devices. Due to the advantages of hydraulic drive systems, excavators using this system are more important than those using a wire drive. The latter, however, are applied in excavators that are used to dig boreholes, which requires considerable working depth.

Today, the hydraulic excavator is the most important machine of this type, as hydrostatic power transmission and conversion are very advantageous in the case of excavators. Hydraulic excavators can be divided into single-purpose machines equipped with only one working device, and universal excavators, which can be equipped with various types of working devices [14.15]. There is a wide variety of such machines. Just regarding their own weight, they range from 0.5 t up to 800 t in the case of hydraulic excavators used in earthwork and open-cast mining. The smaller machines of 0.56 t are often called mini-excavators.

Another parameter used to classify these machines is chassis type:

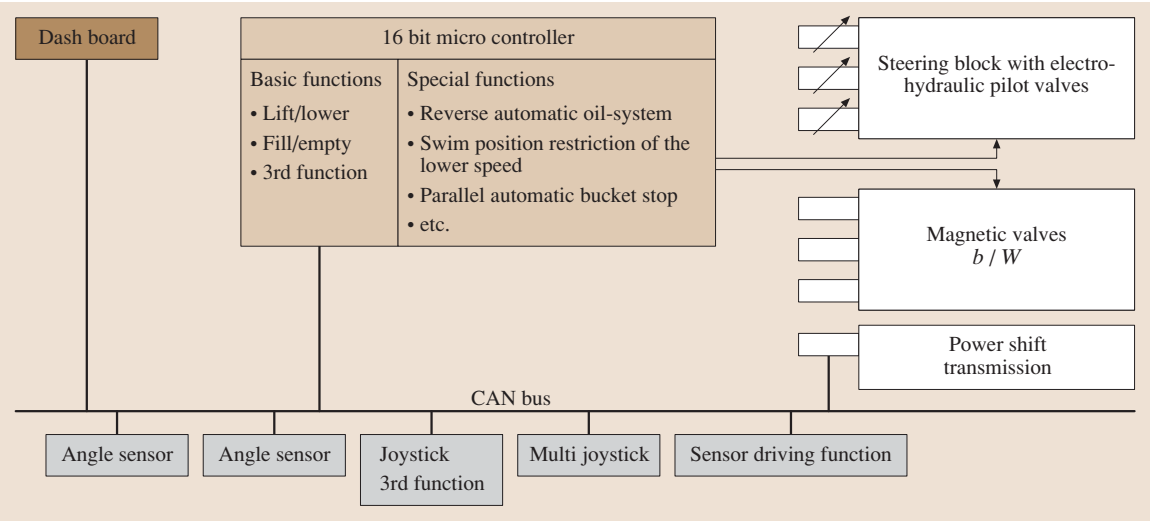

Fig. 14.16 Control system of a wheel loader (after [14.14])

- Tracklaying excavators, with crawlers or rubber-belted tracks
- Mobile excavators, which are equipped with a wheel chassis

Tracklaying excavators are designed for low driving speeds of up to 6 km/h. Normally, they just move on construction sites and do not participate in normal traffic. Mobile excavators or wheel excavators, however, do take part in the normal traffic. As is the case in agriculture, driving speeds are increasing considerably, with some machines traveling with a maximum speed of 50 km/h.

Figure 14.17 shows the basic construction of a hydraulic excavator. It is equipped with a revolving superstructure hinged to the chassis, which may be of chain or wheel type. The revolving superstructure carries the drive, including the oil and fuel containers as well as the cooling system, the filter, the control valve, the actuators, the driver's cabin, and the counterweight. The arrangement of these components is determined by the demand for balanced mass distribution, visibility, and ergonomics.

Another important component is the rotary transmission leadthrough, i. e., the connection between the revolving superstructure and the undercarriage. The hydraulic power needed for the drive is transmitted to the undercarriage by this rotary transmission leadthrough, which is a rotary pipe connection used to transport the fluid power from the rotating revolving superstructure to the drives installed in the undercarriage.

In the case of excavators, the hydraulic system is one of the most important components as all of the drives on the excavator are run hydrostatically. Using a pump power divider, a diesel engine distributes the power to several hydraulic cycles. There are always several power consumers to be supplied, which is a characteristic of excavator application. As a consequence, it is necessary to use control systems facilitating sensitive power-consumption adjustment and good energetic conditions as well.

Nowadays, an excavator's diesel engine is usually run at a rated speed, i. e., there is a constant initial speed of the hydraulic pumps. In some excavators the engine runs at a set of constant initial speeds. Variable-displacement pumps are used to adjust the flow rate depending on individual requirements. To achieve this, various systems can be applied, based on the load-sensing principle.

Hydraulic excavators increasingly make use of electrohydraulic systems. Microcontrollers also enable new possibilities for steering hydraulic devices and controlling and automating working cycles; for example, this kind of steering facilitates teach-in steering of individual motion sequences and automation of individual working cycles. Furthermore, there are even new possibilities regarding excavator management which do not involve running the diesel engine at a constant speed. In these systems, the diesel engine is optimally adjusted depending on individual requirements, which helps to reduce exhaust gas emissions and fuel consumption [14.17, 18].

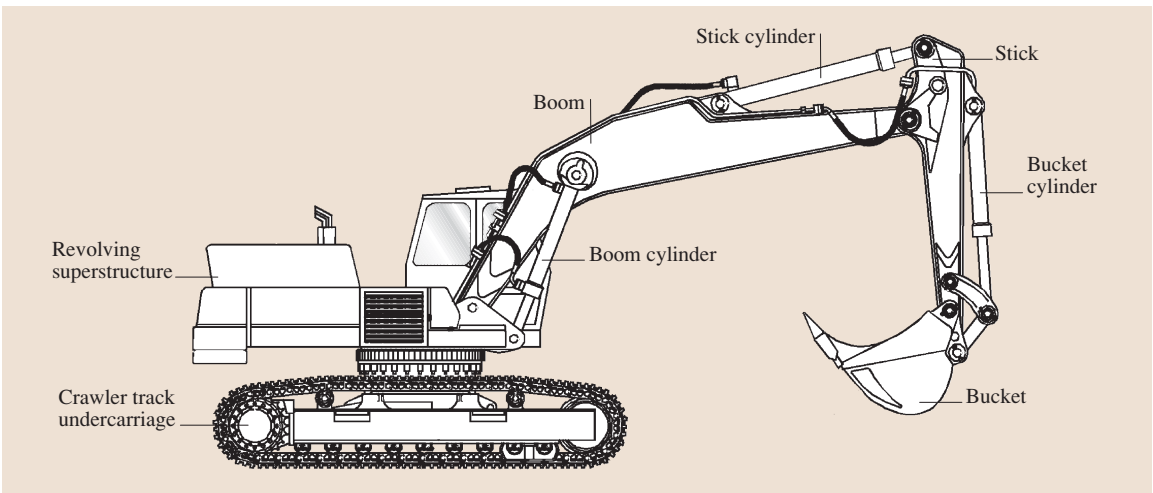

Fig. 14.17 Basic construction of a hydraulic excavator (after [14.16])

