Springer Handbook of Mechanical Engineering

Springer Handbooks provide a concise compilation of approved key information on methods of research, general principles, and functional relationships in physical sciences and engineering. The world's leading experts in the fields of physics and engineering will be assigned by one or several renowned editors to write the chapters comprising each volume. The content is selected by these experts from Springer sources (books, journals, online content) and other systematic and approved recent publications of physical and technical information.

The volumes are designed to be useful as readable desk reference books to give a fast and comprehensive overview and easy retrieval of essential reliable key information, including tables, graphs, and bibliographies. References to extensive sources are provided.

Preface

Mechanical engineering is a broad and complex field within the world of engineering and has close relations to many other fields. It is an important economic factor for all industrialized countries and the global market allows for wide international competition for products and processes in this field. To stay up to date with scientific findings and to apply existing knowledge in mechanical engineering it is important to renew and continuously update existing information.

The editors of this *Springer Handbook on Mechanical Engineering* have worked successfully with 92 authors worldwide to include chapters about all relevant mechanical engineering topics. However, this Handbook cannot claim to cover every aspect or detail of the mechanical engineering areas or fields included, and where mechanical engineers are currently present and contributing their expertise and knowledge towards the challenges of a better world. However, this Handbook will be a valuable guide for all who design, develop, manufacture, operate, and use mechanical artefacts.

We also hope to spark interest in the field of mechanical engineering from others. In this Handbook, high-school students can get a first glance at the options in this field and possible career moves.

We, the editors, would like to express our gratitude and thanks to all of the authors of this Handbook, who have devoted a considerable amount of time towards this project. We would like to thank them for their patience and cooperation, and we hope for a long-lasting partnership in this ambitious project. We would also most sincerely like to thank our managers and friends at Springer and le-tex. The executives at Springer–Verlag were always most cooperative and supportive of this Handbook. Without Dr. Skolaut's continuous help and encouragement and Ms. Moebes' and Mr. Wieczorek's almost daily requests for corrections, improvements, and progress reports it would have taken another few years – if ever – to publish this Handbook. Stürtz has done a fantastic job in printing and binding. Finally we would like to thank all the people we work with in our departments and universities, who tolerated the time and effort spent on this book.

Finally, we know that there is always room for improvement – with this Handbook as with most engineering products and approaches. We, as well as the authors welcome your fair hints, comments, and criticism. Through this Handbook and with the authors' efforts, we would also like to draw your attention to what has been accomplished for the benefit of the engineering world and society.

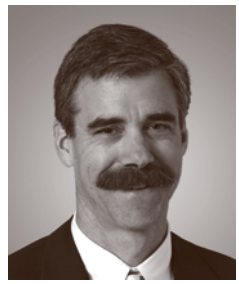
About the Editors

Dr. Karl-Heinrich Grote is a Professor and Chair of the Department of Mechanical Engineering – Engineering Design at the Otto-von-Guericke University in Magdeburg, Germany. He earned his “Diploma in Mechanical Engineering” (Masters of Science in Mechanical Engineering) in 1979 and his “Dr.-Ing.” (Ph.D. in Engineering) in 1984, both from the Technical University in Berlin, Germany. After a post doctoral stay in the USA he joined an automotive supplier as manager of the engineering design department. In 1990 he followed a call to become full professor at the Mechanical Engineering Department at the California State University, Long Beach, USA. In 1992 he received the TRW Outstanding Faculty award and in 1993 the VDI "Ring of Honor" for his research on Engineering Design and Methodology. In 1995 he was named chair of the Engineering Design Department at the Otto-von-Guericke University in Magdeburg, where he is now Dean of the College of Mechanical Engineering. From October 2002 to September 2004 he was Visiting Professor of Mechanical Engineering at the California Institute of Technology (Caltech) USA. Since 1995 he is Editor of the DUBBEL (Taschenbuch für den Maschinenbau) and author of several books.



Dr. Erik Antonsson is a Professor of Mechanical Engineering at the California Institute of Technology in Pasadena, where he organized the Engineering Design Research Laboratory and has conducted research and taught since 1984. He earned a Bachelor of Science in Mechanical Engineering from Cornell University in 1976, and a PhD in Mechanical Engineering from the Massachusetts Institute of Technology, Cambridge in 1982. In 1984 he joined the Mechanical Engineering Faculty at the California Institute of Technology, where he served as the Executive Officer (Chair) from 1998 to 2002. From September, 2002 through January, 2006, Dr. Antonsson was on leave from Caltech and served as the Chief Technologist at NASA’s Jet Propulsion Laboratory (JPL). He was an NSF Presidential Young Investigator (1986-1992), won the 1995 Richard P. Feynman Prize for Excellence in Teaching, and was a co-winner of the 2001 TRW Distinguished Patent Award. Dr. Antonsson is a Fellow of the ASME, and a member of the IEEE, AIAA, SME, ACM, and ASEE. He has published over 110 scholarly papers in the field of engineering design research, has edited two books, and holds eight U.S. patents.

Part A Fundamentals of Mechanical Engineering

Introduction

1. Introduction to Mathematics for Mechanical Engineering

Ramin S. Esfandiari

This chapter is concerned with fundamental mathematical concepts and methods pertaining to mechanical engineering. The topics covered include complex analysis, differential equations, Laplace transformation, Fourier analysis, and linear algebra. These basic concepts essentially act as tools that facilitate the understanding of various ideas, and implementation of many techniques, involved in different branches of mechanical engineering. Complex analysis, which refers to the study of complex numbers, variables and functions, plays an important role in a wide range of areas from frequency response to potential theory. The significance of ordinary differential equations (ODEs) is observed in situations involving the rate of change of a quantity with respect to another. A particular area that requires a thorough knowledge of ODEs is the modeling, analysis, and control of dynamic systems. Partial differential equations (PDEs) arise when dealing with quantities that are functions of two or more variables; for instance, equations of motions of beams and plates. Higher-order differential equations are generally difficult to solve. To that end, the Laplace transformation is used to transform the data from the time domain to the so-called *s*-domain, where equations are algebraic and hence easy to treat. The solution of the differential equation is ultimately obtained when information is transformed back to time domain. Fourier analysis is comprised of Fourier series and Fourier transformation. Fourier series are a specific trigonometric series representation of a periodic signal, and frequently arise in areas such as system response analysis. Fourier transformation maps information from the time to the frequency domain, and its extension leads to the Laplace transformation. Linear algebra refers to the study of vectors and matrices, and plays a central role in the analysis of systems with large numbers of degrees of freedom.

1.1 Complex Analysis

Complex numbers, variables and functions are the main focus of this section. We will begin with complex numbers, their representations, as well as properties. The idea is then extended to complex variables and their functions.

1.1.1 Complex Numbers

A complex number z appears in the rectangular form

$$z = x + \mathrm{i}y\,,$$
$$\mathrm{i} = \sqrt{-1} = \text{imaginary number}\,, \tag{1.1}$$

where x and y are real numbers, called the real and imaginary parts of z, respectively, and denoted by $x = \mathrm{Re}(z)$, $y = \mathrm{Im}(z)$. For example, if $z = -1 + 2\mathrm{i}$, then

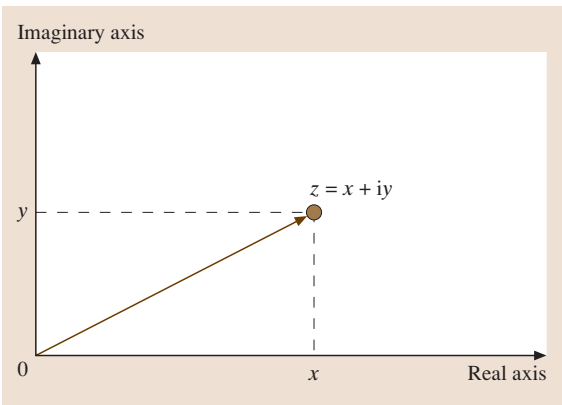

Fig. 1.1 Geometrical representation of complex numbers – the complex plane

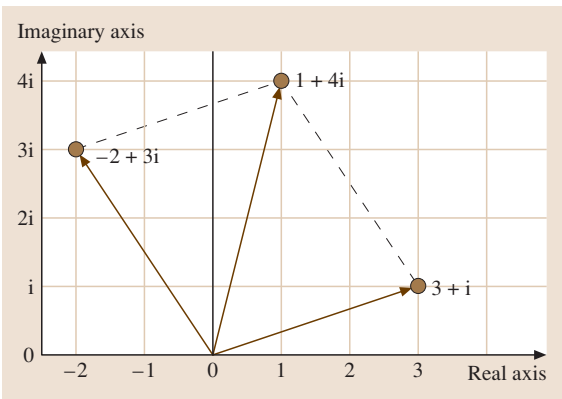

Fig. 1.2 Addition of complex numbers by vector addition

$x = \mathrm{Re}(z) = -1$ and $y = \mathrm{Im}(z) = 2$. A complex number with zero real part is known as pure imaginary, e.g., $z = 4\mathrm{i}$. Two complex numbers are said to be equal if and only if their respective real and imaginary parts are equal. Addition of complex numbers is performed component-wise, that is, if $z_1 = x_1 + \mathrm{i}y_1$ and $z_2 = x_2 + \mathrm{i}y_2$, then

$$\begin{aligned} z_1 + z_2 &= (x_1 + \mathrm{i}y_1) + (x_2 + \mathrm{i}y_2) \\ &= (x_1 + x_2) + \mathrm{i}(y_1 + y_2)\,. \end{aligned} \tag{1.2}$$

Multiplication of two complex numbers is performed in the same way as two binomials with the provision that $\mathrm{i}^2 = -1$, $\mathrm{i}^3 = -\mathrm{i}$, $\mathrm{i}^4 = 1$, etc. need be taken into account, that is,

$$\begin{aligned} z_1 z_2 &= (x_1 + \mathrm{i}y_1)(x_2 + \mathrm{i}y_2) \\ &= x_1 x_2 + \mathrm{i}y_1 x_2 + \mathrm{i}x_1 y_2 + \mathrm{i}^2 y_1 y_2 \\ &= (x_1 x_2 - y_1 y_2) + \mathrm{i}(x_1 y_2 + x_2 y_1)\,. \end{aligned} \tag{1.3}$$

Complex Plane

Since complex numbers consist of a real part and an imaginary part, they have a two-dimensional character, and hence may be represented geometrically as points in a Cartesian coordinate system, known as the complex plane. The x-axis of the complex plane is the real axis, and its y-axis is called the imaginary axis, (Fig. 1.1). Noting that $z = x + \mathrm{i}y$ is uniquely identified by an ordered pair (x, y) of real numbers, we can represent z as a two-dimensional (2-D) vector in the complex plane, with initial point 0 and terminal point $z = x + \mathrm{i}y$; in other words, the position vector of the point z. The imaginary number i, for instance, can be identified by (0, 1). So, the concept of vector addition also applies to the addition of complex numbers. For that, let us consider $z_1 = -2 + 3\mathrm{i}$ and $z_2 = 3 + \mathrm{i}$ in Fig. 1.2. It is then evident that their sum, $z_1 + z_2 = 1 + 4\mathrm{i}$, is exactly what we would obtain by adding the corresponding position vectors of z_1 and z_2.

The magnitude of a complex number $z = x + \mathrm{i}y$ is defined as

$$|z| = \sqrt{x^2 + y^2}\,. \tag{1.4}$$

Geometrically, $|z|$ is the distance from z to the origin of the complex plane. If z is real, it must be located on the x-axis, and its magnitude is equal to its absolute value. If z is pure imaginary ($z = \mathrm{i}y$), then it is on the y-axis, and $|z| = |y|$. The quantity $|z_1 - z_2|$ gives the distance between z_1 and z_2 (Fig. 1.3).

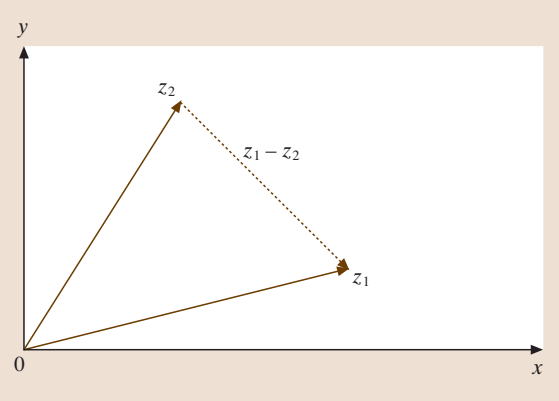

Fig. 1.3 Distance between two complex numbers

Example 1.1: Distance
Given $z_1 = 5+2\mathrm{i}$ and $z_2 = -1+10\mathrm{i}$, then

$$|z_1 - z_2| = |(5+2\mathrm{i}) - (-1+10\mathrm{i})| = |6-8\mathrm{i}| = \sqrt{6^2+(-8)^2} = 10$$

Addition of complex numbers obeys the triangle inequality,

$$|z_1 + z_2| \le |z_1| + |z_2| \,. \tag{1.5}$$

Given a complex number $z = x+\mathrm{i}y$, its conjugate, denoted by $\bar{z}$, is defined as $\bar{z} = x-\mathrm{i}y$. An immediate result is that the product of a complex number ($z \neq 0$) and its conjugate is a positive, real number, equal to the square of its magnitude, that is,

$$z\bar{z} = (x+\mathrm{i}y)(x-\mathrm{i}y) = x^2+y^2 \,. \tag{1.6}$$

Geometrically, a complex number and its conjugate are reflections of one another about the real axis; (Fig. 1.4).

Example 1.2: Conjugation
Given $z = -1+2\mathrm{i}$, we have

$$z\bar{z} = (-1+2\mathrm{i})\overline{(-1+2\mathrm{i})} = (-1+2\mathrm{i})(-1-2\mathrm{i}) = (-1)^2+(2)^2 = 5 \,,$$

which agrees with $|z| = |-1+2\mathrm{i}| = \sqrt{5}$.

Complex conjugation is extremely useful in complex algebra. To begin with, noting that

$$z+\bar{z} = (x+\mathrm{i}y)+(x-\mathrm{i}y) = 2x$$

and

$$z-\bar{z} = (x+\mathrm{i}y)-(x-\mathrm{i}y) = 2\mathrm{i}y$$

we conclude that

$$x = \mathrm{Re}(z) = \frac{1}{2}(z+\bar{z}) \,,$$
$$y = \mathrm{Im}(z) = \frac{1}{2\mathrm{i}}(z-\bar{z}) \,. \tag{1.7}$$

Division of Complex Numbers

Let us consider z_1/z_2 where $z_1 = x_1+\mathrm{i}y_1$ and $z_2 = x_2+\mathrm{i}y_2 (\neq 0)$. Multiply the numerator and the denominator by the conjugate of the denominator, that is, $\bar{z}_2 = x_2 - \mathrm{i}y_2$. Then, by (1.6), the resulting denominator is simply $|z_2|^2 = x_2^2+y_2^2$, a real number. In summary,

$$\begin{aligned}\frac{x_1+\mathrm{i}y_1}{x_2+\mathrm{i}y_2} &= \frac{x_1+\mathrm{i}y_1}{x_2+\mathrm{i}y_2}\frac{x_2-\mathrm{i}y_2}{x_2-\mathrm{i}y_2} \\ &= \frac{(x_1x_2+y_1y_2)+\mathrm{i}\,(y_1x_2-y_2x_1)}{x_2^2+y_2^2} \\ &= \frac{x_1x_2+y_1y_2}{x_2^2+y_2^2} + \frac{y_1x_2-y_2x}{x_2^2+y_2^2}\mathrm{i} \end{aligned} \tag{1.8}$$

where the outcome is represented in the standard rectangular form.

Example 1.3: Division of complex numbers
Perform the following division of complex numbers, and express the result in the standard rectangular form:

$$\frac{2-\mathrm{i}}{-1+4\mathrm{i}}$$

Solution. Multiplication and division by the conjugate of the denominator, yields

$$\begin{aligned}\frac{(2-\mathrm{i})(-1-4\mathrm{i})}{(-1+4\mathrm{i})(-1-4\mathrm{i})} &= \frac{-6-7\mathrm{i}}{17} \\ &= -\frac{6}{17} - \mathrm{i}\frac{7}{17}\end{aligned}$$

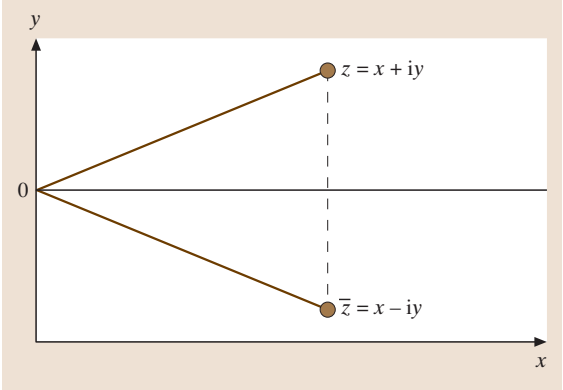

Fig. 1.4 A complex number and its conjugate

Polar Representation of Complex Numbers

Although the standard rectangular form is suitable in certain instances, it is quite inconvenient in most others. For example, imagine the simplification of $(-2+3\mathrm{i})^{10}$. Situations of this type require a special form that simplifies the complex algebra. The polar form of a complex number, as suggested by its name, uses the polar coordinates to represent a complex number in the complex plane. Recall that any point in the plane can be determined by a radial coordinate r and an angular coordinate θ. So, the same holds for a complex number $z = x + \mathrm{i}y \neq 0$ in the complex plane, (Fig. 1.5). The relationship between the rectangular and polar coordinates is given by

$$x = r\cos\theta\,, \quad y = r\sin\theta\,. \tag{1.9}$$

We first introduce Euler's formula,

$$\mathrm{e}^{\mathrm{i}\theta} = \cos\theta + \mathrm{i}\sin\theta\,. \tag{1.10}$$

Then, (1.9) and (1.10) yield

$$z = x + \mathrm{i}y = r\cos\theta + \mathrm{i}\,(r\sin\theta) = r\,\mathrm{e}^{\mathrm{i}\theta}$$

In summary,

$$z = r\,\mathrm{e}^{\mathrm{i}\theta}\,, \tag{1.11}$$

which is called the polar form of the complex number z. Here, the magnitude (or modulus) of z is defined by

$$r = |z| = \sqrt{x^2 + y^2} = \sqrt{z\bar{z}} \tag{1.12}$$

and the phase (or argument) of z is

$$\theta = \arg z = \tan^{-1}\left(\frac{\mathrm{Im}(z)}{\mathrm{Re}(z)}\right) = \tan^{-1}\left(\frac{y}{x}\right)\,. \tag{1.13}$$

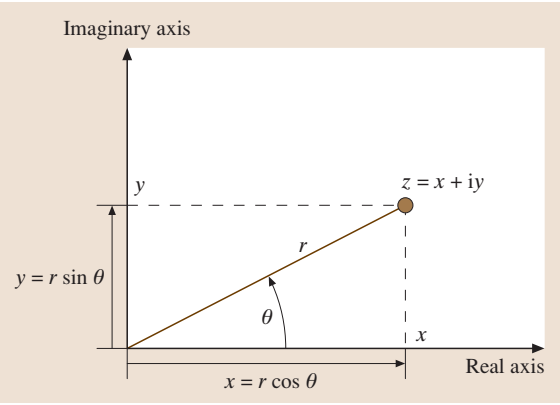

Fig. 1.5 Relation between the rectangular and polar forms of a complex number

The angle θ is measured from the positive real axis and, by convention, is regarded as positive in the sense of the counterclockwise (ccw) direction. It is measured in radians (rad) and is determined in terms of integer multiples of 2π. The specific value of θ that lies in the interval $(-\pi, \pi]$ is called the principal value of $\arg z$ and is denoted by $\arg z$. In engineering analysis, it is also common to express the polar form of z as

$$z = r\angle\theta \tag{1.14}$$

where $\angle$ denotes the angle.