Graders and Scrapers

Graders are machines applied mainly in road construction (Fig. 14.18). The working device used is a blade designed for various applications. It is flexibly mounted between the front and the rear axle. In this position, the blade exhibits less vertical movement when crossing obstacles. In most cases, the chassis consists of pneumatic tyres. Apart from biaxial vehicles, triaxial ones also exist, with two axles combined into a tandem axle. In this case the single axle is used for steering, but machines with four-wheel steering or articulated steering have also been designed.

Graders are driven by a diesel engine with a capacity of 30–210 kW. Usually, the engine drives the tandem axle. Driving speed is 2–40 km/h, and can be accurately adjusted to the requirements of the individual task by using a driving gearbox. This is done through a manual transmission with up to 12 forward and 4 reverse gears. A grader's working weight is 5–30 t, and the wheelbase is 4.5 and 7 m. There are, however, devices that are much larger, weighing more than 90 t and with an engine power of more than 500 kW. For the vehicle's drive, various mechanical transmission types can be used, some of which have hydrodynamic converters or hydrostatic drives. Due to their advantages regarding various arrangement possibilities and considerable converting range, hydrostatic transmission has become increasing important in these machines. A decisive factor for the vehicle's drive is the nominal thrust force, which determines the machine's power capacity. The nominal thrust force depends on the engine power and the machine weight. A 2×2×2 grader delivers a ratio of engine power to machine weight of about 9–10 kW/t. A 1×2×3 grader is expected to deliver a ratio of about 7–8 kW/t [14.19].

Figure 14.19 shows a grader's blade positions. The specialized kinematics facilitate a large variety of blade positions, making the grader a universally applicable machine.

Depending on the chassis type, there are two types of scrapers: the wheel scraper and the tracklaying scraper with crawler, which is mainly utilized for difficult soil conditions. The excavating bucket consists of several parts. It has movable front and back sides in order to pour the material out of the container in a particular direction. Depending on the material and the machine, the cutting depth is 5–200 mm. The container's volume may vary from 1 up to 40 m^3, and the engine power may be as high as 700 kW. The driving speed necessary to transport the material can be 10–50 km/h. Conceptually, the front wheels are most strongly affected by the load, so they are driven. However, four-wheel drives are also in use [14.19].

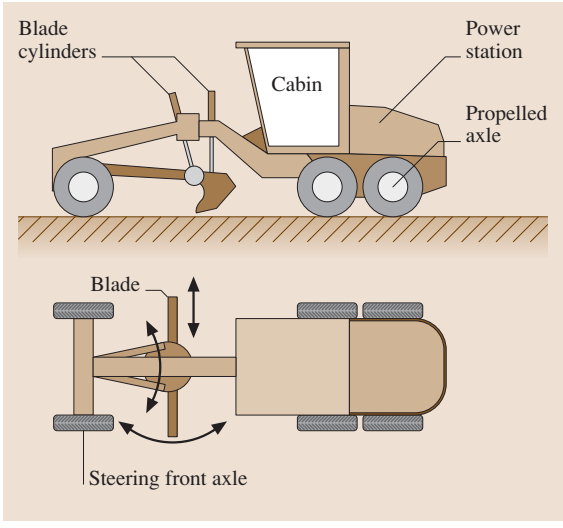

Fig. 14.18 Grader

14.2.4 Road Construction Machinery

Compaction Machinery

Compaction aims to increase the storage density and reduce the pore volume of material. Compaction machines serve to crush cavities and store soil grains at the highest possible density. The methods used depend particularly on the soil type:

- Grit and sand are compacted by vibration or pushing. Material of the same grain size is usefully mixed with other material in order to obtain a sieve classification. Pores between the coarse grains

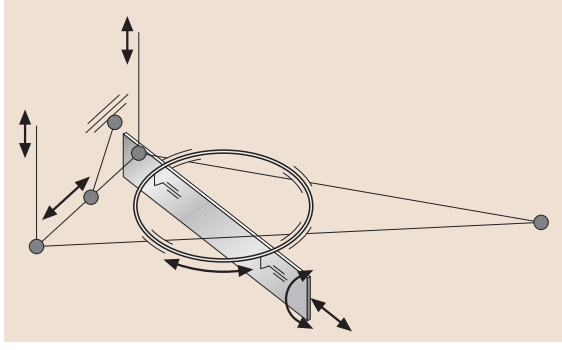

Fig. 14.19 Blade kinematics of a grader

should be filled with finer grains. The devices used are: vibration plates, vibration rollers, and blasting.
- Gravel and detrital rocks are compacted by pounding or pushing, smashing bulky chunks. The devices used are impact stampers, explosions stampers.
- Silt and clay are compacted by rolling or dispersing. There has to be sufficient water content in order to reduce the soil friction. However, the water content should not be lower than the pore volume to be achieved by compaction, otherwise water saturation will occur and the soil will adopt a plastic consistency. The devices in use are rammer butt rollers.

The compaction process consists of several individual processes:

- Ordering or distribution
- Destruction
- Pore water transport
- Displacement

Two main machinery groups can be distinguished:

- Statically working machines
- Dynamically working machines

It is also possible to classify them into rollers and vibratory plates.

Statically working rollers are among the oldest compaction devices, and today they exist in a huge variety. Depending on the number of roll bodies, they are classified into one-, two-, and trial-axle devices, or depending on their arrangement, into tandem or tricycle rollers. The roll body itself may be constructed as a flat roller, equipped with so-called sheep-feet roller, as a grid roller, or having rubber wheels.

Today, earthmoving and road construction make use of dynamically working rollers due to their better compaction performance. Usually, the rollers are equipped with vibratory stimulation; in some machines, there oscillation stimulation is also provided (Fig. 14.20). The unbalanced arrangement of masses and the rotation facilitate the introduction of vertical and rotating swinging into the drum or roller. The vertical swinging corresponds to vibration, and the rotating swinging provokes oscillation. By combining both movements it is possible to work on the material to be compacted according to its compaction potential [14.20]. Special measuring and steering systems enable optimum compaction. In these systems, there is a special focus on measuring the compaction. Modern systems are based on the principle of acceleration sensors that continuously measure the increasing rebound acceleration, comparing it with the result of previous measurements. In the case of the detection of increased compaction, the sensor produces a signal to carry out another drive over. For future documentation, the measurement data are additionally stored in relation as a function of area or position [14.21, 22].

With the vibration stimulation set to make the roller jump, the layer to be compacted will be more or less destroyed as it becomes uneven [14.21, 22].

The forerunner of the stamper was the iron hand stamper, which was used for paving work. In order to increase its stamping effect, engineers have developed heavier devices that are lifted either by excavators (the freefall stamper) or by blasting. The explosion stamper is used for compaction in narrow excavations or shafts. By igniting a fuel mixture, a rammer is thrown up (up to 46 cm), and then falls to the ground under the effect of gravity. This process provokes compaction of the fuel and re-ignition. Compaction of the soil is then effected by the explosion pressure and the rammer's rebound over a large number of strokes. A small stamper weighing up to 100 kg delivers compaction depths of up to 50 cm; heavier devices (500–1200 kg)

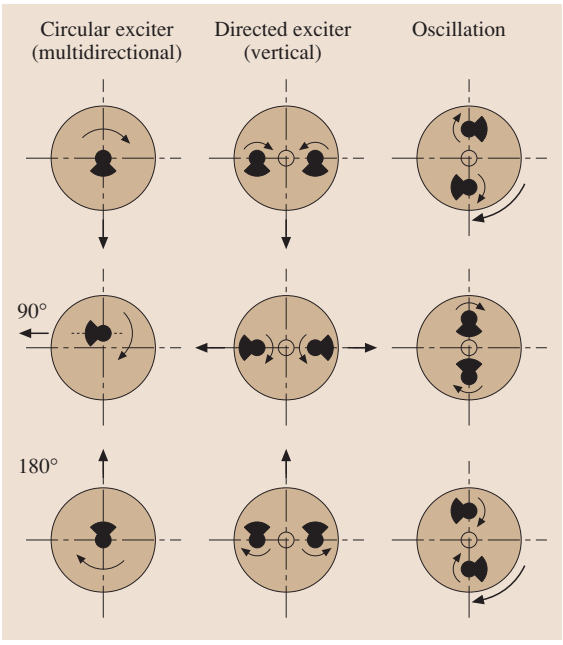

Fig. 14.20 The principle of vibration and oscillation stimulation (after [14.20])

achieve depths of 40–90 cm. Depending on the device used, the number of strokes is 60–80 strokes per minute. Vibratory stampers are used in narrow locations just like the explosion stamper. However, with a weight of 60–96 kg, they are lighter and only jump by 3–8 cm. Their multiple spring system is driven by combustion or electric motors with an average capacity of 2–3 kW. The material is compacted by the huge number of strokes (400–1000 strokes per minute) which cause a riddling effect. The vibratory plates are driven by combustion engines or electric motors. The vibrations are caused by an unbalanced mass vibration generator of various types of construction (directed and undirected vibration). Smaller plates have to be pulled to and fro, whereas larger devices are automotive, being steered by a shaft. It is possible to control their work direction, speed, and vibration.

Machines Used for New Road Construction

A variety of machines are used for road construction, and they shall be described in detail below. Figure 14.21 provides a rough classification of road construction machinery related to the individual construction processes.

Road pavers and slip-form pavers are used to build new road layers. Whereas road pavers are used to install special types of concrete, slip-form pavers are exclusively utilized to lay concrete. When laying asphalt, it is necessary to carry out a final treatment with rollers. When installing concrete, this roller work is not necessary. The slip-form paver compacts the material directly inside the machine, using special elements. In order to achieve the desired surface structure of the road, special-purpose machines are often used to work on the material when the slip-form paver has passed over it.

Road Pavers. The actual laying device is a screed. The road paver's screed is swimming on the material, and thus is also called a *swimming screed*. The buoyancy conditions depend on the weight, the screed's angle, the forward speed, and the material's viscosity.

Fig. 14.21 Process chain of road new construction

By means of tension bars, the screed is connected to the vehicle. The connecting spot is situated approximately in the center of the chassis to ensure that the vehicle's pitch does not affect the screed. If the layer thickness is to be changed, one also has to change the height of the linking point of the tension bars. Due to the swimming principle used in these machines, slow material alteration is created, leading to a long-wavelength height variation which is good for driving comfort. Nowadays, steering is exclusively done by electronic leveling systems, which facilitate separate steering of the left and right linkage point of the tension bar.

The screed itself is equipped with additional compaction devices. Using a tamper, the material is stuffed in front of the screed and compacted. For additional density increase, vibration elements or pressure bars used. In order to produce good installation of the hot material, it is necessary to heat the screed's compaction devices that are in contact with the material. This is done by electric systems powered by a generator that is run by a diesel engine. Furthermore gas and liquid heating systems are used for heating the screed using burners. The working width of road pavers is 1–16 m, with deposition layers of up to 0.35 m being possible. Given appropriate material logistics, large road pavers can install more than 1000 t of material per hour [14.21] (Fig. 14.22).

The paver tractor consists of a frame to which the chassis is mounted. Furthermore, it contains the driving unit, consisting of a diesel engine, the gearbox, the cooler, and the hydraulic system. The driver stand is situated in the upper part of the vehicle, giving the driver a good view of the material container and the screed. The chassis is either a wheel or a caterpillar chassis. The caterpillar chassis is composed of two hydrostatically driven chain tracks which are electronically controlled. Apart from steel chains, rubber bands are also often used. The wheel chassis are often triaxial with a large rear-wheel drive and small wheels mounted under the material container. Usually, two axles are driven, but four-wheel drives are also used. The advantage of a wheel chassis is that driving speed of up to 20 km/h are possible, whereas a crawler chassis only permits driving speeds of up to 6 km/h, and caterpillar chassis equipped with rubber belts enable maximum driving speeds of 16 km/h. However, the crawler chassis offers better traction and is less sen-

sitive to soil unevenness, facilitating more even road construction.

In order to meet the requirements of an even layer density and of very even roads, it is necessary to have a regular work process without interruptions. This is only possible with an automotive material reservoir to transport the material from the trucks to the paver in a regulated way [14.23].

In many cases, factors associated with the construction, e.g., too small construction sites, why the paver must work without such a feeder. For this reason, the traction drive as well as all drives for material transport have to be controllable. The command variable of the individual control cycles is the amount of material. In order to measure the amounts of material in the corresponding transport areas, either mechanical material sensors or ultrasound distance sensors are used, with the measured values being processed by digital steering systems.