Example 1.4: Phase via location
Express $z = \frac{2}{-1+\mathrm{i}}$ in polar form.

Solution. First, express z in standard rectangular form, as

$$z = \frac{2}{-1+\mathrm{i}}\frac{-1-\mathrm{i}}{-1-\mathrm{i}} = \frac{-2-2\mathrm{i}}{2} = -1-\mathrm{i}\,,$$

indicating that z is located in the third quadrant of the complex plane. Next, we use (1.13) to find

$$\theta = \tan^{-1}\left(\frac{-1}{-1}\right) = 45^\circ = \frac{\pi}{4}\mathrm{rad}\,.$$

However, the only information this provides is that the (smallest) angle between OA and the real axis (Fig. 1.6) is 45°. Since z is in the third quadrant, its actual phase is then $180 + 45 = 225^\circ$ ($\pi + \pi/4 = 5\pi/4$ rad) if measured in the ccw direction, or -135° ($-3\pi/4$ rad) in the clockwise (cw) direction. So, the polar form of z can be written as

$$z = -1-\mathrm{i} = \sqrt{2}\,\mathrm{e}^{\mathrm{i}(5\pi/4)} \quad \text{or} \quad z = \sqrt{2}\angle\frac{5\pi}{4}\,.$$

Multiplication and Division in Polar Form. As cited earlier, polar form substantially reduces complex alge-

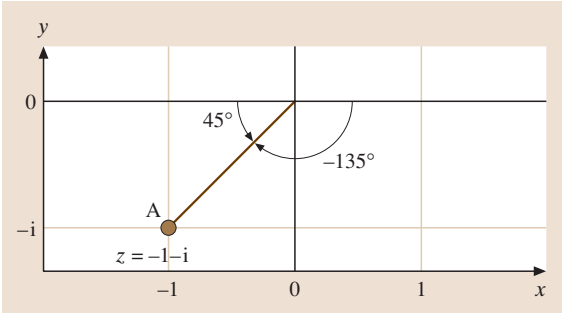

Fig. 1.6 Example 1.4

bra, in particular, multiplication and division. Consider two complex numbers $z_1 = r_1 e^{i\theta_1}$ and $z_2 = r_2 e^{i\theta_2}$. Subsequently,

$$z_1 z_2 = r_1 r_2 e^{i(\theta_1+\theta_2)} \quad \text{or} \quad r_1 r_2 \angle(\theta_1+\theta_2) . \tag{1.15}$$

This means the magnitude and phase of the product $z_1 z_2$ are

$$\begin{aligned} |z_1 z_2| &= r_1 r_2 = |z_1||z_2| \quad \text{and} \\ \arg(z_1 z_2) &= \theta_1 + \theta_2 = \arg(z_1) + \arg(z_2) \end{aligned} \tag{1.16}$$

Similarly, for division of complex numbers, we have

$$\frac{z_1}{z_2} = \frac{r_1}{r_2} e^{i(\theta_1-\theta_2)} \quad \text{or} \quad \frac{r_1}{r_2} \angle(\theta_1-\theta_2) . \tag{1.17}$$

so that

$$\begin{aligned} \left|\frac{z_1}{z_2}\right| &= \frac{r_1}{r_2} = \frac{|z_1|}{|z_2|} \quad \text{and} \\ \arg\left(\frac{z_1}{z_2}\right) &= \theta_1 - \theta_2 = \arg(z_1) - \arg(z_2) \end{aligned} \tag{1.18}$$

Complex Conjugation in Polar Form. Given the polar form of a complex number, $z = r e^{i\theta}$, its conjugate is obtained as

$$\begin{aligned} \bar{z} &= x - iy = r\cos\theta - i(r\sin\theta) \\ &= r(\cos\theta - i\sin\theta) \\ &= r[\cos(-\theta) + i\sin(-\theta)] \overset{\text{Euler's formula}}{=} r e^{-i\theta} . \end{aligned} \tag{1.19}$$

This result makes sense geometrically, since a complex number and its conjugate are reflections of one another through the real axis. Hence, they are equidistant from the origin, that is, $|z| = |\bar{z}| = r$, and the phase of one is the negative of the phase of the other, i. e., $\arg(z) = -\arg(\bar{z})$; Fig. 1.7. The important property of complex conjugation (1.6) can now be confirmed in polar form, as

$$z\bar{z} = (r e^{i\theta})(r e^{-i\theta}) = r^2 = |z|^2 .$$

Integer Powers of a Complex Number

The effectiveness of the polar form may further be demonstrated when raising a complex number to an *integer* power. Letting $z = r e^{i\theta}$, then

$$\begin{aligned} z^n &= (r e^{i\theta})^n = r^n e^{in\theta} \\ &\overset{\text{Euler's formula}}{=} r^n(\cos n\theta + i\sin n\theta) , \end{aligned} \tag{1.20}$$

so that $\mathrm{Re}(z^n) = r^n \cos n\theta$ and $\mathrm{Im}(z^n) = r^n \sin n\theta$.

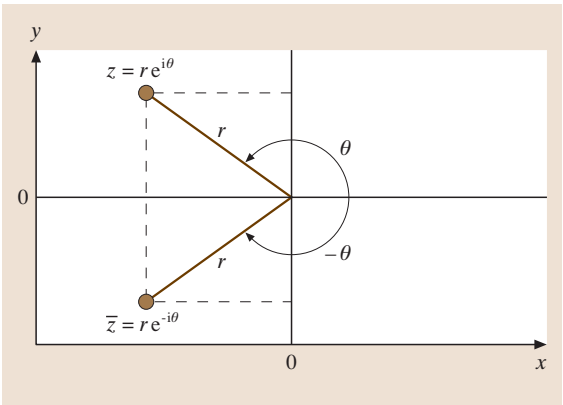

Fig. 1.7 A complex number and its conjugate in polar form

Roots of a Complex Number

In real calculus, if a is a real number then $\sqrt[n]{a}$ has a single value. On the contrary, given a complex number $z \neq 0$, and a positive integer n, then the nth root of z, written $\sqrt[n]{z}$, is *multivalued*. In fact, there are n different values of $\sqrt[n]{z}$, corresponding to each value of $z \neq 0$. For a known $z = r e^{i\theta}$, it can be shown that [1.1, 2]

$$\begin{aligned} \sqrt[n]{z} &= \sqrt[n]{r}\left(\cos\frac{\theta+2k\pi}{n} + i\sin\frac{\theta+2k\pi}{n}\right) , \\ k &= 0, 1, \cdots, n-1 . \end{aligned} \tag{1.21}$$

Geometrically, these n values are described as follows:

1. they all lie on a circle centered at the origin with a radius of $\sqrt[n]{r}$, and
2. they are the n vertices of an n-sided regular polygon.

Example 1.5: Fourth roots of unity
We are seeking $\sqrt[4]{z}$, where $z = 1$. Noting that $z = 1$ is on the positive real axis, one unit from the origin, we conclude that $r = 1$ and $\theta = 0$, hence $z = 1 = 1 e^{i(0)}$. Following (1.21), we find the four roots to be 1, i, -1, and $-$i; Fig. 1.8. Note that all four roots lie on a circle of radius $\sqrt[4]{1} = 1$ centered at the origin (the so-called unit circle), and are the vertices of a regular four-sided polygon, as asserted.

1.1.2 Complex Variables and Functions

If x or y or both vary, then $z = x + iy$ is referred to as a complex variable. The most well-known complex variable is the *Laplace variable* (Sect. 1.3). Letting S be a set of complex numbers, a function f defined on S is a *rule*, which assigns a complex number w to each

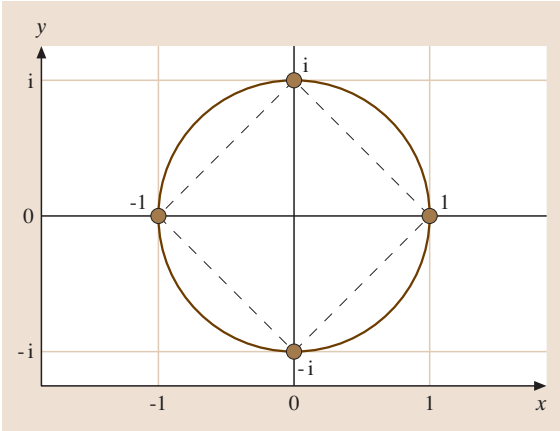

Fig. 1.8 Locations of the fourth roots of unity

$z \in S$. The notation is $w = f(z)$ and the set S is called the domain of definition of f. As an example, the domain of the function $w = z/(3-z)$ is any region that does not contain the point $z = 3$. Because z assumes different values from S, it is clearly a complex variable. Since w is complex, it must have a real part u and an imaginary part v, or $w = u + \mathrm{i}v$. Also $w = f(z)$ implies that w is dependent on $z = x + \mathrm{i}y$. Therefore, w depends on x and y, which means u and v depend on x and y, or

$$w = f(z) = u(x, y) + \mathrm{i}v(x, y) \,. \tag{1.22}$$

In real calculus, much can be learned about a function through its graph. However, when z and w are both complex, such a convenient graph of $w = f(z)$ is no longer available. This is because each z and w is located in a plane rather than on a line; more exactly, each z is in the xy-plane and each w in the uv-plane. However, a function f can still be thought of as a mapping (or transformation) that defines correspondence between points $z = (x, y)$ and $w = (u, v)$. Then, the *image* of a point $z \in S$ is the point $w = f(z)$, and the set of images of all points $z \in S$ that are mapped by f is the range of f, and denoted by

$$\{w | w = f(z), z \in S\} \,.$$

Analytic Functions

A function that is differentiable only at a single point is not of practical interest to us. What is of interest, however, is a function that is differentiable at a point and an entire neighborhood of that point. A neighborhood of a point is an open circular disk centered at the point. A complex function $f(z)$ is analytic (or holomorphic) at a point z_0 if it is differentiable throughout *some* neighborhood of z_0. A function is *analytic in a domain* if it is analytic at all points of that domain. Analytic functions arise in such areas as fluid flow and complex potentials.

Test of Analyticity: Cauchy–Riemann Equations. Suppose $f(z) = u(x, y) + \mathrm{i}v(x, y)$ is defined and continuous in a neighborhood of some point $z = x + \mathrm{i}y$, and that $f'(z)$ exists at that point. Then, the first partial derivatives of u and v with respect to x and y (that is, u_x, u_y, v_x, v_y) exist at that point and satisfy the Cauchy–Riemann equations

$$u_x = v_y, \quad v_x = -u_y \,. \tag{1.23}$$

Consequently, if $f(z)$ is analytic in some domain R, then the Cauchy–Riemann equations hold at every point of R.

Example 1.6: Cauchy–Riemann equations
Decide whether $f(z) = (\mathrm{i}-2)z^2 - 2\mathrm{i}z + \mathrm{i}$ is analytic.

Solution. Inserting $z = x + \mathrm{i}y$, we find

$$u(x, y) = -2xy - 2x^2 + 2y^2 + 2y \,,$$
$$v(x, y) = x^2 - y^2 - 4xy - 2x + 1 \,.$$

Partial differentiation yields

$$u_x = -2y - 4x \,, \quad v_y = -2y - 4x \,,$$
$$v_x = 2x - 4y - 2 \,, \quad u_y = -2x + 4y + 2 \,,$$

so that the Cauchy–Riemann equations hold for all z, and $f(z)$ is analytic for all z.

Cauchy–Riemann Equations in Polar Form. In many cases it is advantageous to use the polar form of the Cauchy–Riemann equations to test the analyticity of a function. The idea is to express z in polar form

$$z = r\,\mathrm{e}^{\mathrm{i}\theta} = r(\cos\theta + \mathrm{i}\sin\theta)$$

so that the function $f(z) = u(x, y) + \mathrm{i}v(x, y)$ can be written as $f(z) = u(r, \theta) + \mathrm{i}v(r, \theta)$. In this event, the Cauchy–Riemann equations in polar form can be derived as [1.1]

$$u_r = \frac{1}{r} v_\theta, \quad v_r = -\frac{1}{r} u_\theta \,. \tag{1.24}$$

This is particularly useful when dealing with z^m for $m \geq 3$, making it much easier to work with than $(x + \mathrm{i}y)^m$.

1.2 Differential Equations

Mathematical models of dynamic systems – mechanical, electrical, electromechanical, liquid-level, etc. – are represented by differential equations [1.3]. Therefore, it is imperative to have a thorough knowledge of their basic properties and solution techniques. In this section we will discuss the fundamentals of differential equations, specifically, ordinary differential equations (ODEs), and present analytical and numerical methods to solve them. Differential equations are divided into two general categories: *ordinary differential equations* and *partial differential equations (PDEs)*. An equation involving an unknown function and one or more of its derivatives is called a differential equation. When there is only one independent variable, the equation is called an ordinary differential equation (ODE). For example, $y' + 2y = e^x$ is an ODE involving the unknown function $y(x)$, its first derivative $y' = dy/dx$, as well as a given function e^x. Similarly, $xy'' - yy' = \sin x$ is an ODE relating $y(x)$ and its first and second derivatives with respect to x, as well as the function $\sin x$. While dealing with time-varying functions – as in many physical applications – the independent variable x will be replaced by t, representing time. In that case, the rate of change of the quantity $y = y(t)$ with respect to the independent variable t is denoted by $\dot{y} = dy/dt$. If the unknown function is a function of more than one independent variable, e.g., $u(x, y)$, the equation is referred to as a partial differential equation. The derivative of the highest order of the unknown function $y(x)$ with respect to x is the order of the ODE; for instance, $y' + 2y = e^x$ is of order one and $xy'' - yy' = \sin x$ is of order two. Consider an nth-order ordinary differential equation in the form

$$a_n y^{(n)} + a_{n-1} y^{(n-1)} + \cdots + a_1 y' + a_0 y = g(x) , \tag{1.25}$$

where $y = y(x)$ and $y^{(n)} = d^n y/dx^n$. If all coefficients $a_0, a_1, \cdots, a_n$ are either constants or functions of the independent variable x, then the ODE is linear. Otherwise, the ODE is nonlinear. Based on this, $y' + 2y = e^x$ describes a linear ODE, while $xy'' - yy' = \sin x$ is nonlinear.

Example 1.7: Order and linearity
Consider $3y''' - (2x+1)y'' + y = e^x$. Since the derivative of the highest order is three, the ODE is third order. Comparison with (1.25) reveals that $n = 3$, and $a_3 = 3$, $a_2 = -(2x+1)$, $a_1 = 0$, $a_0 = 1$, and $g(x) = e^x$. Thus, the ODE is linear.

1.2.1 First-Order Ordinary Differential Equations

First-order ODEs generally appear in the implicit form

$$F(x, y, y') = 0 . \tag{1.26}$$

For example, $y' + y^2 = \cos x$ can be expressed in the above form with $F(x, y, y') = y' + y^2 - \cos x$. In other cases, the equation may be written explicitly as

$$y' = f(x, y) . \tag{1.27}$$

An example would be $y' + 2y = e^x$ where $f(x, y) = e^x - 2y$. A function $y = s(x)$ is a solution of the first-order ODE in (1.26) on a specified (open) interval if it has a derivative $y' = s'(x)$ and satisfies (1.26) for all values of x in the given interval. If the solution is in the form $y = s(x)$, then it is called an explicit solution. Otherwise, it is in the form $S(x, y) = 0$, which is known as an implicit solution. For example, $y = 4e^{-x/2}$ is an explicit solution of $2y' + y = 0$. It turns out that a single formula $y = ke^{-x/2}$ involving a constant $k \neq 0$ generates all solutions of this ODE. Such formula is referred to as a general solution, and the constant is known as the parameter. When a specific value is assigned to the parameter, a particular solution is obtained.

Initial-Value Problem (IVP)

A first-order initial-value problem (IVP) appears in the form

$$y' = f(x, y) , \quad y(x_0) = y_0 , \tag{1.28}$$

where $y(x_0) = y_0$, is called the initial condition.

Example 1.8: IVP
Solve the initial-value problem

$$2y' + y = 0 , \quad y(2) = 3 .$$

Solution. As mentioned earlier, a general solution is $y = ke^{-x/2}$. Applying the initial condition, we obtain

$$y(2) = ke^{-1} = 3 \overset{\text{Solve for k}}{\Rightarrow} k = 3e .$$

Therefore, the particular solution is $y = 3e \cdot e^{-x/2} = 3e^{1-x/2}$.

Separable First-Order Ordinary Differential Equations

A first-order ODE is referred to as separable if it can be written as

$$f(y)y' = g(x)\,. \tag{1.29}$$

Using $y' = \mathrm{d}y/\mathrm{d}x$ in (1.29), we have

$$f(y)\frac{\mathrm{d}y}{\mathrm{d}x} = g(x) \Rightarrow f(y)\,\mathrm{d}y = g(x)\,\mathrm{d}x\,. \tag{1.30}$$

Integrating the two sides of (1.30) separately, yields

$$\int f(y)\,\mathrm{d}y = \int g(x)\,\mathrm{d}x + c\,, \quad c = \text{const.}$$

Example 1.9: Separable ODE
Solve the initial-value problem $\mathrm{e}^x y' = y^2$, $y(0) = 1$.

Solution. The ODE is separable and treated as

$$\begin{aligned}
&\mathrm{e}^x \frac{\mathrm{d}y}{\mathrm{d}x} = y^2 \\
\overset{\text{Provided that } y \neq 0}{\Rightarrow} \quad &\int \frac{1}{y^2}\,\mathrm{d}y = \int \frac{1}{\mathrm{e}^x}\,\mathrm{d}x \\
\Rightarrow \quad &-\frac{1}{y} = -\mathrm{e}^{-x} + c \qquad (c = \text{const.}) \\
\overset{\text{Solve for } y}{\Rightarrow} \quad &y(x) = \frac{1}{\mathrm{e}^{-x} - c}\,,
\end{aligned}$$

which is the general solution to the original differential equation. The specific value of c is determined via the given initial condition, as

$$\left.\begin{aligned} y(0) &= 1 \\ y(0) &= \tfrac{1}{1-c} \end{aligned}\right\} \begin{matrix} \text{Initial condition} \\ \\ \text{By gen. solution} \end{matrix} \Rightarrow \frac{1}{1-c} = 1 \Rightarrow c = 0\,.$$

Substitution into the general solution yields the particular solution $y(x) = \mathrm{e}^x$.

Linear First-Order Ordinary Differential Equations

A differential equation that can be expressed in the form

$$y' + g(x)y = f(x)\,, \tag{1.31}$$

where g and f are given functions of x, is called a linear first-order ordinary ODE. This of course agrees with what was discussed in (1.25) with slight changes in notation. If $f(x) = 0$ for every x in the interval under consideration, that is, if f is identically zero, denoted $f(x) \equiv 0$, then the ODE is called homogeneous, otherwise it is called nonhomogeneous.

Solution of Linear First-Order ODEs

The general solution of (1.31) can be expressed as [1.1, 4]

$$y(x) = \mathrm{e}^{-h(x)}\left[\int \mathrm{e}^{h(x)} f(x)\,\mathrm{d}x + c\right]\,,$$

$$\text{where} \quad h(x) = \int g(x)\,\mathrm{d}x\,. \tag{1.32}$$

Note that the constant of integration in the calculation of h is omitted because c accounts for all constants.