Compacting the asphalt layer is necessary to ensure its stability. Immediate compaction is carried out by the paver's screed. The following rollers are then used to obtain the final density. The following compaction elements are in use:

- Tampers: The tamper is the first compaction device; it is a tamper bar driven by an excenter shaft. The throw is determined by the excenter radius and can be gradually adjusted. Depending on the material, the throw is about 2–7 mm. Another influencing factor is the drive speed, which ranges from 600 to 2400 rpm.
- Double tampers: Another possibility is to use a double tamper, which is driven by an excenter.
- Vibration stimulator: The majority of screeds make use of the vibration principle in order to compact the layers. Usually, a vibration stimulator is mounted on the blade of the screed, being driven mechanically with an adjustable frequency.
- Pressure bars: Pressure bars are similar to tampers. They are driven by pressure impulses which are transmitted into the layer by the bar, thus effecting compaction.

To meet the required geometrical dimension of the road to be constructed, use is made of leveling systems. Graders, dozers, slip-form pavers, and milling machines are also used, designed to fulfil the following tasks [14.21, 24]:

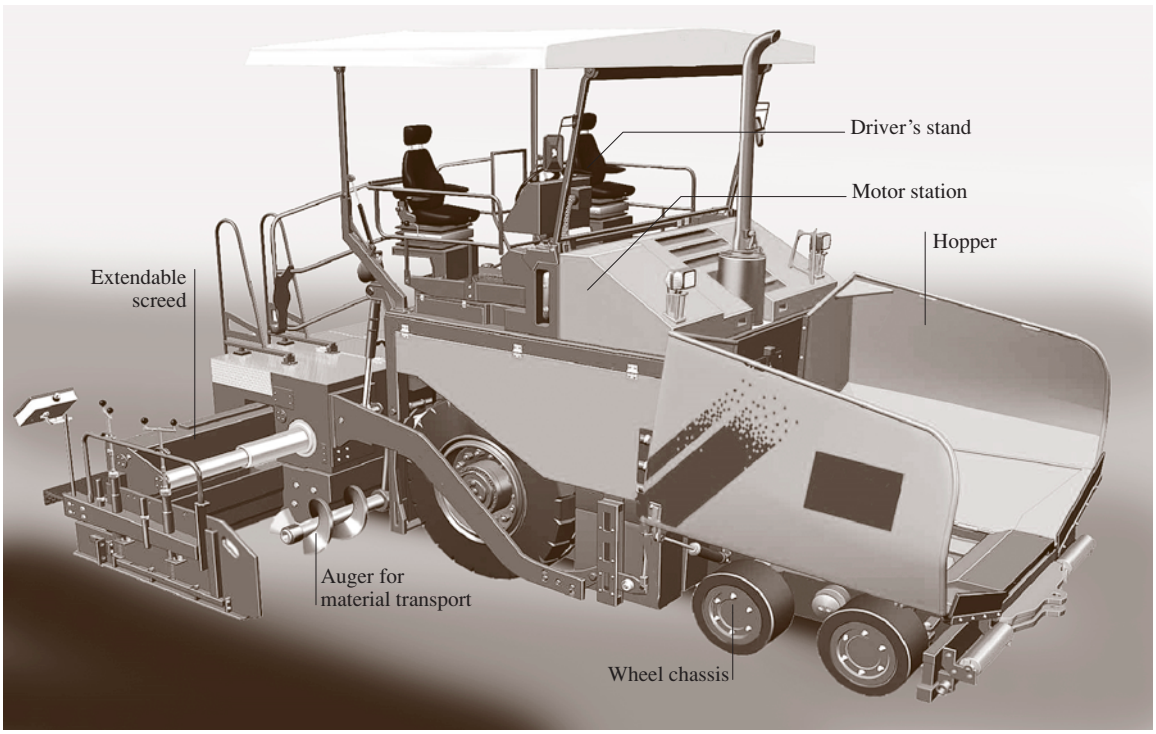

Fig. 14.22 Road pavers

- Position control of the working device
- Height and inclination control of the working device
- Position control of the working device

In the case of road pavers leveling is carried out by height adjustment of the linking points of the tension bar.

Slip-Form Pavers. For concrete road pavement, mainly slip-form pavers are in use today (Fig. 14.23). These machines are characterized by:

- Dragging along the *slipping form*
- Series arrangement of the working devices:
  - To compact the delivered concrete
  - To compact the concrete using vibrators
  - To pave
  - To fix anchors
  - To screed

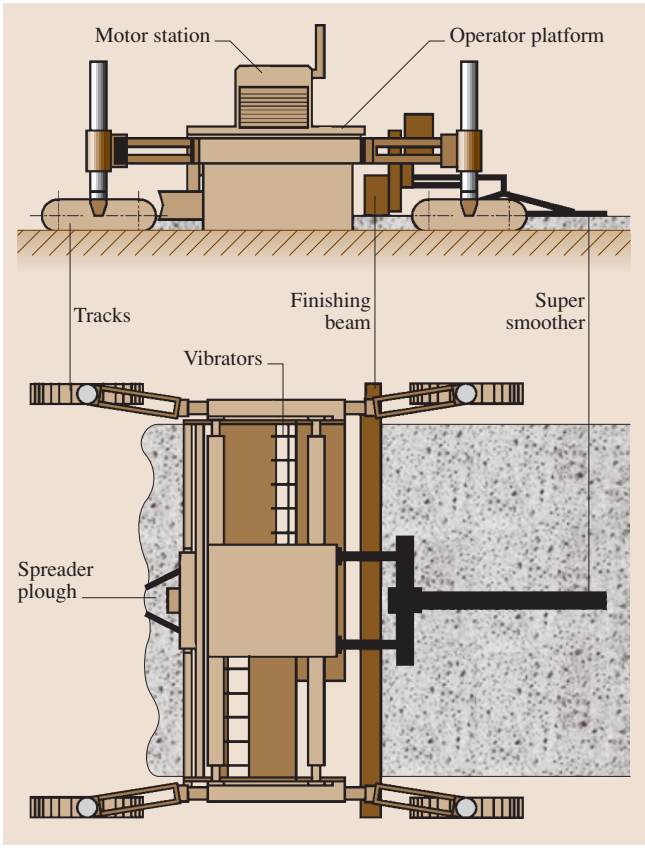

Fig. 14.23 Slip-form paver with variable working widths (after [14.25])

The working devices are connected to the tracklaying chassis in a frame. In contrast to road pavers, leveling in these devices is carried out by lifting and lowering the machine frame. To achieve this, the frame is connected to the tracklaying chassis by hydrostatically driven hydraulic cylinders. Similar to the road pavers, a diesel engine is used for the drive, providing the hydraulic and the electrical system with the energy needed. The installed engine power is about 79 kW in smaller machines, and in larger ones can be up to 300 kW. In smaller machines the chassis consists of three tracks, whereas in larger ones there are four chain tracks. The maximum working width is 16 m, and the layer thickness can be up to 0.45 m [14.21].

Machines Designed for Road Maintenance

Ageing of road materials as well as the weight permanently put on the coating require maintenance measures to be taken in order to ensure the road's function. Machine application depends on the particular road damage and the size of the coat to be worked on. There are five different paving processes [14.26]:

Reshape:	Reshaping of a road layer without new mixing material
Regrip:	Rebuilding of the road grip
Repave:	Rebuilding of a road layer with new mixing material
Remix:	Rebuilding of a road layer with milled and new material
Remix Plus:	Manipulating of the asphalt mixture in combination of rebuilding a road layer

The remix process usually is carried out in situ, i. e., the individual process parts of taking off, mixing, adding new material, laying, and compacting are done in only one stage. Repaving is usually an intermittent process, i. e., after taking off the material (e.g., by cold-milling machines) there is a delayed laying of the material with a paver followed by compaction by rollers.

The focus of the road maintenance process is taking off the damaged material. In the case of asphalt and partially for concrete (Fig. 14.24), this is done by cold milling machines. Here, a diesel engine drives the milling drum using a belt transmission. The milling drum is equipped with cylindric chisels, which serve as cutting instruments, situated in replaceable chisel holders. The roller's equipment as well as the size and the variety of chisels are determined by the application area. In order to avoid dust, the work field is sprayed with water. The removed material is transmit-

ted to a belt conveyor from where it is transported to a truck.

Small milling machines mainly use wheel chassis with three or four wheels. Their working widths are 0.25–1.2 m. Large milling machines, however, offer working widths of up to 2.2 m, with an engine power of about 600 kW. Depending on the machine sizes, milling machines are equipped with wheel or caterpillar tracks which are driven by hydro-motors (Fig. 14.25). The wheels as well as the chain tracks are mounted on lifting cylinders which are connected to the machine's chassis. The milling depth is adjusted by lifting or lowering the machine, controlled by an electronic leveling system.

A machine which is very similar to the milling machine is the recycler (Figs. 14.26, 14.27). It takes off the damaged material and recycles it. Very often various substances or binders such as foamed bitumen, cement or bitumen are added to the material which is to be prepared. Instead of a milling rotor as is used in cold-milling machines, a rotor equipped with cylindric chisels is designed for milling and mixing the milled material with the additional substances.

These vehicles use wheel chassis and tracklaying chassis. Their working widths are up to 3.05 m, working depth is up to 0.5 m, and the installed engine power reaches 500 kW.

The complex processes of in situ road maintenance (shown in Fig. 14.24) requires the machines shown in Fig. 14.27. This machine integrates the work functions of milling, breaking, taking off, mixing and adding new material, spreading, carrying them out in one stage, and precompacting. This helps to save time and reduce traffic obstructions. A machine such as this delivers working widths of 4.2 m.

14.2.5 Farming Equipment

Agriculture's main task is to produce sufficient food to nourish man and farm animals. Since the early Stone Age, when man began to settle and grow plants and animals, people have developed useful devices and

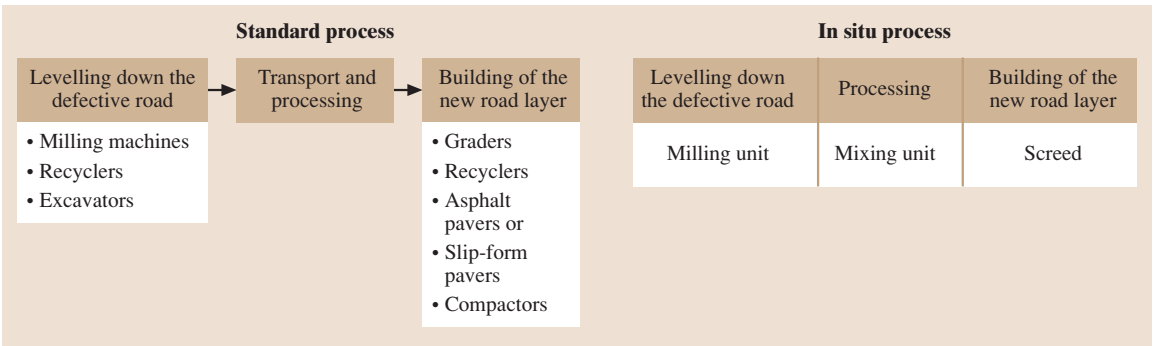

Fig. 14.24 Process chain of road maintenance

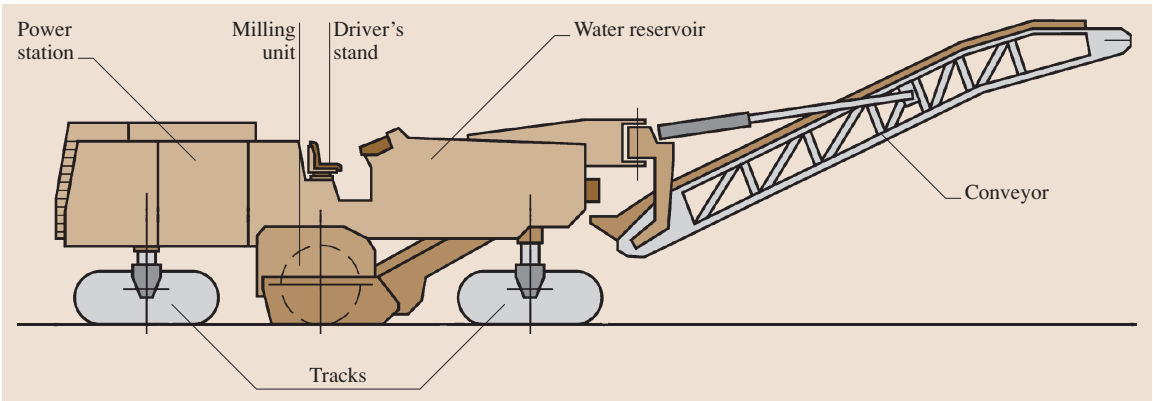

Fig. 14.25 Structure of a cold-milling machine

machines to do the necessary work. Mechanization, however, did not start until the 19th century, when steam engines, which could also drive larger devices such as the steam plough, emerged. Mechanization took a great leap forward in the 1950s when the agricultural sector lost increasing numbers of workers and new production processes were introduced.