Example 1.10: Linear first-order ODE
Find the particular solution to the initial-value problem $2\dot{y} + y = 4\mathrm{e}^{2t}$, $y(0) = 1$.

Solution. Noting that t is now the independent variable, we first rewrite the ODE to agree with the form of (1.31), as

$$\dot{y} + \frac{1}{2}y = 2\mathrm{e}^{2t}$$

so that

$$g = \frac{1}{2}\,, \quad f = 2\mathrm{e}^{2t}\,.$$

With $h = \int g(t)\,\mathrm{d}t = \int \frac{1}{2}\,\mathrm{d}t = \frac{1}{2}t$, the general solution is given by (1.32),

$$\begin{aligned}
y(t) &= \mathrm{e}^{-t/2}\left[\int \mathrm{e}^{t/2}\cdot 2\mathrm{e}^{2t}\,\mathrm{d}t + c\right] \\
&= \mathrm{e}^{-t/2}\left[2\int \mathrm{e}^{5t/2}\,\mathrm{d}t + c\right] = \frac{4}{5}\mathrm{e}^{2t} + c\,\mathrm{e}^{-t/2}\,.
\end{aligned}$$

Applying the initial condition, we find $y(0) = \frac{4}{5} + c = 1 \Rightarrow c = \frac{1}{5}$. The particular solution is $y(t) = \frac{4}{5}\mathrm{e}^{2t} + \frac{1}{5}\mathrm{e}^{-t/2}$.

1.2.2 Numerical Solution of First-Order Ordinary Differential Equations

Recall that a first-order ODE can appear in an implicit form $F(x, y, y') = 0$ or an explicit form $y' = f(x, y)$. We will consider the latter, and assume that it is subject to a prescribed initial condition, that is,

$$y' = f(x, y)\,, \quad y(x_0) = y_0\,, \quad x_0 \le x \le x_N\,. \tag{1.33}$$

If finding a closed-form solution of (1.33) is difficult or impossible, we resort to a numerical solution. What

this means is that we find approximate values for the solution $y(x)$ at several points

$$x_1 = x_0 + h\ ,\ x_2 = x_0 + 2h \cdots x_n$$
$$= x_0 + nh\ ,\cdots,\ x_N = x_0 + Nh$$

known as mesh points, where h is called the step size. Note that the mesh points are equally spaced. Among many numerical methods to solve (1.33), the fourth-order Runge–Kutta method is most commonly used in practice. The difference equation for the fourth-order Runge–Kutta method (RK4) is derived as [1.5, 6]

$$y_{n+1} = y_n + \frac{1}{6}(q_1 + 2q_2 + 2q_3 + q_4)\ , \qquad (1.34)$$
$$n = 0,\ 1,\cdots,\ N-1\ ,$$

where

$$q_1 = h f(x_n,\ y_n)$$
$$q_2 = h f\left(x_n + \frac{h}{2},\ y_n + \frac{q_1}{2}\right)\ ,$$
$$q_3 = h f\left(x_n + \frac{h}{2},\ y_n + \frac{q_2}{2}\right)\ ,$$
$$q_4 = h f(x_n + h,\ y_n + q_3)\ .$$

Example 1.11: Fourth-order Runge–Kutta method
Apply RK4 with step size $h = 0.1$ to solve $y' + y = 2x^2$, $y(0) = 3$, $0 \le x \le 1$.

Solution. Knowing that $f(x_n,\ y_n) = -y_n + 2x_n^2$, the four function evaluations/step of the RK4 are

$$q_1 = h\left[-y_n + 2x_n^2\right]\ ,$$
$$q_2 = h\left[-\left(y_n + \frac{1}{2}q_1\right) + 2\left(x_n + \frac{1}{2}h\right)^2\right]\ ,$$
$$q_3 = h\left[-\left(y_n + \frac{1}{2}q_2\right) + 2\left(x_n + \frac{1}{2}h\right)^2\right]\ ,$$
$$q_4 = h\left[-(y_n + q_3) + 2(x_n + h)^2\right]\ .$$

Upon completion of each step, y_{n+1} is calculated by (1.34). So, we start with $n = 0$, corresponding to $x_0 = 0$ and $y_0 = 3$, and continue the process up to $n = 10$. Numerical results are generated as

$$y(0) = 3\ ,$$
$$y(0.1) = 2.7152\ ,$$
$$y(0.2) = 2.4613\ ,$$
$$y(0.3) = 2.2392\ ,\cdots,$$
$$y(0.9) = 1.6134\ ,$$
$$y(1) = 1.6321\ .$$

Further inspection reveals that RK4 produces the exact values (at least to five-decimal place accuracy) of the solution at the mesh points.

1.2.3 Second- and Higher-Order, Ordinary Differential Equations

The application of basic laws such as Newton's second law and Kirchhoff's voltage law (KVL) leads to mathematical models that are described by second-order ODEs [1.3]. Although it is quite possible that the system models contain nonlinear elements, in this section we will mainly focus on linear second-order differential equations. Nonlinear systems may be treated via numerical techniques such as the fourth-order Runge–Kutta method (Sect. 1.2), or via linearization [1.3]. In agreement with (1.25), a second-order ODE is said to be linear if it can be expressed in the form

$$y'' + g(x)y' + h(x)y = f(x)\ , \qquad (1.35)$$

where f, g, and h are given functions of x. Otherwise, it is called nonlinear.

Homogeneous Linear Second-Order ODEs

If y_1 and y_2 are two solutions of the homogeneous linear ODE

$$y'' + g(x)y' + h(x)y = 0 \qquad (1.36)$$

on some open interval, their linear combination $y = c_1 y_1 + c_2 y_2$ (c_1, c_2 constants) is also a solution on the same interval. This is known as the principle of superposition.

General Solution of Linear Second-Order ODEs – Linear Independence

A general solution of (1.36) is based on the idea of linear independence of functions, which involves what is known as the Wronskian. We first mention that a 2×2 determinant (Sect. 1.5.1) is evaluated as

$$\begin{vmatrix} p & q \\ r & s \end{vmatrix} = ps - qr\ .$$

If each of the functions $y_1(x)$ and $y_2(x)$ has at least a first derivative, then their Wronskian is denoted by $W(y_1,\ y_2)$ and is defined as the 2×2 determinant

$$W(y_1,\ y_2) = \begin{vmatrix} y_1 & y_2 \\ y_1' & y_2' \end{vmatrix} = y_1 y_2' - y_2 y_1'\ . \qquad (1.37)$$

If there exists a point $x^* \in (a,\ b)$ where $W \neq 0$, then y_1 and y_2 are linearly independent on the entire interval $(a,\ b)$.

Example 1.12: Independent solutions – the Wronskian
The functions $y_1 = e^{2x}$ and $y_2 = e^{-3x}$ are linearly independent for all x because their Wronskian is

$$W(y_1, y_2) = \begin{vmatrix} y_1 & y_2 \\ y_1' & y_2' \end{vmatrix} = \begin{vmatrix} e^{2x} & e^{-3x} \\ 2e^{2x} & -3e^{-3x} \end{vmatrix} = -5e^{-x} \neq 0$$

for all x.

If y_1 and y_2 are two linearly independent solutions of (1.36) on the interval (a, b), they form a basis of solutions for (1.36) on (a, b). A general solution of (1.36) on (a, b) is a linear combination of the basis elements, that is,

$$y = c_1 y_1 + c_2 y_2 \quad (c_1, c_2 \text{ constants}) . \tag{1.38}$$

Example 1.13: General solution, basis
It can be easily verified that $y_1 = e^{2x}$ and $y_2 = e^{-3x}$ are solutions of $y'' + y' - 6y = 0$ for all x. They are also linearly independent by Example 1.12. Consequently, $y_1 = e^{2x}$ and $y_2 = e^{-3x}$ form a basis of solutions for the ODE at hand, and a general solution for this ODE is $y = c_1 e^{2x} + c_2 e^{-3x}$ (c_1, c_2 constants).

Example 1.14: Unique solution of an IVP
Find the particular solution of $y'' + y' - 6y = 0$, $y(0) = -1$, $y'(0) = 8$.

Solution. By Example 1.13, a general solution is $y = c_1 e^{2x} + c_2 e^{-3x}$. Differentiating and applying the initial conditions, we have

$$\begin{aligned} y(0) &= c_1 + c_2 = -1 \\ y'(0) &= 2c_1 - 3c_2 = 8 \end{aligned} \quad \overset{\text{Solve the system}}{\Rightarrow} \quad \begin{aligned} c_1 &= 1 \\ c_2 &= -2 \end{aligned} .$$

Therefore, the unique solution of the IVP is obtained as $y = e^{2x} - 2e^{-3x}$.

Homogeneous Second-Order Differential Equations with Constant Coefficients

Consider a homogeneous linear second-order ODE with constant coefficients,

$$y'' + a_1 y' + a_2 y = 0 \quad (a_1, a_2 \text{ constants}) \tag{1.39}$$

and assume that its solution is in the form $y = e^{\lambda x}$, where λ, known as the *characteristic value*, is to be determined. Substitution into (1.39), yields

$$\lambda^2 e^{\lambda x} + a_1 \lambda e^{\lambda x} + a_2 e^{\lambda x} = 0$$
$$\Rightarrow \; e^{\lambda x}\left(\lambda^2 + a_1 \lambda + a_2\right) = 0 .$$

Since $e^{\lambda x} \neq 0$ for any finite values of x and λ, then

$$\lambda^2 + a_1 \lambda + a_2 = 0$$
$$\overset{\text{Solve the characteristic equation}}{\Rightarrow} \quad \begin{aligned} \lambda_1 &= \tfrac{1}{2}\left(-a_1 + \sqrt{a_1^2 - 4a_2}\right) \\ \lambda_2 &= \tfrac{1}{2}\left(-a_1 - \sqrt{a_1^2 - 4a_2}\right) \end{aligned} .$$

(1.40)

The solutions λ_1 and λ_2 of the characteristic equation are the characteristic values. The assumption was $y = e^{\lambda x}$, hence the solutions of (1.39) are $y_1 = e^{\lambda_1 x}$ and $y_2 = e^{\lambda_2 x}$. To find a general solution of (1.39), the two independent solutions must be identified. But this depends on the nature of the characteristic values λ_1 and λ_2, as discussed below.

Case 1: Two Distinct Real Roots $\left(a_1^2 - 4a_2 > 0, \lambda_1 \neq \lambda_2\right)$.
In this case, the solutions $y_1 = e^{\lambda_1 x}$ and $y_2 = e^{\lambda_2 x}$ are linearly independent, as may easily be verified. Thus, they form a basis of solution for (1.39). Therefore, a general solution is

$$y(x) = \underbrace{c_1 e^{\lambda_1 x} + c_2 e^{\lambda_2 x}}_{\text{General solution} - \lambda_1 \neq \lambda_2 \text{ , real}} . \tag{1.41}$$

Case 2: Double (Real) Root $\left(a_1^2 - 4a_2 = 0, \; \lambda_1 = \lambda_2 = -\tfrac{1}{2}a_1\right)$. It can be shown [1.1] that the two linearly independent solutions are $y_1 = e^{-a_1 x/2}$ and $y_2 = x e^{-a_1 x/2}$. Therefore,

$$\begin{aligned} y(x) &= c_1 e^{-\frac{1}{2}a_1 x} + c_2 x e^{-\frac{1}{2}a_1 x} \\ &= \underbrace{(c_1 + c_2 x) e^{-\frac{1}{2}a_1 x}}_{\text{General solution} - \lambda_1 = \lambda_2 \text{ , real}} . \end{aligned} \tag{1.42}$$

Case 3: Complex Conjugate Pair $\left(a_1^2 - 4a_2 < 0, \lambda_1 = \bar{\lambda}_2\right)$.
The characteristic values are given as $\lambda_{1,2} = \frac{1}{2}(-a_1 \pm \sqrt{a_1^2 - 4a_2})$. Since $a_1^2 - 4a_2 < 0$, we write

$$\begin{aligned} \lambda_{1,2} &= \frac{1}{2}\left[-a_1 \pm \sqrt{-\left(4a_2 - a_1^2\right)}\right] \\ &= \frac{1}{2}\left[-a_1 \pm \sqrt{-1}\sqrt{4a_2 - a_1^2}\right] \\ &= \frac{1}{2}\left[-a_1 \pm i\sqrt{4a_2 - a_1^2}\right] = -\sigma \pm i\omega , \end{aligned}$$

$(i = \sqrt{-1})$

where

$$\sigma = \frac{1}{2}a_1 \,,$$
$$\omega = \frac{1}{2}\sqrt{4a_2 - a_1^2} \,. \tag{1.43}$$

The two independent solutions are $y_1 = \mathrm{e}^{-\sigma x}\cos\omega x$ and $y_2 = \mathrm{e}^{-\sigma x}\sin\omega x$, and a general solution of (1.39) is obtained as

$$y(x) = \underbrace{\mathrm{e}^{-\sigma x}(c_1\cos\omega x + c_2\sin\omega x)}_{\text{General solution — } \lambda_1 = \bar{\lambda}_2 \text{ , complex conjugates}} \,. \tag{1.44}$$

Example 1.15: Case (3)
Solve $y'' + 2y' + 2y = 0$, $y(0) = 1$, $y'(0) = 0$.

Solution. We first find the characteristic equation and the corresponding characteristic values, as

$$\lambda^2 + 2\lambda + 2 = 0$$
$$\Rightarrow \lambda_{1,2} = -1 \pm \mathrm{i} \,.$$

Complex conjugate pair, Case (3)

By (1.43), we identify $\sigma = 1$ and $\omega = 1$, so that the general solution by (1.44) is

$$y(x) = \mathrm{e}^{-x}(c_1\cos x + c_2\sin x) \,.$$

Next, we differentiate this to obtain

$$y'(x) = -\mathrm{e}^{-x}(c_1\cos x + c_2\sin x) + \mathrm{e}^{-x}(-c_1\sin x + c_2\cos x)$$

Finally, by the initial conditions,

$$\begin{aligned} y(0) &= c_1 = 1 \\ y'(0) &= -c_1 + c_2 = 0 \end{aligned} \quad \Rightarrow \quad \begin{aligned} c_1 &= 1 \\ c_2 &= 1 \end{aligned}$$

and the solution is $y(x) = \mathrm{e}^{-x}(\cos x + \sin x)$.

Boundary-Value Problems (BVP). In certain applications involving second-order differential equations, a pair of information is provided at the boundary points of an open interval (a, b) on which the ODE is to be solved. This pair is referred to as the boundary conditions, and the problem

$$y'' + a_1 y' + a_2 y = 0 \,,$$
$$\underbrace{y(a) = A \,,\; y(b) = B}_{\text{Boundary conditions}} \tag{1.45}$$

is called a boundary-value problem (BVP).

Nonhomogeneous Linear Second-Order ODEs

Nonhomogeneous second-order ODEs appear in the form

$$y'' + g(x)y' + h(x)y = f(x) \,, \qquad f(x) \not\equiv 0 \,. \tag{1.46}$$

A general solution for this equation is then obtained as

$$y(x) = \underbrace{y_\mathrm{h}(x)}_{\text{Homogeneous solution}} + \underbrace{y_\mathrm{p}(x)}_{\text{Particular solution}} \,. \tag{1.47}$$

Homogeneous Solution $y_\mathrm{h}(x)$. $y_\mathrm{h}(x)$ is a general solution of the homogeneous equation (1.36), and as previously discussed, it is given by

$$y_\mathrm{h} = c_1 y_1 + c_2 y_2 \,, \quad (c_1, c_2 \text{ constants})$$

where y_1 and y_2 are linearly independent and form a basis of solutions for (1.36). Note that the homogeneous solution involves two arbitrary constants.

Particular Solution $y_\mathrm{p}(x)$. $y_\mathrm{p}(x)$ is a particular solution of (1.46), and does not involve any arbitrary constants. The nature of $y_\mathrm{p}(x)$ depends on the nature of $f(x)$, as well as its relation to the independent solutions y_1 and y_2 of the homogeneous equation.

Method of Undetermined Coefficients

When (1.46) happens to have constant coefficients and the function $f(x)$ is of a special type – polynomial, exponential, sine and/or cosine or a combination of them – then the particular solution can be obtained by the method of undetermined coefficients as follows. Consider

$$y'' + a_1 y' + a_2 y = f(x) \quad (a_1, a_2 \text{ constants}) \,. \tag{1.48}$$

Since the coefficients are constants, the homogeneous solution y_h is found as before. So all we need to do is to find the particular solution y_p. We will make a proper selection for y_p based on the nature of $f(x)$ and with the

Table 1.1 Selection of particular solution – the method of undetermined coefficients

Term in $f(x)$	Proper choice of y_p
$a_n x^n + \ldots + a_1 x + a_0$	$K_n x^n + \ldots + K_1 x + K_0$
$A\,\mathrm{e}^{ax}$	$K\,\mathrm{e}^{ax}$
$A\sin\omega x$ or $A\cos\omega x$	$K_1\cos\omega x + K_2\sin\omega x$

aid of Table 1.1. This choice involves unknown coefficients, which will be determined by substituting y_p and its derivatives into (1.48). The details, as well as special cases that may occur, are given below.

Procedure.

Step 1: Homogeneous Solution $y_h(x)$. Solve the homogeneous equation $y'' + a_1 y' + a_2 y = 0$ to find the two independent solutions y_1 and y_2, and the general solution $y_h(x) = c_1 y_1(x) + c_2 y_2(x)$.

Step 2: Particular Solution $y_p(x)$. For each term in $f(x)$ choose a proper y_p as suggested by Table 1.1. For instance, if $f(x) = x + 2e^x$ then pick $y_p = K_1 x + K_2 + K e^x$. Note that, if instead of x we had $3x - 2$, for example, the choice of y_p would still be the same because they both represent first-degree polynomials. We then substitute our choice of y_p, along with its derivatives, into the original ODE to find the undetermined coefficients.

Special cases.

I. Suppose a term in our choice of y_p coincides with a solution (y_1 or y_2) of the homogeneous equation, and that this solution is associated with a *simple* (i. e., nonrepeated) characteristic value. Then, make the modification by multiplying y_p by x.

II. If a term in the choice of y_p coincides with a solution of the homogeneous equation, and that this solution is associated with a *repeated* characteristic value, modify by multiplying y_p by x^2.

Example 1.16: Special case II

Solve

$$y'' + 2y' + y = x + 1 + 3e^{-x}, \quad y(0) = 1, \quad y'(0) = 0.$$

Step 1: Homogeneous Solution. The characteristic equation $(\lambda + 1)^2 = 0$ yields a *double root* $\lambda = -1$. This means $y_1 = e^{-x}$ and $y_2 = x e^{-x}$, so that the homogeneous solution is $y_h(x) = (c_1 + c_2 x)e^{-x}$.