The basic tasks of agricultural mechanization are:

- Improving productivity
- Increasing plant and animal yield
- Loss reduction
- Improving work productivity
- Reducing working hours
- Improving work process efficiency
- Improving workers' conditions

These aims lead to greater productivity and reduced resource consumption. Thus, agriculture has the same basic goals as industrial production, but of different goods. The decisive difference is the fact that agriculture is highly dependent on external conditions which cannot be influenced, such as weather and soil conditions. Due to the fact that agriculture is closely related to nature, it is necessary to consider ecological aspects as well.

Classification of Agricultural Machines

In general, agricultural machines are classified into machines used for livestock farming and those used for cultivation. Livestock farming deals with the production of animal products with the corresponding buildings, milking systems, etc. Machines from the mobile working sector are used for outdoor farming, as described in detail below. Due to the large variety of cultivated plants and considerable regional differences, numerous different agricultural production methods and machines have emerged. These machines may be classified as follows:

- *Tillage*: Tillage aims to change soil resources and conditions in order to provide plants with optimum growing conditions.
- *Sowing and planting*: These machines are designed to introduce the seed or the plants into the soil. Due

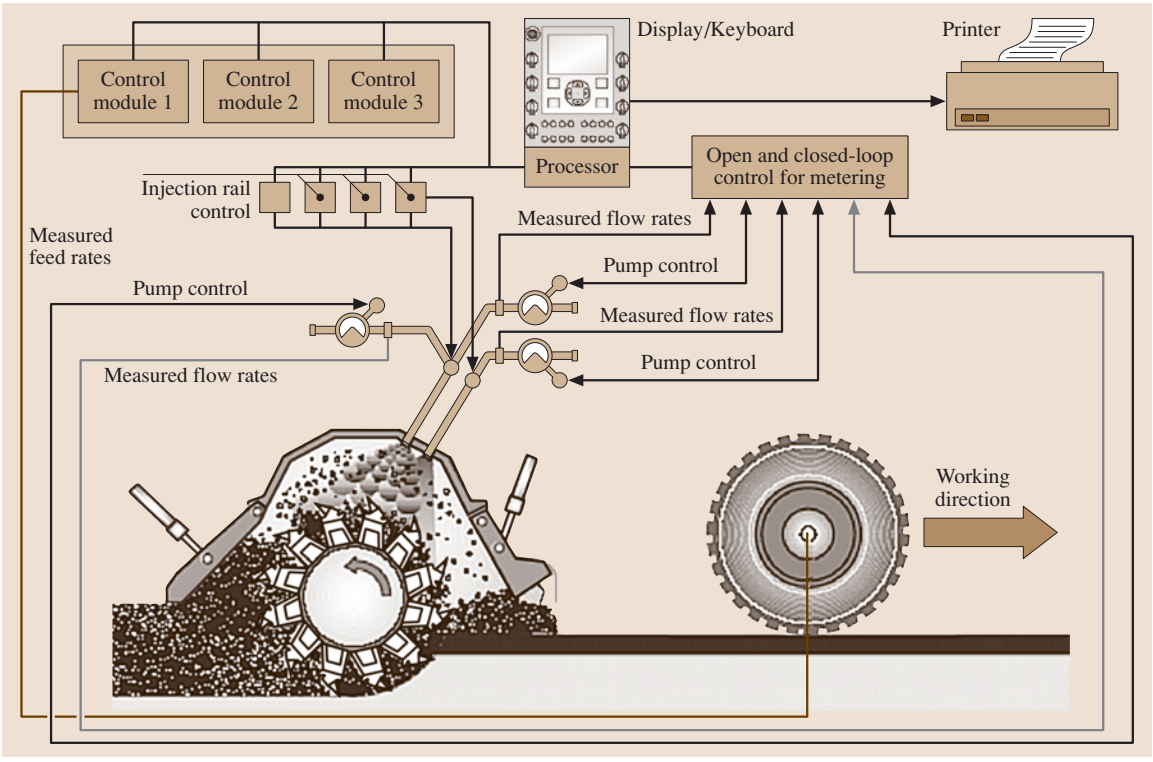

Fig. 14.26 Schematic diagram of the microprocessor control for simultaneous injection of foamed bitumen and water in a recycler (after [14.27])

to the large differences between plants, machine designs vary greatly:

- Drilling machines: Using dose-measuring devices and seed pipes, drilling machines are used to sow seeds. Usually seeds are sown in rows, with their distribution being as regular as possible and continuously adjustable.
- Single-seed drilling machine: This machine lays a single seed at a particular soil location. This is necessary, e.g., with corn and sugar beets, which need to be planted at a specified separation to ensure successful growth.
- Planting machine: These are special machines designed to lay tubers, e.g., potatoes, into the seed bed. They should fulfil the following requirements: regular, constant planting depth, exact tuber distance even with different tuber sizes and shapes, and regular row distance with even soil covering of the tubers.
- Transplanters: They are for plants, e.g., trees or certain sorts of vegetable.

- *Fertilizing*: Fertilizing machines are designed to distribute fertilizers regularly onto fields. There are two main groups of fertilizers:
  - Organic fertilizers (e.g., solid and fluid manure)
  - Mineral fertilizers
- *Plant protection*: The aim of plant protection is to protect crop plants against damage effected by weeds, fungi, and diseases. To achieve this, various methods are employed:
  - Physical-mechanical methods
  - Chemical methods
  - Biological methods

Mechanical plant protection removes weeds mechanically. Chemical and biological plant protection make use of plant-protecting agents. The machines used for this purpose are sprayers that mix fluid plant-protection agents and distribute them by using a hydraulic pump system equipped with spray valves. Modern sensor systems are able to identify damaged plants so that the agents can be distributed as required. Fruit culture and viniculture additionally make use of vaporizers, which – in contrast to sprayers – use air to support the drop transport.