Step 2: Particular Solution. The right-hand side of the ODE consists of two functions,

$$\underbrace{x + 1}_{\text{First-degree polynomial}} \quad \text{and} \quad e^{-x}.$$

The first term, $x + 1$, does not coincide with either y_1 or y_2, so the proper choice by Table 1.1 is $K_1 x + K_0$. The second term involves e^{-x}, which happens to be a homogeneous solution associated with a double root. Therefore, by special case II the modified choice is $K x^2 e^{-x}$. Consequently, the particular solution is in the form

$$y_p(x) = \underbrace{K_1 x + K_0}_{\text{First term}} + \underbrace{K x^2 e^{-x}}_{\text{Second term}}.$$

Substitution of y_p and its derivatives into the nonhomogeneous ODE, and collecting terms, results in

$$2K e^{-x} + K_1 x + K_0 + 2K_1 = x + 1 + 3e^{-x}.$$

Equating the coefficients of like terms, we have

$$\begin{aligned} 2K &= 3 && K = \tfrac{3}{2} \\ K_1 &= 1 \quad \Rightarrow && K_1 = 1 \\ K_0 + 2K_1 &= 1 && K_0 = -1 \end{aligned}$$

$$\Rightarrow y_p(x) = x - 1 + \frac{3}{2} x^2 e^{-x}.$$

Step 3: General Solution. The general solution is then found as

$$y(x) = (c_1 + c_2 x)e^{-x} + x - 1 + \frac{3}{2} x^2 e^{-x}.$$

Step 4: Initial Conditions. Applying the initial conditions, we obtain $c_1 = 2$ and $c_2 = 1$. Finally, the solution to the IVP is

$$y(x) = (2 + x)e^{-x} + x - 1 + \frac{3}{2} x^2 e^{-x}.$$

Higher-Order Ordinary Differential Equations

Many of the techniques for the treatment of differential equations of order three or higher are merely extensions of those applied to second-order equations. Here we will only discuss nth-order, linear nonhomogeneous ODEs with constant coefficients, that is,

$$y^{(n)} + a_{n-1} y^{(n-1)} + \cdots + a_1 y' + a_0 y = f(x), \tag{1.49}$$

where $a_0, a_1, \cdots, a_{n-1}$ are constants. As in the case of second-order ODEs, a general solution consists of the homogeneous solution and the particular solution. For cases when $f(x)$ is of a special type, the particular solution is obtained via the method of undetermined coefficients.

Method of Undetermined Coefficients. The idea introduced for second-order ODEs is now extended to find y_p for (1.49). As before, a proper choice of y_p is made assuming that $f(x)$ consists of terms that are listed in Table 1.1. If none of the terms in $f(x)$ happens to be

an independent homogeneous solution, then no modification is necessary. Otherwise, the following special cases need be taken into account.

Special Cases.

1. If a term in our choice of y_p coincides with a homogeneous solution, which corresponds to a *simple* (nonrepeated) characteristic value, then we make the modification by multiplying y_p by x.
2. If a term in y_p coincides with a solution of the homogeneous equation, and this solution is associated with a characteristic value of *multiplicity* m, we modify by multiplying y_p by x^m.

Example 1.17: Special case II
Solve

$$y''' - 4y'' = 1 + 12x\,,$$
$$y(0) = 0\,, \quad y'(0) = 4\,, \quad y''(0) = 15\,.$$

Solution.
Step 1: Homogeneous Solution. Characteristic equation:

$$\lambda^3 - 4\lambda^2 = \lambda^2(\lambda - 4) = 0 \Rightarrow \lambda = 0, 0, 4\,.$$

Therefore $y_h = c_1 + c_2 x + c_3 e^{4x}$.

Step 2: Particular Solution. Noting that $f(x) = 1 + 12x$ is a first-degree polynomial, we pick $y_p = K_1 x + K_0$. But x happens to be a homogeneous solution associated with a double root ($\lambda = 0$). Hence, the modification is $y_p = (K_1 x + K_0)x^2$. Substituting this and its derivatives into the original ODE, and simplifying, we arrive at

$$(6K_1 - 8K_0) - 24K_1 x = 1 + 12x$$
$$\Rightarrow \begin{array}{l} 6K_1 - 8K_0 = 1 \\ -24K_1 = 12 \end{array} \Rightarrow \begin{array}{l} K_1 = -\frac{1}{2} \\ K_0 = -\frac{1}{2} \end{array}$$
$$\Rightarrow y_p = -\frac{1}{2}(x+1)x^2$$

Step 3: General Solution. Combination of y_h and y_p gives a general solution $y = c_1 + c_2 x + c_3 e^{4x} - \frac{1}{2}(x+1)x^2$.

Step 4: Initial Conditions. Applying the initial conditions to the general solution and its derivatives, we obtain

$$\begin{array}{ll} y(0) = c_1 + c_3 = 0 & c_1 = -1 \\ y'(0) = c_2 + 4c_3 = 4 & \Rightarrow\ c_2 = 0 \\ y''(0) = 16c_3 - 1 = 15 & c_3 = 1 \end{array}$$
$$\Rightarrow y(x) = -1 + e^{4x} - \frac{1}{2}x^3 - \frac{1}{2}x^2\,.$$

1.3 Laplace Transformation

In Sect. 1.2 we mainly learned to solve linear time-invariant (LTI) ODEs without ever leaving the time domain. In this section we introduce a systematic approach to solve such ODEs in a more-expedient manner. The primary advantage gained here is that the arbitrary constants in the general solution need not be found separately. The idea is simple: in order to solve an ODE and corresponding initial-value problem (IVP) or boundary-value problem (BVP), transform the problem to the so-called s domain, in which the transformed problem is an algebraic one. This algebraic problem is then treated properly, and the data is ultimately transformed back to time domain to find the solution of the original problem. The transform function is a function of a complex variable, denoted by s. If a function $f(t)$ is defined for all $t \geq 0$, then its Laplace transform is defined by

$$F(s) \overset{\text{Notation}}{=} \mathbf{L}[f(t)]$$
$$\overset{\text{Definition}}{=} \int_0^\infty e^{-st} f(t)\,dt \qquad (1.50)$$

provided that the integral exists. The complex variable s is the Laplace variable, and $\mathbf{L}$ is the Laplace transform operator. It is common practice to denote a time-dependent function by a lower-case letter, say, $f(t)$, and its Laplace transform by the same letter in upper case, $F(s)$.

1.3.1 Inverse Laplace Transform

Suppose we are seeking the solution $x(t)$ of an ODE. The ODE is first transformed into the s domain by means of the operator $\mathbf{L}$. In this domain, the transformed version of the ODE is an algebraic equation involving the transform function $X(s)$ of $x(t)$. This equation is then manipulated to find $X(s)$, which in turn will be transformed back into time domain to determine $x(t)$. This is done through the inverse Laplace transformation, as in Fig. 1.9.

$$x(t) = \mathbf{L}^{-1}[X(s)]$$

Consistent with (1.50), we have

$$f(t) = \mathbf{L}^{-1}[F(s)] \,. \tag{1.51}$$

Example 1.18: Laplace transform
Given $g(t) = 1$ for $t \geq 0$, find $\mathbf{L}[g(t)]$.

Solution

Following the definition given by (1.50), we have

$$\mathbf{L}[g(t)] = \mathbf{L}(1) = \int_0^\infty \mathrm{e}^{-st}\,\mathrm{d}t = \left.\frac{\mathrm{e}^{-st}}{-s}\right|_{t=0}^{\infty} = \frac{1}{s}$$

for $s > 0$.

Example 1.19: Laplace transform
Suppose $h(t) = \mathrm{e}^{-at}$ (a = const) for $t \geq 0$. Determine $H(s)$.

Solution

By definition,

$$H(s) = \mathbf{L}[\mathrm{e}^{-at}] = \int_0^\infty \mathrm{e}^{-st}\,\mathrm{e}^{-at}\,\mathrm{d}t = \int_0^\infty \mathrm{e}^{-(s+a)t}\,\mathrm{d}t = \left.\frac{\mathrm{e}^{-(s+a)t}}{-(s+a)}\right|_{t=0}^{\infty} = \frac{1}{s+a}$$

for $s + a > 0$.

Linearity of Laplace and Inverse Laplace Transforms

The Laplace transform operator $\mathbf{L}$ is linear, that is, if the Laplace transforms of functions $f_1(t)$ and $f_2(t)$ exist, and a_1 and a_2 are constant scalars, then

$$\begin{aligned}
&\mathbf{L}[a_1 f_1(t) + a_2 f_2(t)] \\
&= \int_0^\infty \mathrm{e}^{-st}[a_1 f_1(t) + a_2 f_2(t)]\,\mathrm{d}t \\
&= a_1 \int_0^\infty \mathrm{e}^{-st} f_1(t)\,\mathrm{d}t + a_2 \int_0^\infty \mathrm{e}^{-st} f_2(t)\,\mathrm{d}t \\
&= a_1 \mathbf{L}[f_1(t)] + a_2 \mathbf{L}[f_2(t)] \\
&= a_1 F_1(s) + a_2 F_2(s) \,.
\end{aligned} \tag{1.52}$$

To establish the linearity of $\mathbf{L}^{-1}$, take the inverse Laplace transforms of the expressions on the far left and far right of (1.52) to obtain

$$a_1 f_1(t) + a_2 f_2(t) = \mathbf{L}^{-1}[a_1 F_1(s) + a_2 F_2(s)] \,.$$

Noting that $f_1(t) = \mathbf{L}^{-1}[F_1(s)]$ and $f_2(t) = \mathbf{L}^{-1}[F_2(s)]$, the result follows.

Example 1.20: Linearity of $\mathbf{L}$
Find $\mathbf{L}[2 - 3\mathrm{e}^{4t}]$.

Solution. Using the linearity of $\mathbf{L}$, we write $\mathbf{L}[2 - 3\mathrm{e}^{4t}] = 2\mathbf{L}[1] - 3L[\mathrm{e}^{4t}]$. But, by Example 1.18 we have $\mathbf{L}[1] = 1/s$. And by Example 1.18 (with $a = -4$) we have $\mathbf{L}[\mathrm{e}^{4t}] = 1/(s-4)$. Thus $\mathbf{L}[2 - 3\mathrm{e}^{4t}] = 2/s - 3/(s-4) = (-(s+8))/(s(s-4))$.

Table of Laplace Transform Pairs. Laplace transforms of several functions are listed in Table 1.2 at the end of this section. We will refer to this frequently. For a better understanding of the concepts, however, we try to derive the most fundamental results on our own.

Theorem 1.1: Shift on the s-axis. Suppose that $F(s) = \mathbf{L}[f(t)]$ and that a is a constant. Then,

$$\mathbf{L}[\mathrm{e}^{-at} f(t)] = F(s+a) \,. \tag{1.53}$$

$$\mathbf{L}^{-1}[F(s+a)] = e^{-at} f(t)\,. \tag{1.54}$$

Example 1.21: Shift on the s-axis
Find $\mathbf{L}[e^{3t}\cos t]$.

Solution. Let $f(t)=\cos t$ so that $F(s)=s/(s^2+1)$; see Table 1.2. Then, by (1.53) with $a=-3$,

$$\mathbf{L}[e^{3t}\cos t] \overset{\substack{f(t)=\cos t\\ a=-3}}{=} F(s-3) = \frac{s-3}{(s-3)^2+1}$$

Differentiation and Integration of Laplace Transforms

We now turn our attention to two specific types of situations: (1) $\mathbf{L}[tf(t)]$, (2) $\mathbf{L}[f(t)/t]$. In both cases,

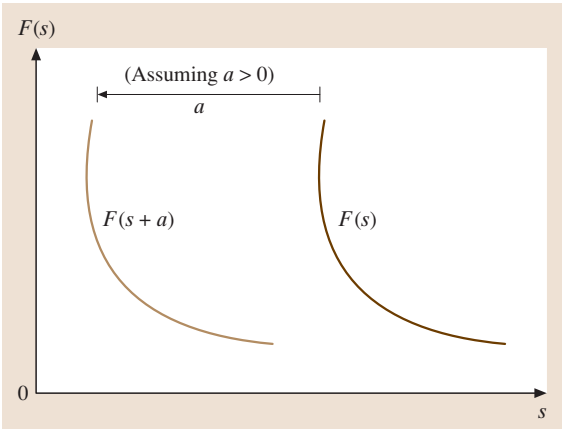

Fig. 1.10 Shift on the s-axis (Theorem 1.1)

we assume that $f(t)$ is such that $F(s) = \mathbf{L}[f(t)]$ is either known directly from Table 1.2 or can be determined by other means. Either way, once $F(s)$ is available, the two transforms labeled (1) and (2) will be obtained in terms of the derivative and integral of $F(s)$, respectively. Before presenting two key results pertaining to these situations we make the following definition. If a transform function is in the form $F(s) = N(s)/D(s)$, then each value of s for which $D(s) = 0$ is called a pole of $F(s)$. A pole with a *multiplicity* (number of occurrences) of one is known as a simple pole.

Theorem 1.2: Differentiation of Laplace Transforms. If $\mathbf{L}[f(t)] = F(s)$ exists, then at any point except at the poles of $F(s)$, we have

$$\mathbf{L}[tf(t)] = -\frac{\mathrm{d}}{\mathrm{d}s}F(s) = -F'(s) \tag{1.55}$$

or alternatively,

$$tf(t) = -\mathbf{L}^{-1}[F'(s)]\,. \tag{1.56}$$

The general form of (1.55) for $n = 1, 2, 3, \cdots$ is given by

$$\mathbf{L}[t^n f(t)] = (-1)^n \frac{\mathrm{d}^n}{\mathrm{d}s^n}F(s) = (-1)^n F^{(n)}(s)\,. \tag{1.57}$$

Example 1.22: Differentiation of $F(s)$
Find $\mathbf{L}[t \sin 3t]$.

Solution. Comparing with the left side of (1.55), we have $f(t) = \sin 3t$ so that $F(s) = 3/(s^2+9)$. Therefore,

$$\begin{aligned}\mathbf{L}[t \sin 3t] &= -\frac{\mathrm{d}}{\mathrm{d}s}\left(\frac{3}{s^2+9}\right)\\ &= \frac{6s}{(s^2+9)^2}\end{aligned}$$

Theorem 1.3: Integration of Laplace transforms. If $\mathbf{L}[f(t)/t]$ exists, and the order of integration can be interchanged, then

$$\mathbf{L}\left[\frac{f(t)}{t}\right] = \int_s^\infty F(\sigma)\,\mathrm{d}\sigma\,. \tag{1.58}$$

Alternatively,

$$f(t) = t\mathbf{L}^{-1}\left[\int_s^\infty F(\sigma)\,\mathrm{d}\sigma\right]\,. \tag{1.59}$$

Example 1.23: Theorem 1.3
Show that

$$\mathbf{L}\left[\frac{\sin \omega t}{t}\right] = \cot^{-1}\frac{s}{\omega}\,.$$

Solution. Comparing with (1.58), $f(t) = \sin \omega t$ so that $F(s) = \omega/(s^2+\omega^2)$. Subsequently,

$$\begin{aligned}\mathbf{L}\left[\frac{\sin \omega t}{t}\right] &= \int_s^\infty \frac{\omega}{\sigma^2+\omega^2}\,\mathrm{d}\sigma\\ &= \int_s^\infty \frac{1}{1+(\sigma/\omega)^2}\frac{d\sigma}{\omega}\\ &= \left[\tan^{-1}\frac{\sigma}{\omega}\right]_{\sigma=s}^\infty\\ &= \frac{\pi}{2} - \tan^{-1}\frac{s}{\omega} = \cot^{-1}\frac{s}{\omega}\,.\end{aligned}$$

1.3.2 Special Functions

Much can be learned about the characteristics of a system based on its response to specific external disturbances. To perform the response analysis, these disturbances must first be mathematically modeled, which is where special functions play an important role. In this section we will introduce the step, ramp, pulse, and impulse functions, as well as their Laplace transforms.

Unit Step $u(t)$

The unit-step function (Fig. 1.11) is analytically defined as

$$u(t) = \begin{cases} 1 & \text{if} \quad t > 0\\ 0 & \text{if} \quad t < 0\\ \text{undefined (finite)} & \text{if} \quad t = 0\end{cases}\,. \tag{1.60}$$

This may be physically realized as a constant signal (of magnitude 1) suddenly applied to the system at time $t = 0$. By the definition of the Laplace transform, we find

$$\begin{aligned}\mathbf{L}[u(t)] \overset{\text{Notation}}{=} U(s) &= \int_0^\infty \mathrm{e}^{-st}u(t)\,\mathrm{d}t\\ &= \int_0^\infty \mathrm{e}^{-st}\,\mathrm{d}t = \frac{1}{s}\,.\end{aligned} \tag{1.61}$$

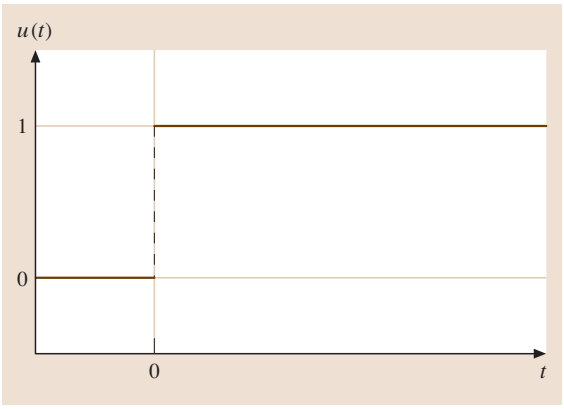

Fig. 1.11 The unit step function $u(t)$

When the magnitude is some $A \neq 1$, we refer to the signal as a step function, denoted by $Au(t)$. In this case,

$$\mathbf{L}[Au(t)] = \int_0^\infty \mathrm{e}^{-st} A \, \mathrm{d}t = \frac{A}{s} \, .$$

When the unit step function occurs at some time $a \neq 0$ (Fig. 1.12), it is denoted by $u(t-a)$, and

$$u(t-a) = \begin{cases} 1 & \text{if} \quad t > a \\ 0 & \text{if} \quad t < a \\ \text{undefined (finite)} & \text{if} \quad t = a \end{cases} \, . \tag{1.62}$$

As before, if the magnitude happens to be $A \neq 1$, the notation is modified to $Au(t-a)$. To find the Laplace transform of $u(t-a)$, we first need to discuss the shift on the t-axis, see Theorem 1.4 below.