- *Crop harvesting*: The majority of agricultural goods are crops such as grasses or cereals. Harvesting these culture plants means mowing their stems. The cutting method depends on several factors, the most important of which are:
  - Crop humidity
  - Crop geometry and stability
  - Harvest aim

  After the cutting process, the crop is further processed. In the case of grass, conditioners are used to destroy the external blade strata in order to cause the humidity to leave the plants faster, thus accelerating the drying process. Hay treatment machines are used to turn the grass so that it dries faster. They are additionally used to gather the crop into swaths so that a forage harvester or compactor can pick it up subsequently. It is the compactor's task to compact the crop, thus reducing its transport volume. Crop choppers are designed to chop the material so that it can be processed to become silage.
- *Grain harvesting*: Grain is one of the most important agricultural plant to be cultivated; it is

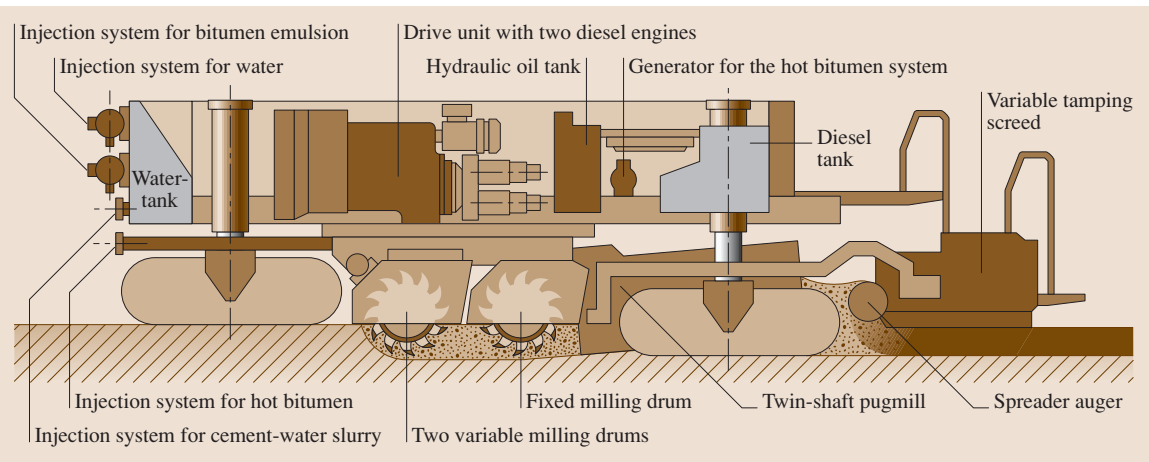

Fig. 14.27 Configuration of an in situ recycler (after [14.27])

harvested by combine harvesters. These machines are extremely complex, applying several mechanical process technology features:
- Cutting stems and ears
- Conveying stems and ears
- Threshing
- Separating grains from straw
- Cleaning
- Temporary crop storage
- Chopping straw

- *Root crop harvesting*: Potatoes and sugar beets are among the most important root crops. Harvesting them involves digging the crops out of the soil, cleaning, and then transporting them from the field. In terms of complexity, machines for this purpose can be compared to combine harvesters.
- *Engineering for intensive cropping*: The machines used for this task are special-purpose machines such as cotton harvesters or grapes harvesters.

Tractors

In the area of agriculture, tractors are of special importance as half of all agricultural machine investment is for tractors [14.9]. The tractor's tasks are [14.10]:

- Traction work on the field
- Transport work on the farm
- Driving mobile and stationary machines and devices
- Working with mounted devices

Figure 14.28 shows the most important tractor constructions. Most of the tractors used today are standard tractors. If one looks at the specified construction types, the universal tractor (standard tractor), equipped with a comfortable cabin and four-wheel drive, is of central importance. The huge range of different tractor concepts is reflected in the installed engine power capacity, which may vary from a few to several hundred kW.

Frames

The frame is the actual undercarriage of mobile working machines. In the case of tractors, the function of carrying is partially integrated in key components such as engine, gears, and axles so that there are different construction types:

- Block construction or frameless construction: This is the prevailing construction type used in standard tractors. Its characteristic feature is the link of axles, gears, and engine by means of flanges. The cases of these components are usually self-supporting cast constructions.
- Partial frame construction: This is a combination of block and frame construction, with various possible configurations. Here, the engine and the front axle are usually mounted on a steel frame. The gears and the rear axle, however, are still constructed as self-supporting components. In the case of the so-called *three-fourth frame*, only the rear axle is a self-supporting construction.

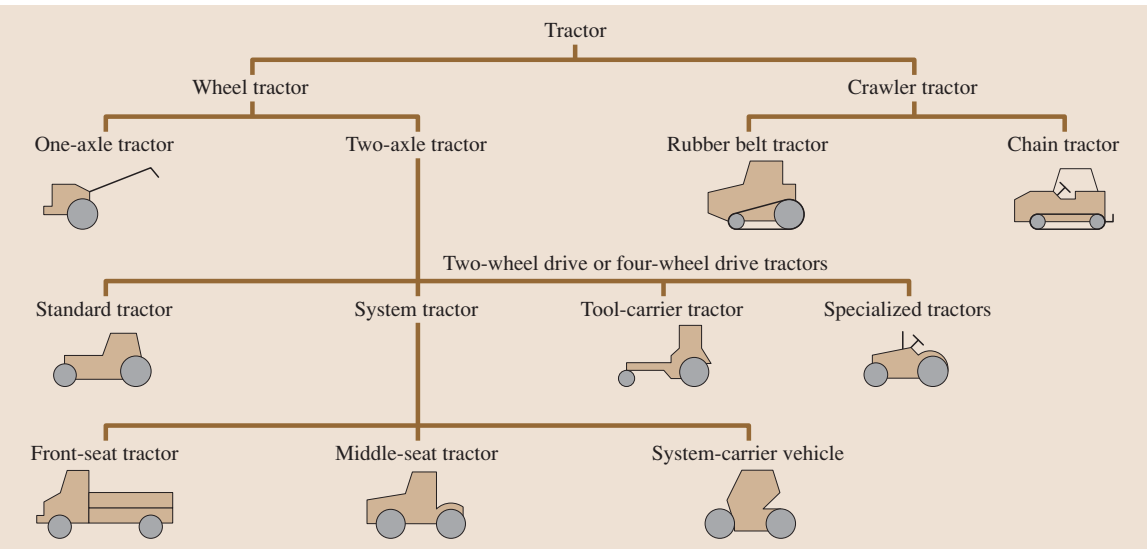

Fig. 14.28 Systematic classification of tractors (after [14.10, 28])

- Full-frame construction: Here the frame has to completely fulfil the task of the chassis. This approach is mostly used in machines with a small number of pieces, in system tractors, and in machines with a large range of engine and gear variants.