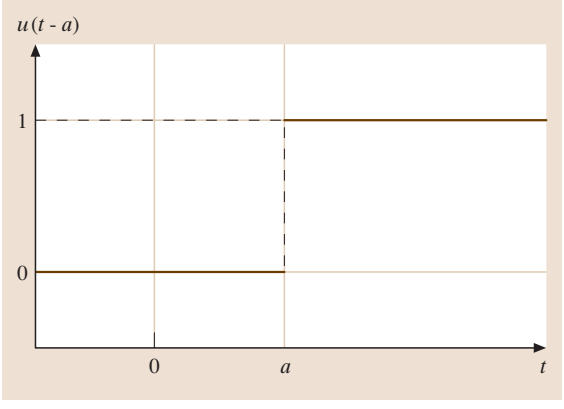

Fig. 1.12 The unit -step function occurring at $t = a$

Theorem 1.4: Shift on the t-axis. Given that $F(s) = \mathbf{L}[f(t)]$ exists, then

$$\mathbf{L}[f(t-a)u(t-a)] = \mathrm{e}^{-as} F(s) \, , \tag{1.63}$$

or, alternatively,

$$\mathbf{L}^{-1}[\mathrm{e}^{-as} F(s)] = f(t-a)u(t-a) \, . \tag{1.64}$$

Finding $\mathbf{L}[u(t-a)]$ via Theorem 1.4. We now have the tools to determine $\mathbf{L}[u(t-a)]$. In particular, comparing $\mathbf{L}[u(t-a)]$ with the left-hand side of (1.63), we deduce that $f(t-a) = 1$. Which implies that $f(t) = 1$, hence $F(s) = 1/s$. As a result,

$$\mathbf{L}[u(t-a)] = \frac{\mathrm{e}^{-as}}{s} \, . \tag{1.65}$$

Unit Ramp $u_\mathrm{r}(t)$. The unit ramp function (Fig. 1.13) is analytically defined as

$$u_\mathrm{r}(t) = \begin{cases} t & \text{if} \quad t \geq 0 \\ 0 & \text{if} \quad t < 0 \, . \end{cases}$$

Physically, this models a signal that changes linearly with a unit rate. By (1.50),

$$\begin{aligned} \mathbf{L}[u_\mathrm{r}(t)] \overset{\text{Notation}}{=} U_\mathrm{r}(s) &= \int_0^\infty t \, \mathrm{e}^{-st} \, \mathrm{d}t \\ &= \left(t \frac{\mathrm{e}^{-st}}{-s} \right)_{t=0}^{\infty} - \int_0^\infty \frac{\mathrm{e}^{-st}}{-s} \, \mathrm{d}t \\ &= \left[\frac{\mathrm{e}^{-st}}{-s^2} \right]_{t=0}^{\infty} = \frac{1}{s^2} \, . \end{aligned} \tag{1.66}$$

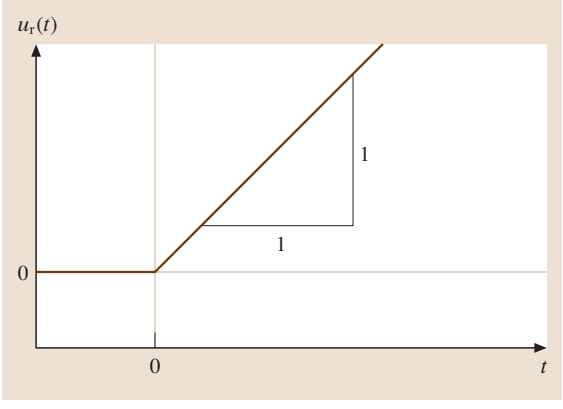

Fig. 1.13 The unit ramp function $u_\mathrm{r}(t)$

Note that $u_r(t) = tu(t)$. When the rate is $A \neq 1$, the signal is called a ramp function, denoted by $Au_r(t)$. In that case,

$$\mathbf{L}[Au_r(t)] = \frac{A}{s^2} .$$

Unit Pulse $u_p(t)$. The unit pulse function (Fig. 1.14) is defined as

$$u_p(t) = \begin{cases} 1/t_1 & \text{if} \quad 0 < t < t_1 \\ 0 & \text{if} \quad t < 0 \quad \text{and} \quad t > t_1 . \end{cases}$$

The word 'unit' signifies that the signal occupies an area of unity. Its Laplace transform is derived as

$$\mathbf{L}[u_p(t)] \overset{\text{Notation}}{=} U_p(s) = \int_0^{t_1} \frac{1}{t_1} e^{-st} \, dt = \frac{1 - e^{-st_1}}{st_1} . \qquad (1.67)$$

If the area is $A \neq 1$, the signal is called a pulse, written $Au_p(t)$, and

$$\mathbf{L}[Au_p(t)] = \frac{A(1 - e^{-st_1})}{st_1} .$$

Unit Impulse (Dirac Delta) $\delta(t)$. Consider the unit pulse of Fig. 1.14 and let $t_1 \to 0$; Fig. 1.15. In this limit, the rectangular-shaped signal occupies a region with an infinitesimally small width and a large height (Fig. 1.16). The area, however, remains unity throughout the process. This limiting signal is known as the unit impulse (or Dirac delta), denoted by $\delta(t)$. If the area is $A \neq 1$, it is an impulse, denoted by $A\delta(t)$. If an external disturbance (such as an applied force or voltage) is a pulse with very large magnitude and applied for a very short period of time, then it can be approximated as an impulse. Since $\delta(t)$ is the limit of $u_p(t)$ as $t_1 \to 0$, we

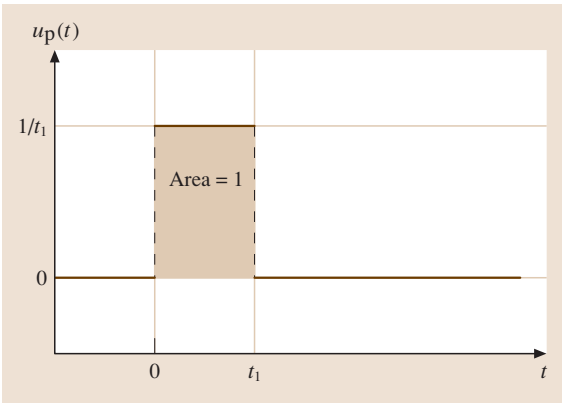

Fig. 1.14 The unit pulse $u_p(t)$

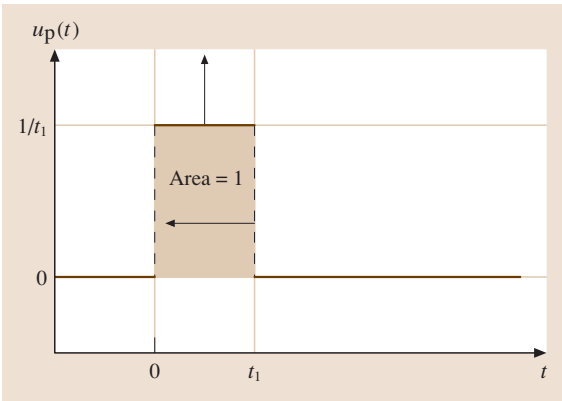

Fig. 1.15 The unit pulse as $t_1 \to 0$

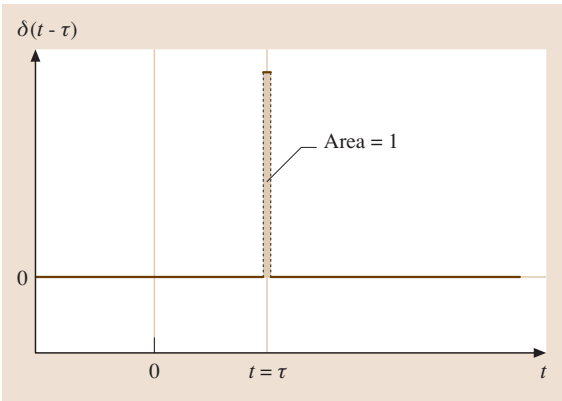

Fig. 1.17 The unit impulse occurring at $t = \tau$

have

$$\mathbf{L}[\delta(t)] \overset{\text{Notation}}{=} \Delta(s) = \lim_{t_1 \to 0} \left(\frac{1 - \mathrm{e}^{-st_1}}{st_1} \right) \overset{\text{L'Hôspital's rule}}{=} \lim_{t_1 \to 0} \left(\frac{s\,\mathrm{e}^{-st_1}}{s} \right) = 1 \,. \tag{1.68}$$

If the unit impulse occurs at some time $t = \tau$ (Fig. 1.17) it is represented by $\delta(t - \tau)$, and

$$\mathbf{L}[\delta(t - \tau)] = \mathrm{e}^{-\tau s} \,. \tag{1.69}$$

This signal has the property $\delta(t - \tau) = 0$ for $t \neq \tau$, $\delta(t - \tau) = \infty$ for $t = \tau$, and $\int_{-\infty}^{\infty} \delta(t - \tau)\,\mathrm{d}t = 1$. It also has the filtering property,

$$\int_{-\infty}^{\infty} f(\tau)\delta(t - \tau)\,\mathrm{d}\tau = f(t) \,. \tag{1.70}$$

1.3.3 Laplace Transform of Derivatives and Integrals

Since engineering systems are generally modeled by differential equations of various orders, we need to have knowledge of the Laplace transform of derivatives of different orders. In other occasions, the system may be described by an equation that contains not only derivatives, but also integrals; for instance, a circuit involving a resistor, an inductor, and a capacitor (RLC circuit) [1.3]. We will also present a systematic approach for solving initial-value problems.

Theorem 1.5: Laplace transform of derivatives
If $F(s) = \mathbf{L}[f(t)]$, then

$$\mathbf{L}[\dot{f}(t)] = sF(s) - f(0) \tag{1.71}$$

and

$$\mathbf{L}[\ddot{f}(t)] = s^2 F(s) - sf(0) - \dot{f}(0) \,. \tag{1.72}$$

In general,

$$\mathbf{L}[f^{(n)}(t)] = s^n F(s) - s^{n-1} f(0) - s^{n-2} \dot{f}(0) - \cdots - f^{(n-1)}(0) \,. \tag{1.73}$$

Theorem 1.6: Laplace transform of integrals
If $F(s) = \mathbf{L}[f(t)]$, then

$$\mathbf{L}\left[\int_0^t f(\tau)\,\mathrm{d}\tau \right] = \frac{1}{s} F(s) \,. \tag{1.74}$$

Alternatively,

$$\mathbf{L}^{-1}\left[\frac{1}{s} F(s) \right] = \int_0^t f(\tau)\,\mathrm{d}\tau \,. \tag{1.75}$$

Solving Initial-Value Problems. The role of the Laplace transforms of derivatives and integrals of time-varying functions is most significant when solving an initial-value problem. Schematically, the solution method is as in Fig. 1.18.

Example 1.24: Second-order IVP
Solve $\ddot{x} + 2\dot{x} + x = 0$, $x(0) = 1$, $\dot{x}(0) = 1$.

Solution. Laplace transformation results in

$$[s^2 X(s) - sx(0) - \dot{x}(0)] + 2[sX(s) - x(0)] + X(s) = 0 \overset{\text{Solve for X(s)}}{\Rightarrow} X(s) = \frac{s + 3}{(s + 1)^2} \,.$$

Before inversion, we rewrite this last expression as

$$X(s) = \frac{s + 3}{(s + 1)^2} = \frac{(s + 1) + 2}{(s + 1)^2} = \frac{1}{s + 1} + \frac{2}{(s + 1)^2} \,.$$

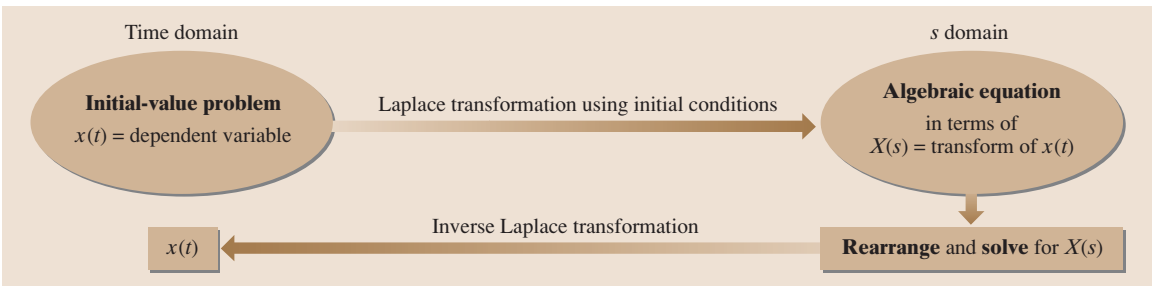

Fig. 1.18 The solution method for initial-value problems

Finally,

$$x(t) = \mathbf{L}^{-1}[X(s)] = \mathrm{e}^{-t} + 2t\,\mathrm{e}^{-t} = (2t+1)\mathrm{e}^{-t}\,.$$

1.3.4 Inverse Laplace Transformation

Inverse Laplace transformation clearly plays a vital role in completing the procedure for solving differential equations. In this section we will learn a systematic technique, using partial fractions, to treat a wide range of inverse Laplace transforms. We will also introduce the convolution method, which is quite important from a physical standpoint.

Partial Fractions Method

When solving an ODE in terms of $x(t)$ through Laplace transformation, the very last step involves finding $\mathbf{L}^{-1}[X(s)]$. And we almost always find ourselves looking for the inverse Laplace transform of functions in the form of

$$X(s) = \frac{N(s)}{D(s)} = \frac{\text{Polynomial of degree } m}{\text{Polynomial of degree } n},\ m < n\,. \tag{1.76}$$

The case $m \geq n$ is purely mathematical and does not occur in engineering analysis. The idea behind the partial fractions method is simple: express $X(s) = N(s)/D(s)$ as a suitable sum of fractions, and find $\mathbf{L}^{-1}$ of each fraction accordingly. So, it all boils down to how to break the original fraction into partial fractions, and this depends on the nature of the poles of $X(s)$ – the roots of $D(s)$. In the most general sense, these roots can be real or complex. For instance, $D(s) = s^3 - s^2 - 2s$ has roots $s = 0, -1, 2$, all real, so we express $D(s)$ as $D(s) = s(s+1)(s-2)$. On the other hand, the roots of $D(s) = s^3 + 2s^2 + 2s$ are $s = 0, -1 \pm \mathrm{i}$. In this case, instead of writing $D(s) = s(s+1+\mathrm{i})(s+1-\mathrm{i})$ we write $D(s) = s(s^2+2s+2)$. In other words, the quadratic polynomial with complex roots remains intact. Any second-degree polynomial with complex roots is called an irreducible polynomial.

Structure of Partial Fractions. There are four possible cases that arise in the process of finding $\mathbf{L}^{-1}[X(s)]$. We must first identify the factors of $D(s)$, which could be linear, repeated linear, irreducible polynomial, or repeated irreducible polynomial. Then, each identified factor will have its own fraction (or fractions) associated with them. The details follow.

Case 1: Linear Factor $s - p_i$. Each typical linear factor $s - p_i$ of $D(s)$ is associated with a fraction in the form

$$\frac{A}{s-p_i}\,,$$

where $A = \text{const.}$ is to be determined appropriately. We note that $s = p_i$ is called a simple pole of $X(s)$.

Example 1.25: Linear factors
Find $\mathbf{L}^{-1}[X(s)]$ where

$$X(s) = \frac{s+1}{(s+3)(s+4)}\,.$$

Solution. The poles of $X(s)$ are $p_1 = -3$, $p_2 = -4$. Since there are two linear factors, there will be two fractions. We write

$$X(s) = \frac{s+1}{(s+3)(s+4)} = \frac{A_1}{s+3} + \frac{A_2}{s+4} = \frac{A_1(s+4)+A_2(s+3)}{(s+3)(s+4)} \overset{\text{Collect like terms}}{=} \frac{(A_1+A_2)s + 4A_1 + 3A_2}{(s+3)(s+4)}\,,$$

$$A_1,\ A_2 = \text{const.}$$

The denominators of the original and the final fractions are identical (by design), so we force their respective numerators to be identical, that is,

$$s + 1 \equiv (A_1 + A_2)s + 4A_1 + 3A_2\,.$$

But this identity holds only if the coefficients of like powers of s on both sides are the same. So, we have

$$\begin{aligned} &\text{Coefficient of } s\text{:} && 1 = A_1 + A_2 \\ &\text{Constant term:} && 1 = 4A_1 + 3A_2\,. \end{aligned} \quad \overset{\text{Solve}}{\Rightarrow} \quad \begin{aligned} A_1 &= -2 \\ A_2 &= 3 \end{aligned}$$

Insert these into the partial fractions, and perform a term-by-term inverse Laplace transformation, to obtain

$$X(s) = \frac{-2}{s+3} + \frac{3}{s+4} \quad \overset{\mathbf{L}^{-1}}{\Rightarrow}$$

$$x(t) \overset{\text{Linearity}}{=} -2\mathbf{L}^{-1}\left(\frac{1}{s+3}\right) + 3\mathbf{L}^{-1}\left(\frac{1}{s+4}\right) = -2\mathrm{e}^{-3t} + 3\mathrm{e}^{-4t}\,.$$

Case 2: Repeated Linear Factor $(s - p_i)^k$. If a root of $D(s)$, say, p_i, happens to have multiplicity k, then $D(s)$ contains the factor $(s - p_i)^k$. This factor is then associated with partial fractions

$$\frac{A_k}{(s-p_i)^k} + \frac{A_{k-1}}{(s-p_i)^{k-1}} + \cdots + \frac{A_2}{(s-p_i)^2} + \frac{A_1}{s-p_i}\,,$$

where the constants $A_k, \cdots, A_1$ are determined as in case 1. As an example, we first write

$$X(s) = \frac{4s+7}{(s+1)^2(s+4)} = \underbrace{\frac{A_2}{(s+1)^2}}_{\text{Double pole; case 2}} + \frac{A_1}{s+1} + \underbrace{\frac{A_3}{s+4}}_{\text{Simple pole; case 1}}$$

and then proceed as before to determine the constants.

Case 3: Irreducible Polynomial s^2+as+b. This occurs when $X(s)$ has a pair of complex-conjugate poles. Each irreducible polynomial is associated with a single fraction in the form

$$\frac{Bs+C}{s^2+as+b},$$

where the constants B and C are found as before. Before taking the inverse Laplace transform, we must first complete the square in the irreducible polynomial, that is, $s^2+as+b=(s+\sigma)^2+\omega^2$. Then, at some point, we need to determine

$$\mathbf{L}^{-1}\left[\frac{Bs+C}{(s+\sigma)^2+\omega^2}\right].$$

The key is to split the fraction in terms of the two expressions

$$\frac{\omega}{(s+\sigma)^2+\omega^2} \quad \text{and} \quad \frac{s+\sigma}{(s+\sigma)^2+\omega^2}$$

so that we can ultimately use the relations [see Table 1.2]

$$\mathbf{L}^{-1}\left[\frac{\omega}{(s+\sigma)^2+\omega^2}\right] = \mathrm{e}^{-\sigma t}\sin\omega t\,,$$
$$\mathbf{L}^{-1}\left[\frac{s+\sigma}{(s+\sigma)^2+\omega^2}\right] = \mathrm{e}^{-\sigma t}\cos\omega t\,. \qquad (1.77)$$

Case 4: Repeated Irreducible Polynomial $(s^2+as+b)^k$. The fractions are formed as

$$\frac{B_k s+C_k}{(s^2+as+b)^k}+\cdots+\frac{B_2 s+C_2}{(s^2+as+b)^2}+\frac{B_1 s+C_1}{s^2+as+b}.$$

Convolution Method

In systems analysis, the problem of determining the time history of a function often comes down to $\mathbf{L}^{-1}[G(s)H(s)]$, where the inverse Laplace transforms of $G(s)$ and $H(s)$ are known. The convolution method allows us to determine $\mathbf{L}^{-1}[G(s)H(s)]$ using knowledge of $g(t)$ and $h(t)$.

Notation: $\mathbf{L}^{-1}[G(s)H(s)] \overset{\text{Notation}}{=} (g*h)(t)$ is read "*convolution* of g and h"

Theorem 1.7: Convolution. Let $G(s)=\mathbf{L}[g(t)]$, $H(s)=\mathbf{L}[h(t)]$, and $F(s)=G(s)H(s)$. Then,

$$\mathbf{L}^{-1}[F(s)] = f(t) = (g*h)(t) = \int_0^t g(\tau)h(t-\tau)\,\mathrm{d}\tau = \int_0^t h(\tau)g(t-\tau)\,\mathrm{d}\tau = (h*g)(t)\,:$$

The result clearly indicates that the convolution of two functions is *symmetric*.

Example 1.26: Convolution
Find $\mathbf{L}^{-1}\left[\frac{1}{s^2(s+2)}\right]$.

Solution. Write $F(s)=\frac{1}{s^2}\cdot\frac{1}{s+2}=G(s)H(s)$ and pick $G(s)=1/s^2$, $H(s)=1/(s+2)$ so that $g(t)=t$, $h(t)=\mathrm{e}^{-2t}$. Then

$$f(t)=(g*h)(t)=\int_0^t \tau\cdot\mathrm{e}^{-2(t-\tau)}\,\mathrm{d}\tau$$
$$\overset{\text{Integration by parts}}{=}\left[\tau\cdot\frac{1}{2}\mathrm{e}^{-2(t-\tau)}\right]_{\tau=0}^{t} - \frac{1}{2}\int_0^t \mathrm{e}^{-2(t-\tau)}\,\mathrm{d}\tau$$
$$=\frac{1}{2}t-\frac{1}{4}(1-\mathrm{e}^{-2t})=\frac{1}{4}(\mathrm{e}^{-2t}+2t-1)\,.$$

1.3.5 Periodic Functions

Physical systems are often subjected to external disturbances that exhibit repeated behavior over long periods

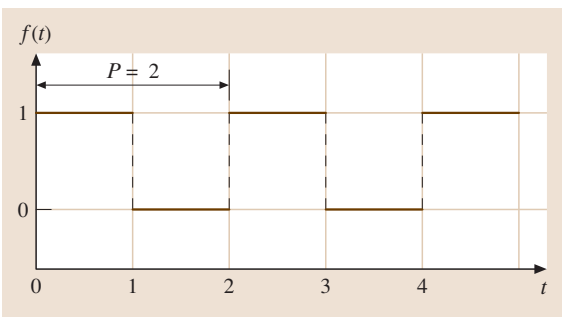

Fig. 1.19 Periodic function of Example 1.27

of time. A function $f(t)$ is called periodic with *period* $P > 0$ if it is defined for all $t > 0$, and $f(t+P) = f(t)$ for all $t > 0$.

It can then be shown [1.1] that the Laplace transform of this function is

$$F(s) = \frac{1}{1 - \mathrm{e}^{-Ps}} \int_0^P \mathrm{e}^{-st} f(t)\,\mathrm{d}t \,. \tag{1.78}$$

Example 1.27: Periodic signal
Find the Laplace transform of the periodic function in Fig. 1.19.

Solution. It is evident that the period is $P = 2$. With this, the integral in (1.78) is

$$\int_0^2 \mathrm{e}^{-st} f(t)\,\mathrm{d}t$$

$$\underset{f(t)=0 \text{ for } 1<t<2}{\overset{f(t)=1 \text{ for } 0<t<1}{=}} \int_0^1 \mathrm{e}^{-st}\,\mathrm{d}t = (1 - \mathrm{e}^{-s})/s \,.$$

Then, by (1.78), $F(s) = (1 - \mathrm{e}^{-s})/(s(1 - \mathrm{e}^{-2s}))$. Noting that $1 - \mathrm{e}^{-2s} = 1 - (\mathrm{e}^{-s})^2 = (1 - \mathrm{e}^{-s})(1 + \mathrm{e}^{-s})$, the above expression reduces to $F(s) = 1/(s(1 + \mathrm{e}^{-s}))$.

1.4 Fourier Analysis

This section will focus on the concepts of Fourier series and transformation and their properties. The idea of Fourier series is based on representing periodic functions in terms of series of sine and cosine components whose periods are integral multiples of each other. The Fourier transform is an operation that maps a function defined in the time domain into one in the frequency domain; its extension leads to the familiar Laplace transformation.

1.4.1 Fourier Series

Let $f(x)$ be periodic with period $P > 0$, that is, $f(x)$ is defined for all real x, and $f(x+P) = f(x)$ for all x. Then, assuming that $f(x)$ has a Fourier series representation, it is in the form

$$\frac{1}{2}a_0 + \sum_{n=1}^{\infty} \left(a_n \cos\frac{2n\pi x}{P} + b_n \sin\frac{2n\pi x}{P} \right) , \tag{1.79}$$

where the constants are generated by the *Euler–Fourier formulas*, as [1.1, 7]

$$a_0 = \frac{2}{P} \int_{-P/2}^{P/2} f(x)\,\mathrm{d}x \,, \tag{1.80}$$

$$a_n = \frac{2}{P} \int_{-P/2}^{P/2} f(x) \cos\frac{2n\pi x}{P}\,\mathrm{d}x \,,$$

$$n = 1, 2, 3, \cdots \,, \tag{1.81}$$

$$b_n = \frac{2}{P} \int_{-P/2}^{P/2} f(x) \sin\frac{2n\pi x}{P}\,\mathrm{d}x \,,$$

$$n = 1, 2, 3, \cdots \,. \tag{1.82}$$

In (1.79), each of the sinusoidal components with different frequencies is called a harmonic, with *amplitude* a_n or b_n. The harmonics basically describe the variations of $f(x)$ about its average value of $\frac{1}{2}a_0$. In certain cases, only a few harmonics may be needed to represent $f(x)$ with reasonable accuracy. On the other hand, there are situations where many of them may be required. At the points of discontinuity of $f(x)$ the partial sums assume the average value of the left- and right-hand limits.

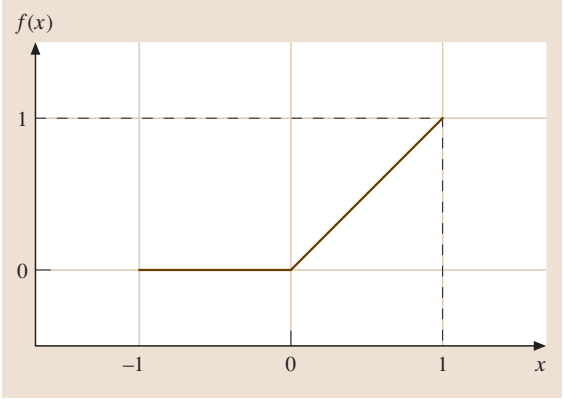

Fig. 1.20 A periodic function with period $P = 2$

Example 1.28: Fourier series

Find the Fourier series representation of the periodic function whose description in one period is shown in Fig. 1.20.

Solution

By (1.80), we have $a_0 = \int_{-1}^{1} f(x)\,\mathrm{d}x = \int_{0}^{1} x\,\mathrm{d}x = 1/2$. For $n = 1, 2, 3, \cdots$, (1.81) and (1.82) yield

$$
\begin{aligned}
a_n &= \int_{-1}^{1} f(x)\cos n\pi x\,\mathrm{d}x = \int_{0}^{1} x\cos n\pi x\,\mathrm{d}x \\
&= \frac{1}{(n\pi)^2}(\cos n\pi - 1) \\
&= \frac{1}{(n\pi)^2}[(-1)^n - 1] = \begin{cases} 0 & \text{if} \quad n = \text{even} \\ -\frac{2}{(n\pi)^2} & \text{if} \quad n = \text{odd}\,, \end{cases} \\
b_n &= \int_{-1}^{1} f(x)\sin n\pi x\,\mathrm{d}x = \int_{0}^{1} x\sin n\pi x\,\mathrm{d}x \\
&= -\frac{1}{n\pi}[x\cos n\pi]_0^1 + \frac{1}{(n\pi)^2}[\sin n\pi x]_0^1 \\
&= \frac{1}{n\pi}(-1)^{n+1}\,.
\end{aligned}
$$

Equation (1.79) gives the Fourier series of $f(x)$, as

$$
\begin{aligned}
&\frac{1}{4} - \frac{2}{\pi^2}\cos\pi x + \frac{1}{\pi}\sin\pi x - \frac{1}{2\pi}\sin 2\pi x \\
&- \frac{2}{9\pi^2}\cos 3\pi x + \frac{1}{3\pi}\sin 3\pi x + \cdots \\
&\overset{\text{Collect terms}}{=} \frac{1}{4} - \frac{2}{\pi^2}\left(\cos\pi x + \frac{1}{9}\cos 3\pi x + \cdots\right) \\
&+ \frac{1}{\pi}\left(\sin\pi x - \frac{1}{2}\sin 2\pi x + \frac{1}{3}\sin 3\pi x - \cdots\right)\,.
\end{aligned}
$$

The third and ninth partial sums, together with the original function, are shown in Fig. 1.21. As mentioned earlier, at the points of discontinuity of $f(x)$ the partial sums assume the average value of the left- and right-hand limits, that is, 1/2.

1.4.2 Fourier Transformation

In Sect. 1.3 the notation $F(s)$ was used to represent the Laplace transform of $f(t)$, i. e., $F(s) = \mathbf{L}[f(t)]$. Similarly, $\hat{f}(\omega)$ is used to denote the Fourier transform of $f(t)$, that is, $\hat{f}(\omega) = \mathbf{F}[f(t)]$. Since ω is complex in general, $\hat{f}(\omega)$ is expected to be complex-valued as well. With this, we then write $f(t) = \mathbf{F}^{-1}[\hat{f}(\omega)]$ describing the inverse Fourier transform of $\hat{f}(\omega)$. We define the Fourier transform pair as

$$
\hat{f}(\omega) = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty} f(\tau)\,\mathrm{e}^{-\mathrm{i}\omega\tau}\,\mathrm{d}\tau\,, \tag{1.83}
$$

$$
f(t) = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty} \hat{f}(\omega)\,\mathrm{e}^{\mathrm{i}\omega t}\,\mathrm{d}\omega\,. \tag{1.84}
$$

Fourier transformation can be thought of as a *mapping* that assigns to a given function of time t an integral function of frequency ω. In general, any trans-

formation with this type of property is known as an *integral transformation*. The obvious similarities between the Laplace and Fourier transforms are credited to the Laplace transformation being an integral transformation itself. Fourier transforms of several functions are listed in Table 1.3.

Example 1.29: Fourier transform
Find the Fourier transform of

$$f(t) = \begin{cases} 0 & \text{if} \quad t < 0 \\ e^{-at} & \text{if} \quad t > 0 \end{cases} (a > 0)\,.$$

Solution. By (1.83),

$$\begin{aligned} \hat{f}(\omega) &= \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} f(\tau)\, e^{-i\omega\tau}\, d\tau \\ &= \frac{1}{\sqrt{2\pi}} \int_{0}^{\infty} e^{-a\tau}\, e^{-i\omega\tau}\, d\tau \\ &= \frac{1}{\sqrt{2\pi}} \frac{-1}{a+i\omega} \Big[e^{-(a+i\omega)\tau} \Big]_0^{\infty} \\ &= \frac{1}{\sqrt{2\pi}} \frac{1}{a+i\omega}\,. \end{aligned}$$

Using $\hat{f}(\omega)$ above in (1.84), we find

$$\begin{aligned} f(t) &= \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} \frac{1}{\sqrt{2\pi}} \frac{1}{a+i\omega}\, e^{i\omega t}\, d\omega \\ &= \frac{1}{2\pi} \int_{-\infty}^{\infty} \frac{1}{a+i\omega}\, e^{i\omega t}\, d\omega\,. \end{aligned}$$

This is known as the complex Fourier integral representation of the function under consideration.

1.5 Linear Algebra

In this section we present the fundamentals of linear algebra, specifically, vectors and matrices, and their relation to linear systems of algebraic and differential equations. The methods of linear algebra are mainly useful in the treatment of systems of equations that are heavily coupled, that is, when a large number of equations in the system involve many of the unknown variables. In these cases, techniques such as direct substitution and elimination are no longer suitable due to their lack of computational efficiency. We focus on algebraic systems first, then extend the ideas to systems of differential equations.

1.5.1 Vectors and Matrices

An n-dimensional vector $\boldsymbol{v}$ is an ordered set of n scalars, and is written as $\boldsymbol{v} = (v_1, v_2, \cdots, v_n)$. Each v_i $(i = 1, 2, \cdots, n)$ is called a component of the vector $\boldsymbol{v}$. In a general sense, an n-dimensional vector helps us locate a point in an n-dimensional space, regardless of the nature of its components or perhaps what physical quantity each may represent.

Matrices

A collection of numbers (real or complex) or possibly functions, arranged in a rectangular array and enclosed by brackets, is referred to as a matrix. Each of the elements in a matrix is called an entry (or element) of the matrix. The horizontal and vertical lines are referred to as rows and columns of the matrix, respectively. A matrix is called a row vector if it consists of one row only, and a column vector if it has one column only. The number of rows and columns of a matrix determine the size of that matrix. If a matrix $\mathbf{A}$ has m rows and n columns, then it is said to be of size $m \times n$. If the number of rows and columns are the same, we speak of a square matrix, otherwise, a rectangular matrix. We denote matrices by bold-faced capital letters, such as $\mathbf{A}$. The abbreviated form of an $m \times n$ matrix is

$$\mathbf{A} = [a_{ij}]_{m\times n}\ ,\ i = 1, 2, \cdots, m\ ,\ j = 1, 2, \cdots, n\ ,$$

where a_{ij} is known as the (i, j) entry of $\mathbf{A}$, located at the intersection of the ith row and the jth column of $\mathbf{A}$ so that a_{12}, for instance, occupies the entry at which the first row and the second column meet. In the event that $\mathbf{A}$ is a square matrix $(m = n)$, the elements $a_{11}, a_{22}, \cdots, a_{nn}$ are referred to as the *diagonal entries* of $\mathbf{A}$. These diagonal elements form the main diagonal of $\mathbf{A}$. The diagonal directly below the main is known as the *subdiagonal* and the one above the main is called the *superdiagonal*. Two matrices $\mathbf{A} = [a_{ij}]$ and $\mathbf{B} = [b_{ij}]$ are said to be equal if they have the same size, and the same entries in the respective locations. If some rows or columns (or possibly both) of $\mathbf{A}$ are deleted, the outcome is a submatrix of $\mathbf{A}$. If no rows or columns of $\mathbf{A}$ are omitted, we have $\mathbf{A}$ as a submatrix of itself. Submatrices play important roles in such areas of matrix analysis as determinants and rank.

Matrix Operations

Matrices of the same size can be added. The result, or the sum, is a matrix of the same size. If $\mathbf{A} = [a_{ij}]$ and $\mathbf{B} = [b_{ij}]$ are $m \times n$, their sum $\mathbf{C} = [c_{ij}]$ is also $m \times n$. Matrix addition is performed entry-wise, that is, the entry of $\mathbf{C}$ in the (i, j) slot is the sum of the entries of $\mathbf{A}$ and $\mathbf{B}$ in that same slot. The $m \times n$ zero matrix, denoted by $\mathbf{0}_{m\times n}$, is an $m \times n$ matrix all of whose entries are zero. If $\mathbf{A} = [a_{ij}]$ is $m \times n$ and k is a scalar, then $k\mathbf{A}$ is an $m \times n$ matrix whose entries are those of $\mathbf{A}$ multiplied by k in every slot, that is, $k\mathbf{A} = [ka_{ij}]_{m\times n}$. Let $\mathbf{A} = [a_{ij}]_{m\times n}$ and $\mathbf{B} = [b_{ij}]_{n\times p}$. It is important to note that the number of columns of $\mathbf{A}$ is n, which is equal to the number of rows of $\mathbf{B}$. Then, their product $\mathbf{C} = \mathbf{AB}$ is $m \times p$ whose entries are obtained as

$$c_{ij} = \sum_{k=1}^{n} a_{ik}b_{kj}\ ,\ i = 1, 2, \cdots, m\ ,\ j = 1, 2, \ldots, p\ . \tag{1.85}$$

This is shown schematically in Fig. 1.22. If the number of columns of $\mathbf{A}$ does not match the number of rows of

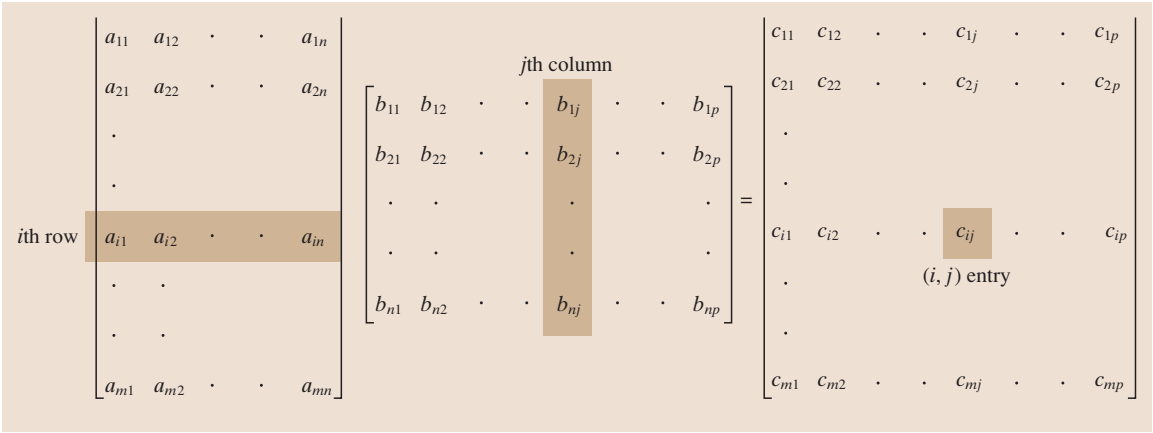

Fig. 1.22 Construction of the matrix product $\mathbf{AB} = \mathbf{C}$

B, the product is undefined. If the product is defined, then to get the (i, j) entry of **C**, we proceed as follows: the ith row of **A** is clearly a $1\times n$ vector. The jth column of **B** is an $n\times 1$ vector, hence these two vectors have the same number of components, n. In these two vectors, multiply the first components, the second components, etc., up to the nth components. Then add the individual products together. The result is c_{ij}.

Example 1.30: Matrix Multiplication
Find

$$\mathbf{AB} = \begin{pmatrix} 1 & -2 & 3 \\ 0 & 1 & 4 \end{pmatrix}_{2\times 3} \begin{pmatrix} -2 & -1 & 4 \\ 1 & 2 & 0 \\ 3 & 5 & 1 \end{pmatrix}_{3\times 3} .$$

Solution. We first note that the operation is valid because **A** has three columns and **B** has three rows. And, **AB** will be 2×3. Following the strategy outlined above, we find the product as

$$\mathbf{AB} = \begin{pmatrix} 1\cdot(-2)+(-2)\cdot 1+3\cdot 3 & 1\cdot(-1)+(-2)\cdot 2+3\cdot 5 & 1\cdot 4+(-2)\cdot 0+3\cdot 1 \\ 0\cdot(-2)+1\cdot 1+4\cdot 3 & 0\cdot(-1)+1\cdot 2+4\cdot 5 & 0\cdot 4+1\cdot 0+4\cdot 1 \end{pmatrix} = \begin{pmatrix} 5 & 10 & 7 \\ 13 & 22 & 4 \end{pmatrix}_{2\times 3} .$$

Matrix Transpose

Given an $m\times n$ matrix **A**, its transpose, denoted by $\mathbf{A}^{\mathrm{T}}$, is an $n\times m$ matrix with the property that its first row is the first column of **A**, its second row is the second column of **A**, and so on. Given that all matrix operations are valid,

$$(\mathbf{A}+\mathbf{B})^{\mathrm{T}} = \mathbf{A}^{\mathrm{T}} + \mathbf{B}^{\mathrm{T}} \tag{1.86}$$

$$(k\mathbf{A})^{\mathrm{T}} = k\mathbf{A}^{\mathrm{T}}, \quad \text{scalar } k \tag{1.87}$$

$$(\mathbf{AB})^{\mathrm{T}} = \mathbf{B}^{\mathrm{T}}\mathbf{A}^{\mathrm{T}} . \tag{1.88}$$

Special Matrices

A square matrix **A** is symmetric if $\mathbf{A}^{\mathrm{T}} = \mathbf{A}$ and skew-symmetric if $\mathbf{A}^{\mathrm{T}} = -\mathbf{A}$. A square matrix $\mathbf{A}_{n\times n} = [a_{ij}]$ is called upper-triangular if $a_{ij} = 0$ for all $i > j$, that is, every entry below the main diagonal is zero, lower-triangular if $a_{ij} = 0$ for all $i < j$, that is, all elements above the main diagonal are zeros, and diagonal if $a_{ij} = 0$ for all $i \neq j$. The $n\times n$ identity matrix is a diagonal matrix whose diagonal entries are all equal to 1, and is denoted by **I**.