Chassis and Axles

In modern tractors, it is possible to drive all axles; pure rear-axle drives are the exception rather than the rule. The advantages of the four-wheel drive are:

- Larger traction force for field work (up to about 40% more for a traction weight increase of only 20%)
- Increased traction capacity, with equal slip and engine use
- Reduced energy consumption relative to tractive capacity
- Improved work with front devices, such as frontend mowers
- Improved driving safety
- Soil protection
- Smaller rear wheels
- Cost-saving front wheel brake

The disadvantages of the four-wheel drive are:

- Higher costs for the same engine capacity
- Greater losses, even with passive four-wheel drive
- Increased maintenance standards
- Larger turning circle

In the case of tractors, suspension and damping of the vehicle is done completely by the tyres. Due to the increased speed of standard tractors, up to 40–50 km/h, the suspension of the machine is of growing importance. As the rear axles are rigid, except for in a few exceptions, standard tractors are equipped with suspended front axles. Much use is now made of front-axle suspension with rigid axles, height control, and the possibility of locking the suspension for frontend loader work [14.29].

Power Transmissions

Tractors mainly use diesel engines due to their lower fuel consumption. This is achieved by direct diesel injection and the engine being charged by an exhaust gas turbocharger and air cooling. Over the last few years, there has been increased use of electronic engine controllers, facilitating directed control of the injected fuel and the injection time, which again helps to increase the engine capacity. Furthermore, it is necessary to combine modern injection systems and charging systems in order to keep in line with stricter exhaust gas regulations.

Tractor engine development is very closely related to that of other commercial vehicles today. The tractor's frameless construction impeded the use of standard engines whose case constructions could not take up the loads that would have been necessary for block construction. Meanwhile many tractors have a frame construction, easing this restriction.

Due to the complexity of the drive – the power take-off (p.t.o.) drive and four-wheel drive – a tractor's transmission makes production very complex. It is the gears' main task to adjust the tractor's driving speed to the individual working conditions. The tractor's rated power can only be transmitted with the rated torque. Therefore, the drive wheels' torque has to be adjusted in order to transmit the desired power capacity. Further tasks of the gears are changing the driving direction and driving auxiliary drives (p.t.o., four-wheel drive, frontend mower).

In standard tractors, the basic construction of the gears has been influenced by the frameless construction for a long time (Fig. 14.29). However, in recent

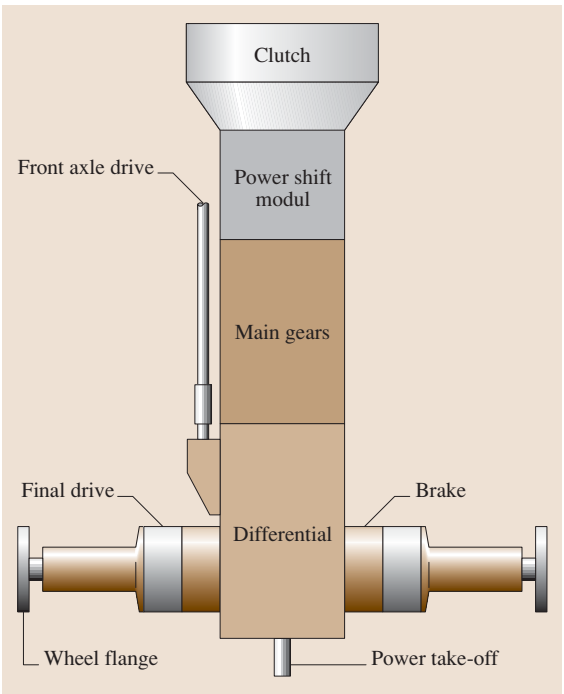

Fig. 14.29 Widespread arrangement of the most important functional groups in tractor gears of the main work pieces area (after [14.9])

years a tendency towards using frame constructions has emerged.

The engine transmits the power to the gears through the driving coupling and p.t.o. coupling. After fruitless attempts to establish direct conventional transmission in standard tractors until recent years, engineers mainly worked on power-shifted transmissions. Gear-shifted transmissions are often constructed according the so-called *group principle*. This variety of construction saves both gears and time. Due to the multiplication effect, a maximum of eight wheel pairs are needed; e.g., 16 forward steps with four basic gears and four groups. In practice, the groups are arranged in order to provide the driver with favorable work speeds (e.g., one field group "L" and one road group "H").

The latest result of tractor development is the continuously variable transmission. The advantages of this concept are good driver comfort, wide spread speeds, good efficiency, and flexible distribution of the load to the drive and p.t.o. In a continuously variable transmission, the power from the diesel engine is distributed by a planetary gear to a mechanical and a hydrostatic gear unit. Before leaving the gears, the changed power parts are added again. This results in good use of the mechanical drive's high efficiency as well as of the hydrostatic drive's shifted work process.

Figure 14.30 shows the basic construction of a tractor's continuously variable transmission using two gears. Due to the mechanical two gear transmission, which is applied only in the standard tractor, there are two driving speeds: 0–32 km/h and 0–50 km/h.

It is an important task of tractors to supply power to drive working devices. Apart from the p.t.o. delivering the mechanical power, tractors also supply hydraulic power. On the one hand, the latter is needed for driving working machines; on the other hand, hydraulics are also used to drive the hitch. Hydraulic systems for tractors have gained in importance. Today, there are two main tractor hydraulic systems to be distinguished in their basic construction:

- *Constant-flow system*. These simple hydraulic systems mainly use gear wheel pumps. The system's pressure depends on the required load, with the maximum pressure being determined by a pressure restriction valve. When a wheel gear pump is used, volume flow inside the system is only possible by varying the pump's rotation speed. The striking advantage of this system is its low cost. The disadvantage of these systems is that, if several devices are consuming power, they will influence one another. Furthermore, it is always the consumer with the smallest load that is supplied first. Another disadvantage is that the part of the volume flow that is not needed by a consumer has to be throttled away, which results in considerable losses. Modern constant-flow systems use multicycle systems running different consumers independently from one another by using separate pumps.
- *Load-sensing systems*. These are the modern hydraulic systems used in tractors, making use of axial piston displacement pumps. They allow continuous adjustment of the volume flow. A characteristic feature of a load-sensing system is that the volume flow is adjusted by a valve depending on a pressure drop. With the valve closed, only a small volume flow is provided to maintain a pressure of 2–3 MPa. When a valve is opened, the load pressure increases and is transmitted to the displacement pump's control by means of load pressure re-registration. The volume flow controller shifts the pump to a higher volume, thus keeping the pressure flow through the valve at a constant rate. The advantage of this system is that several power consumers can be supplied simultaneously with oil by one pump.