Example 1.31: Special matrices
Matrices **U**, **L**, and **D** are upper triangular, lower triangular, and diagonal, respectively:

$$\mathbf{U} = \begin{pmatrix} -2 & 1 & 2 \\ 0 & 5 & 0 \\ 0 & 0 & 3 \end{pmatrix} , \quad \mathbf{L} = \begin{pmatrix} 1 & 0 & 0 \\ 2 & 0 & 0 \\ 4 & 7 & -1 \end{pmatrix} ,$$

$$\mathbf{D} = \begin{pmatrix} 3 & 0 & 0 \\ 0 & -4 & 0 \\ 0 & 0 & 1 \end{pmatrix} .$$

Note that in **U** and **L** zeros are allowed along the main diagonal. In fact, the main diagonal may consist of all zeros. On the other hand, **D** may have one or more zero diagonal elements, as long as they are not all zeros. In the event that all entries of an $n\times n$ matrix are zeros, it is called the $n\times n$ *zero matrix* $\mathbf{0}_{n\times n}$.

Determinant

The determinant of a square matrix $\mathbf{A} = [a_{ij}]_{n\times n}$ is a real scalar denoted by $|\mathbf{A}|$ or $\det(\mathbf{A})$. For the most trivial case of $n = 1$, $\mathbf{A} = [a_{11}]$, and we define the determinant simply as $|\mathbf{A}| = a_{11}$. For $n \geq 2$, the determinant is defined as

using the i-th row

$$|\mathbf{A}| = \sum_{k=1}^{n} a_{ik}(-1)^{i+k} M_{ik} , \quad i = 1, 2, \cdots, n \tag{1.89}$$

or

using the j-th column

$$|\mathbf{A}| = \sum_{k=1}^{n} a_{kj}(-1)^{k+j} M_{kj} , \quad j = 1, 2, \cdots, n \tag{1.90}$$

Here M_{ik} is the minor of the entry a_{ik}, defined as the determinant of the $(n-1)\times(n-1)$ submatrix of **A** obtained by deleting the ith row and the kth column of **A**. The quantity $(-1)^{i+k}M_{ik}$ is known as the cofactor of a_{ik} and is denoted by C_{ik}. Also note that $(-1)^{i+k}$ is responsible for whether a term is multiplied by $+1$ or -1. Equations (1.89) and (1.90) suggest that the determinant of a square matrix can be calculated using any row or any column of the matrix. However, for all practical purposes, it is wise to use the row (or column) containing the most number of zeros, or if none, the one with the smallest entries. A square matrix with a nonzero determinant is known as a nonsingular matrix. Otherwise, it is called singular. The rank of any matrix **A**, denoted by $\mathrm{rank}(\mathbf{A})$, is the size of the largest nonsingular submatrix of **A**. If $|\mathbf{A}_{n\times n}| = 0$, we conclude that $\mathrm{rank}\,(\mathbf{A}) < n$.

Example 1.32: 3×3 determinant
Find the determinant of

$$\mathbf{A} = \begin{pmatrix} 1 & 2 & -3 \\ 4 & -1 & 1 \\ 2 & 0 & 1 \end{pmatrix} .$$

Solution. We will use the third row because it happens to contain a zero. Following (1.89),

$$\begin{aligned} |\mathbf{A}| &= 2\cdot(-1)^{3+1}M_{31} + 0 + 1\cdot(-1)^{3+3}M_{33} \\ &= 2\begin{vmatrix} 2 & -3 \\ -1 & 1 \end{vmatrix} + \begin{vmatrix} 1 & 2 \\ 4 & -1 \end{vmatrix} \\ &= 2(2-3) + (-1-8) = -11 . \end{aligned}$$

Properties of Determinant. The determinant of a matrix possesses a number of important properties, some of which are listed below [1.1]:

- A square matrix $\mathbf{A}$ and its transpose have the same determinant, that is, $|\mathbf{A}| = |\mathbf{A}^{\mathrm{T}}|$.
- The determinant of diagonal, upper-triangular and lower-triangular matrices is the product of the diagonal entries.
- If an entire row (or column) of a square matrix $\mathbf{A}$ is zero, then $|\mathbf{A}| = 0$.
- If $\mathbf{A}$ is $n\times n$ and k is scalar, then $|k\mathbf{A}| = k^n\,|\mathbf{A}|$.
- If any two rows (or columns) of $\mathbf{A}$ are interchanged, the determinant of the resulting matrix is $-|\mathbf{A}|$.
- The determinant of the product of two matrices obeys $|\mathbf{AB}| = |\mathbf{A}|\,|\mathbf{B}|$.
- Any square matrix with any number of linearly dependent rows (or columns) is singular.

Determinant of Block Matrices. We define a block-diagonal matrix as a square matrix partitioned such that its diagonal elements are square matrices, while all other elements are zeros; see Fig. 1.23a. Similarly, a block-triangular matrix is a square matrix partitioned so that its diagonal elements are square blocks, while all entries either above or below this main block diagonal are zeros; see Fig. 1.23b,c.

Many properties of these special block matrices are basically extensions of those of diagonal and triangular matrices. In particular, the determinant of each of these matrices is equal to the product of the individual determinants of the blocks along the main diagonal. Consequently, a block diagonal (or triangular) matrix is singular if and only if one of the blocks along the main diagonal is singular.

Inverse of a Matrix. Given a square matrix $\mathbf{A}_{n\times n}$, its inverse is denoted by $\mathbf{A}^{-1}$ with the property that

$$\mathbf{A}\mathbf{A}^{-1} = \mathbf{I} = \mathbf{A}^{-1}\mathbf{A} , \tag{1.91}$$

where $\mathbf{I}$ denotes the $n\times n$ identity matrix. If $\mathbf{A}^{-1}$ exists, then it is unique. A square matrix has an inverse if and only if it is nonsingular. Equivalently, $\mathbf{A}_{n\times n}$ has an inverse if and only if rank $(\mathbf{A}) = n$. A square matrix with an inverse is called invertible. An immediate application of the inverse is in the solution process of a linear system $\mathbf{A}\boldsymbol{x} = \boldsymbol{b}$. Multiplying this equation from the left, known as premultiplication, by $\mathbf{A}^{-1}$, yields

$$\begin{aligned} & \mathbf{A}^{-1}(\mathbf{A}\boldsymbol{x}) = \mathbf{A}^{-1}\boldsymbol{b} \\ \Rightarrow\ & (\mathbf{A}^{-1}\mathbf{A})\boldsymbol{x} = \mathbf{A}^{-1}\boldsymbol{b} \\ \Rightarrow\ & \mathbf{I}\boldsymbol{x} = \mathbf{A}^{-1}\boldsymbol{b} \\ \Rightarrow\ & \boldsymbol{x} = \mathbf{A}^{-1}\boldsymbol{b} . \end{aligned}$$

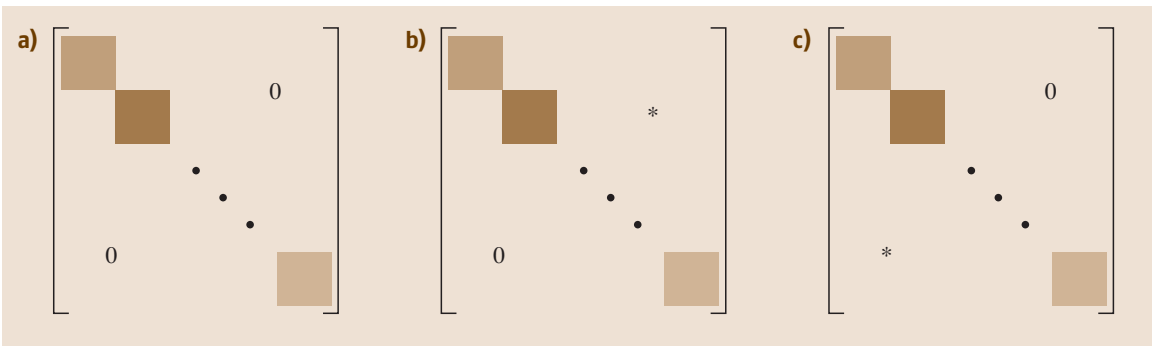

Fig. 1.23 (a) Block-diagonal matrix. (b) Block-upper-triangular matrix. (c) Block-lower-triangular matrix

Inverse via the Adjoint Matrix. The inverse of an invertible matrix $\mathbf{A} = [a_{ij}]_{n\times n}$ is determined using the adjoint of $\mathbf{A}$, denoted by adj($\mathbf{A}$) and defined as [1.1]

$$\begin{aligned}
&\text{adj}(\mathbf{A}) \\
&= \begin{pmatrix}
(-1)^{1+1}M_{11} & (-1)^{2+1}M_{21} & \cdots & (-1)^{n+1}M_{n1} \\
(-1)^{1+2}M_{12} & (-1)^{2+2}M_{22} & \cdots & (-1)^{n+2}M_{n2} \\
\vdots & \vdots & & \vdots \\
(-1)^{1+n}M_{1n} & (-1)^{2+n}M_{2n} & \cdots & (-1)^{n+n}M_{nn}
\end{pmatrix} \\
&= \begin{pmatrix}
C_{11} & C_{21} & \cdots & C_{n1} \\
C_{12} & C_{22} & \cdots & C_{n2} \\
\vdots & \vdots & & \vdots \\
C_{1n} & C_{2n} & \cdots & C_{nn}
\end{pmatrix} . \qquad (1.92)
\end{aligned}$$

Note that each minor M_{ij} (or cofactor C_{ij}) occupies the (j, i) position in the adjoint matrix, the opposite of what one would normally expect. Then, the inverse of $\mathbf{A}$ is simply defined by

$$\mathbf{A}^{-1} = \frac{1}{|\mathbf{A}|}\text{adj}(\mathbf{A}) . \qquad (1.93)$$

Example 1.33: Formula for the inverse of a 2×2 matrix
Find a formula for the inverse of

$$\mathbf{A} = \begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix} .$$

Solution. Following the procedure outlined above, we find

$$\begin{aligned}
M_{11} &= a_{22} , \quad & C_{11} &= a_{22} , \\
M_{12} &= a_{21} , \quad & C_{12} &= -a_{21} , \\
M_{21} &= a_{12} , \quad & C_{21} &= -a_{12} , \\
M_{22} &= a_{11} , \quad & C_{22} &= a_{11} .
\end{aligned}$$

Then,

$$\mathbf{A}^{-1} = \frac{1}{|\mathbf{A}|}\begin{pmatrix} a_{22} & -a_{12} \\ -a_{21} & a_{11} \end{pmatrix} , \qquad (1.94)$$

which is a useful formula for 2×2 matrices, allowing us to omit the intermediate steps.

Inverses of Special Matrices. If the main diagonal entries are all nonzero, the inverse of a diagonal matrix is again diagonal. The diagonal elements of the inverse are simply the reciprocals of the diagonal elements of the original matrix. The inverse of an upper-triangular matrix is upper-triangular. The diagonal elements of the inverse are the reciprocals of the diagonal entries of the original matrix, while the off-diagonal entries do not obey any pattern. A similar result holds for lower-triangular matrices. Furthermore, it turns out that a block-diagonal matrix and its inverse have exactly the same structure.

Properties of Inverse. Some important properties of the inverse [1.1, 8] are given below. The assumption is that all listed inverses exist.

- $(\mathbf{A}^{-1})^{-1} = \mathbf{A}$.
- $(\mathbf{AB})^{-1} = \mathbf{B}^{-1}\mathbf{A}^{-1}$.
- $(\mathbf{A}^{\mathrm{T}})^{-1} = (\mathbf{A}^{-1})^{\mathrm{T}}$.
- The inverse of a symmetric matrix is symmetric.
- $(\mathbf{A}^{p})^{-1} = (\mathbf{A}^{-1})^{p}$, where p is a positive integer.
- $\det(\mathbf{A}^{-1}) = 1/\det(\mathbf{A})$.

1.5.2 Eigenvalues and Eigenvectors

The fundamentals of linear algebra are now extended to treat systems of differential equations, which are of particular importance to us since they represent the mathematical models of dynamic systems. In the analysis of such systems, one frequently encounters the *eigenvalue problem*, solutions of which are *eigenvalues* and *eigenvectors*. This knowledge enables the analyst to determine the natural frequencies and responses of systems. Let $\mathbf{A}$ be an $n\times n$ matrix, $\boldsymbol{v}$ a nonzero $n\times1$ vector, and λ a number (complex in general). Consider

$$\mathbf{A}\boldsymbol{v} = \lambda\boldsymbol{v} \qquad (1.95)$$

A number λ for which (1.95) has a nontrivial solution ($\boldsymbol{v} \neq \mathbf{0}_{n\times1}$) is called an eigenvalue or characteristic value of matrix $\mathbf{A}$. The corresponding solution $\boldsymbol{v} \neq \mathbf{0}$ of (1.95) is the eigenvector or characteristic vector of $\mathbf{A}$ corresponding to λ. Eigenvalues, together with eigenvectors form the eigensystem of $\mathbf{A}$. The problem of determining eigenvalues and the corresponding eigenvectors of $\mathbf{A}$, described by (1.95), is called an eigenvalue problem. The trace of a square matrix $\mathbf{A} = [a_{ij}]_{n\times n}$, denoted by tr($\mathbf{A}$), is defined as the sum of the eigenvalues of $\mathbf{A}$. It turns out that tr($\mathbf{A}$) is also the sum of the diagonal elements of $\mathbf{A}$. A matrix and its transpose have the same eigenvalues.

Solving the Eigenvalue Problem

Let us consider (1.95), $\mathbf{A}\boldsymbol{v} = \lambda\boldsymbol{v}$. Because equations in this form involve scalars, vectors, and matrices, it is im-

perative that extra caution is taken while working with them. First, rewrite and manipulate (1.95) as

$$\mathbf{A}\boldsymbol{v} - \lambda\boldsymbol{v} = \mathbf{0}_{n\times 1} \Rightarrow (\mathbf{A} - \lambda \boldsymbol{I})\boldsymbol{v} = \mathbf{0}\,, \tag{1.96}$$

where we note that every term here is an $n\times 1$ vector. The identity matrix $\mathbf{I} = \mathbf{I}_n$ has been inserted so that the two terms in parentheses are compatible; otherwise we would have $\mathbf{A} - \lambda$, which is meaningless. This equation has a nontrivial solution ($\boldsymbol{v} \neq \mathbf{0}$) if and only if the coefficient matrix, $\mathbf{A} - \lambda\mathbf{I}$, is singular. That means

$$|\mathbf{A} - \lambda\mathbf{I}| = 0\,. \tag{1.97}$$

This is called the characteristic equation of $\mathbf{A}$. The determinant $|\mathbf{A} - \lambda\mathbf{I}|$ is an nth-degree polynomial in λ and is known as the characteristic polynomial of $\mathbf{A}$ whose roots are precisely the eigenvalues of $\mathbf{A}$. Once the eigenvalues have been identified, each eigenvector corresponding to each of the eigenvalues is determined by solving (1.96).

Example 1.34: Eigenvalues and eigenvectors
Find the eigenvalues and eigenvectors of

$$\mathbf{A} = \begin{pmatrix} -1 & -3 \\ 0 & 2 \end{pmatrix}\,.$$

Solution. To find the eigenvalues of $\mathbf{A}$, we solve the characteristic equation,

$$\begin{aligned} &|\mathbf{A} - \lambda\mathbf{I}| = 0 \\ \Rightarrow &\begin{vmatrix} -1-\lambda & -3 \\ 0 & 2-\lambda \end{vmatrix} = 0 \\ &\Rightarrow (\lambda+1)(\lambda-2) = 0 \\ &\Rightarrow \lambda_{1,2} = -1, 2\,. \end{aligned}$$

Without losing any information, let us assign $\lambda_1 = -1$. To find the eigenvector, solve (1.96) with $\lambda = \lambda_1 = -1$,

$$(\mathbf{A} - \lambda_1\mathbf{I})\boldsymbol{v}_1 = \mathbf{0} \overset{\lambda_1 = -1}{\Rightarrow} (\boldsymbol{A} + \mathbf{I})\boldsymbol{v}_1 = \mathbf{0}\,, \tag{1.98}$$

where $\boldsymbol{v}_1$ is the 2×1 eigenvector corresponding to λ_1. Letting $\boldsymbol{v}_1 = \begin{pmatrix} v_{11} \\ v_{21} \end{pmatrix}$ and using $\mathbf{A}$ in (1.98), we find

$$\begin{pmatrix} 0 & -3 \\ 0 & 3 \end{pmatrix}\begin{pmatrix} v_{11} \\ v_{21} \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix}\,. \tag{1.99}$$

As expected, this system has nontrivial solutions because the coefficient matrix is singular. To solve (1.99), we apply suitable elementary row operations [1.1] to the augmented matrix to reduce it to

$$\begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix}\,.$$

The second row suggests that there is a free variable, implying that the two equations contained in (1.99) are linearly dependent. From the first row, we have $v_{21} = 0$ so that v_{21} cannot be the free variable, so v_{11} must be. In this example, since we already have $v_{21} = 0$, then $v_{11} \neq 0$ because otherwise $\boldsymbol{v}_1 = \mathbf{0}$, which is not valid. For simplicity, let $v_{11} = 1$, so

$$\boldsymbol{v}_1 = \begin{pmatrix} 1 \\ 0 \end{pmatrix}\,.$$

Similarly, the eigenvector corresponding to $\lambda_2 = 2$ can be shown to be $\boldsymbol{v}_2 = [-1\ 1]^{\mathrm{T}}$. The set $(\boldsymbol{v}_1, \boldsymbol{v}_2)$ is the basis of all eigenvectors of matrix $\mathbf{A}$.

Special Matrices

The eigenvalues of triangular and diagonal matrices are the diagonal entries. The eigenvalues of block-triangular and diagonal matrices are the eigenvalues of the block matrices along the main diagonal. All eigenvalues of a symmetric matrix are real, while those of a skew-symmetric matrix are either zero or pure imaginary.

Generalized Eigenvectors

If λ_k is an eigenvalue of $\mathbf{A}$ occurring m_k times, then m_k is the algebraic multiplicity of λ_k, denoted by $\mathrm{AM}(\lambda_k)$. The maximum number of linearly independent eigenvectors associated with λ_k is called the geometric multiplicity of λ_k, $\mathrm{GM}(\lambda_k)$. In general, $\mathrm{GM}(\lambda_k) \leq \mathrm{AM}(\lambda_k)$. In Example 1.34 the AM and GM of each of the two eigenvalues was 1. When $\mathrm{GM}(\lambda_k) < \mathrm{AM}(\lambda_k)$, there are fewer eigenvectors than one would expect. For instance, if $\mathrm{AM}(\lambda) = 2$ and $\mathrm{GM}(\lambda) = 1$, then only one independent eigenvector can be found for λ, while one is missing; the missing one is called a generalized eigenvector [1.1].

Similarity Transformation – Diagonalization

Two matrices $\mathbf{A}_{n\times n}$ and $\mathbf{B}_{n\times n}$ are said to be similar if there exists a nonsingular matrix $\boldsymbol{S}_{n\times n}$ such that $\mathbf{B} = \mathbf{S}^{-1}\mathbf{A}\mathbf{S}$. We say that $\mathbf{B}$ is obtained from $\mathbf{A}$ through a similarity transformation. Similar matrices have the same eigenvalues. Suppose $\mathbf{A}_{n\times n}$ has n linearly independent eigenvectors $\boldsymbol{v}_1, \boldsymbol{v}_2, \cdots, \boldsymbol{v}_n$ associated with eigenvalues $\lambda_1, \lambda_2, \cdots, \lambda_n$. Form the $n\times n$ matrix $\mathbf{P} = [\ \boldsymbol{v}_1\ \ \boldsymbol{v}_2\ \ .\ .\ \boldsymbol{v}_n\ ]$, known as the modal matrix, whose columns are the eigenvectors of $\mathbf{A}$. Then, $\mathbf{P}$

is nonsingular, and

$$\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \mathbf{\Lambda} = \begin{pmatrix} \lambda_1 & & 0 \\ & \ddots & \\ 0 & & \lambda_n \end{pmatrix} , \qquad (1.100)$$

where the order of the appearance of the λ_i along the main diagonal agrees with the order of the corresponding $\boldsymbol{v}_i$ in matrix $\mathbf{P}$. Any matrix $\mathbf{A}$ that satisfies (1.100) is called diagonalizable. It is clear that $\mathbf{A}$ and $\mathbf{\Lambda}$ are similar, hence share the same eigenvalues.

Example 1.35: Modal matrix
In reference to Example 1.34, the modal matrix is

$$\mathbf{P} = \begin{pmatrix} 1 & -1 \\ 0 & 1 \end{pmatrix} , \text{ which satisfies}$$

$$\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \mathbf{\Lambda} = \begin{pmatrix} -1 & 0 \\ 0 & 2 \end{pmatrix} = \begin{pmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{pmatrix} .$$

1.5.3 Numerical Solution of Higher-Order Systems of ODEs

In this section we present a two-step process to treat one or more ODEs of order higher than one. The first stage is concerned with the conversion of the original ODEs into a system of first-order ODEs. The second stage deals with the application of the fourth-order Runge–Kutta method to solve this system numerically; also see Sect. 1.2.2. It should be mentioned that we are not interested in mathematically fabricated, higher-order systems, but rather those of physical significance. The first step is handled via the state variables, explained below.

State Variables

The smallest possible set of independent variables that completely describes the state of a system is referred to as the set of state variables. Since independence is essential, state variables cannot be expressible as algebraic functions of one another. Moreover, the set of state variables for a certain system is *not unique*. Given a set of differential equations describing a certain physical system, two key questions need be answered [1.1, 3].

1. How many state variables are there?
   The number of state variables is equal to the number of initial conditions required to completely solve the system's governing equations.
2. What are chosen as the state variables?
   Those variables for which initial conditions are required in (1) are chosen as the state variables.

Example 1.36: State variables
The equation of motion for the mass–spring–damper system in Fig. 1.24 is given as

$$m\ddot{x} + c\dot{x} + kx = f(t) .$$

For a complete description, we need the initial conditions $x(0) = x_0$ (initial displacement) and $\dot{x}(0) = v_0$ (initial velocity).

Since two initial conditions are required, there are two state variables. And, since these conditions are required for x and $\dot{x}$, the state variables are

$$x_1 = x , \quad x_2 = \dot{x} .$$

State-Variable Equations. The idea now is to use the selected set of state variables to transform the original system into a larger system of first-order ODEs. Each of the resulting differential equations consists of the time derivative of one of the state variables on one side, and a linear combination of the state variables and possibly system inputs on the other side. Each of these first-order ODEs just described is called a state-variable equation.

Example 1.37: State-variable equations
Referring to Example 1.36, since there are two state variables, two first-order ODEs must be obtained in terms of x_1 and x_2. The first equation is simply $\dot{x}_1 = x_2$. To obtain the second equation, we use the equation of motion as

$$\dot{x}_2 = \frac{1}{m}[-kx_1 - cx_2 + f(t)] .$$

The state-variable equations are then

$$\begin{cases} \dot{x}_1 = x_2 \\ \dot{x}_2 = \frac{1}{m}[-kx_1 - cx_2 + f(t)] . \end{cases}$$

These can be expressed in matrix form, as

$$\dot{\boldsymbol{x}} = \boldsymbol{f}(t, \boldsymbol{x}) , \boldsymbol{x}(0) = \boldsymbol{x}_0 , \qquad (1.101)$$

where

$$\boldsymbol{x} = \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} ,$$

$$\boldsymbol{f}(t, \boldsymbol{x}) = \begin{pmatrix} x_2 \\ -(k/m)x_1 - (c/m)x_2 + (1/m)f(t) \end{pmatrix} ,$$

$$\boldsymbol{x}_0 = \begin{pmatrix} x_0 \\ v_0 \end{pmatrix} .$$

Fourth-Order Runge–Kutta Method for Systems

Numerical solution of the state-variable equations – such as that in (1.101) of Example 1.37 – is then obtained via the extension of RK4 discussed in Sect. 1.2.2. Consider a system in the form

$$\dot{\boldsymbol{x}}(t) = \boldsymbol{f}(t, \boldsymbol{x}(t)) \,, \quad \boldsymbol{x}(a) = \boldsymbol{x}_0 \,, \quad a \le t \le b \,, \tag{1.102}$$

where

$$\boldsymbol{x}(t) = \begin{pmatrix} x_1(t) \\ x_2(t) \\ \vdots \\ x_n(t) \end{pmatrix} \,,$$

$$\boldsymbol{f}(t, \boldsymbol{x}(t)) = \begin{pmatrix} f_1(t, x_1, x_2, \cdots, x_n) \\ f_2(t, x_1, x_2, \cdots, x_n) \\ \vdots \\ f_n(t, x_1, x_2, \cdots, x_n) \end{pmatrix} \,,$$

$$\boldsymbol{x}_0 = \boldsymbol{x}(a) = \begin{pmatrix} \alpha_1 \\ \alpha_2 \\ \vdots \\ \alpha_n \end{pmatrix} \,.$$

Define an integer $N > 0$ and let $h = (b-a)/N$ be the step size. The mesh points $t_i = a + ih$, $i = 0, 1, \cdots, N-1$, then partition the interval $[a, b]$ into

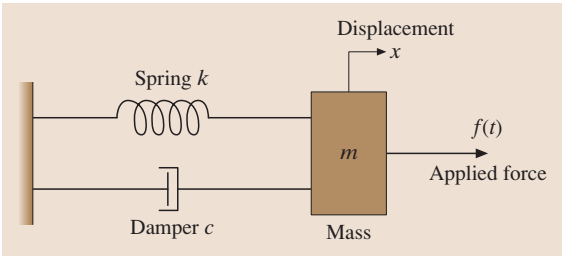

Fig. 1.24 A mechanical system

N subintervals. The fourth-order Runge–Kutta method (RK4) for a system of first-order ODEs is as follows [1.5]. Knowing the initial vector $\boldsymbol{x}_0$, the solution vector $\boldsymbol{x}_i$ at each of the subsequent mesh points t_i is obtained via

$$\boldsymbol{x}_{i+1} = \boldsymbol{x}_i + \frac{1}{6}[\boldsymbol{q}_1 + 2\boldsymbol{q}_2 + 2\boldsymbol{q}_3 + \boldsymbol{q}_4], \quad i = 0, 1, 2, \cdots, N-1 \,,$$

where

$$\boldsymbol{q}_1 = h\boldsymbol{f}(t_i, \boldsymbol{x}_i) \,,$$

2. Mechanics

Hen-Geul Yeh, Hsien-Yang Yeh, Shouwen Yu

Mechanics is the study of the motion of matter and the forces that cause such motion, and is based on the concepts of time, space, force, energy, and matter. A knowledge of mechanics is needed for the study of all branches of physics, chemistry, biology, and engineering [2.1]. The subject of mechanics is logically divided into two parts: statics, which is concerned with the equilibrium of bodies under the action of forces, and dynamics, which is concerned with the motion of bodies. The principles of mechanics as a science are rigorously expressed by mathematics, which therefore plays an important role in the application of these principles to the solution of practical problems [2.2]. A force is a vector quantity, because its effect depends on the direction as well as on the magnitude of the action. In addition to the tendency to move a body in the direction of its application, a force can also tend to rotate a body about an axis. This rotational tendency is known as the moment of the force and therefore, moment can be expressed as a vector quantity as well. When a body is in equilibrium, the resultant of all forces acting on it is zero. Thus, the resultant force and the resultant moment are both zero and the equilibrium equations are satisfied.

A large number of problems involving actual structures, however, can be reduced to problems concerning the equilibrium of a particle. This is done by choosing a significant particle and drawing a separate diagram showing this particle and all the forces acting on it. Such a diagram is called a free-body diagram. The same concept is applied to the solution of a rigid-body equilibrium problem as well [2.3]. A truss is a structure composed of (usually straight) members joined together at their end points and loaded only at the joints. Trusses are commonly seen supporting the roofs of buildings as well as large railroad and highway bridges [2.4]. The analysis of truss structures is a typical engineering application of statics. To analyze systems of forces distributed over an area or volume, we have to evaluate the centroids and center of gravity as well as moments of inertia.

Consider a practical question: what is the steepest incline on which a truck can be parked without slipping? To answer this question, we must examine the nature of friction forces in more detail. Eventually the first variational principle we encounter in the science of mechanics is that of virtual work, which controls the equilibrium of a mechanical system and is fundamental to the development of analytical mechanics.

Dynamic mechanics can be divided into two parts: (1) kinematics, which is the study of a geometry of motion and is used to relate displacement, velocity, acceleration, and time, without taking into account forces and moments as causes of the motion, and (2) dynamics, which is the study of the relation between the forces and moments acting on a body, and the mass and motion of the body; it is used to predict the motion caused by given forces and moments or to determine the forces and moments required to produce a given motion.

This chapter is also devoted to kinematics, which is the starting point from which begin the analysis of the basic motion of particles and rigid bodies and the dynamics of a single particle. This is a fundamental concept in which Newton's laws and certain principles of dynamics are introduced. Furthermore, advanced materials, such as the dynamics of systems of particles, momentum equations, Lagrange's equations, energy equations, D'Alembert's principle, and the dynamics of rigid bodies are also included. Lagrange's equations of motion for linear systems are introduced at the end of the chapter, although this can be regarded as the beginning of the vibration.

2.1 Statics of Rigid Bodies

Statics is a branch of classical mechanics, which is part of the foundation of physics and modern engineering technology. Statics is the study of the equilibrium of rigid bodies under the action of forces and moments. According to Newton's Laws, equilibrium prevails if a body is at rest or is in uniform motion along a straight line.

A rigid body can be represented as a collection of particles. The size and shape of a rigid body remain constant at all times and under all loading conditions. In other words, rigid bodies as understood in statics as bodies of which the deformations are so small that the points at which force is applied undergo negligible displacement.

2.1.1 Force

A force represents the action of one body on another and is generally characterized by its point of application, magnitude, and direction. Thus, force is a vector quantity.

Introducing the unit vectors $\boldsymbol{e}_x$, $\boldsymbol{e}_y$, and $\boldsymbol{e}_z$, or $\boldsymbol{i}$, $\boldsymbol{j}$, and $\boldsymbol{k}$, directed along the x, y, and z axes, respectively, the force $\boldsymbol{F}$ can be expressed in the form (Fig. 2.1a,b)

$$\begin{aligned}\boldsymbol{F} &= F_x\boldsymbol{e}_x + F_y\boldsymbol{e}_y + F_z\boldsymbol{e}_z \\ &= F_x\boldsymbol{i} + F_y\boldsymbol{j} + F_z\boldsymbol{k} \\ &= (F\cos\alpha)\,\boldsymbol{e}_x + (F\cos\beta)\,\boldsymbol{e}_y + (F\cos\gamma)\,\boldsymbol{e}_z \\ &= (F\cos\theta_x)\,\boldsymbol{i} + \left(F\cos\theta_y\right)\boldsymbol{j} + (F\cos\theta_z)\,\boldsymbol{k}, \end{aligned} \quad (2.1)$$

where

$$F = |F| = \sqrt{F_x^2 + F_y^2 + F_z^2}\,. \quad (2.2)$$

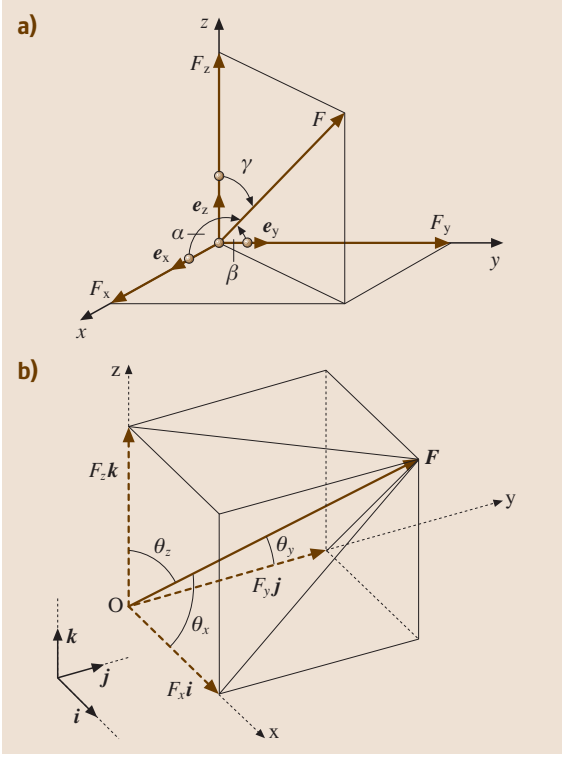

Fig. 2.1a,b Vector representation of a force F

The direction cosines are defined as $\cos\alpha = \cos\theta_x = F_x/F$, $\cos\beta = \cos\theta_y = F_y/F$, $\cos\gamma = \cos\theta_z = F_z/F$, and $\cos^2\alpha + \cos^2\beta + \cos^2\gamma = \cos^2\theta_x + \cos^2\theta_y + \cos^2\theta_z = 1$. When solving three-dimensional problems, it is necessary to find the x, y, and z scalar components of a force. In most cases, the direction of a force is described by two points on the line of action of the force (Fig. 2.1a), or by two angles which orient the line of action (Fig. 2.1b):

1. The direction of a force $\boldsymbol{F}$ is defined by the coordinates of two points $M(x_1, y_1, z_1)$ and $N(x_2, y_2, z_2)$, located on its line of action (Fig. 2.2a). Consider the vector $\boldsymbol{MN}$ joining M and N and of the same sense as $\boldsymbol{F}$. Therefore

$$\boldsymbol{MN} = (x_2 - x_1)\boldsymbol{i} + (y_2 - y_1)\boldsymbol{j} + (z_2 - z_1)\boldsymbol{k} \,. \tag{2.3}$$

The unit vector $\boldsymbol{\lambda}$ along the line of action of $\boldsymbol{F}$ is obtained by dividing the vector $\boldsymbol{MN}$ by its magnitude MN, thus

$$\begin{aligned}\boldsymbol{\lambda} &= \frac{\boldsymbol{MN}}{\mathrm{MN}} \\ &= \frac{(x_2 - x_1)\boldsymbol{i} + (y_2 - y_1)\boldsymbol{j} + (z_2 - z_1)\boldsymbol{k}}{\sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2 + (z_2 - z_1)^2}} \\ &= \frac{d_x\boldsymbol{i} + d_y\boldsymbol{j} + d_z\boldsymbol{k}}{d} \,,\end{aligned} \tag{2.4}$$

and $\boldsymbol{F} = F\boldsymbol{\lambda}$, where F is the magnitude of the force $\boldsymbol{F}$,

$$\begin{aligned} &d_x = x_2 - x_1 \,, \quad d_y = y_2 - y_1 \,, \\ &d_z = z_2 - z_1 \quad \text{and} \\ &d = \sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2 + (z_2 - z_1)^2} \,. \end{aligned}$$

The angles θ_x, θ_y, and θ_z that $\boldsymbol{F}$ forms with the coordinate axes can be expressed as

$$\cos\theta_x = \frac{d_x}{d} \,, \quad \cos\theta_y = \frac{d_y}{d} \,, \quad \cos\theta_z = \frac{d_z}{d} \,.$$

2. Consider the geometry of Fig. 2.2b, assuming that the angles θ and ϕ are known. First resolve $\boldsymbol{F}$ into its horizontal and vertical components:

$$F_{xy} = F\cos\phi \,, \quad F_z = F\sin\phi \,.$$

Then resolve the horizontal components F_{xy} into the x-and y-components

$$\begin{aligned} F_x &= F_{xy}\cos\theta = F\cos\phi\cos\theta \,, \\ F_y &= F_{xy}\sin\theta = F\cos\phi\sin\theta \,. \end{aligned}$$

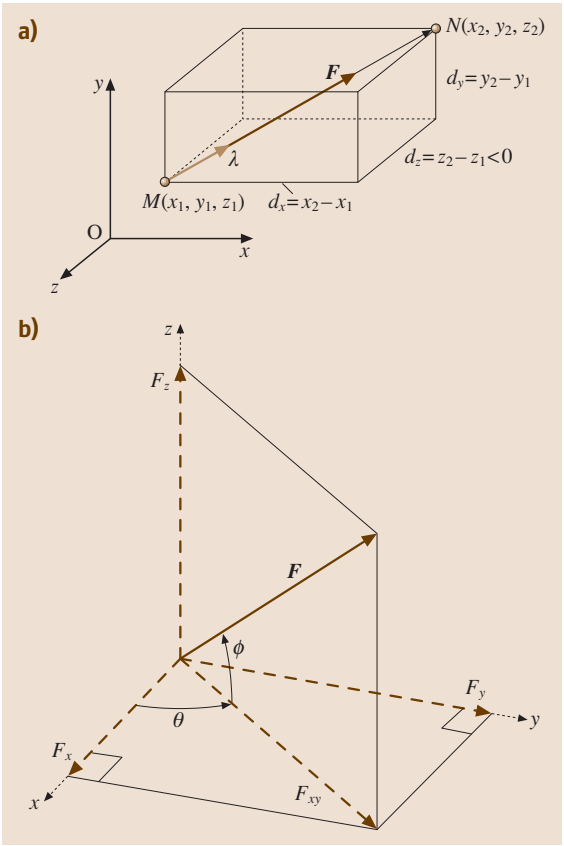

Fig. 2.2a,b Force defined by its magnitude and two points on its line of action

The quantities F_x, F_y, and F_z are the desired scalar components of $\boldsymbol{F}$. Forces acting on rigid bodies can be separated into two groups: (a) external, and (b) internal forces. The external forces represent the action of other bodies on the rigid body under consideration. The internal forces are the forces that hold together the particles forming the rigid body.

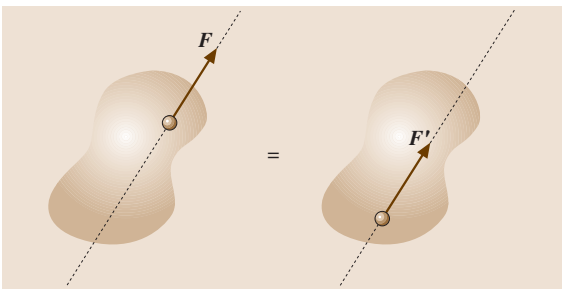

Fig. 2.3 Principle of transmissibility

The principle of transmissibility states that the conditions of equilibrium or motion of a rigid body remain unchanged if a force $\boldsymbol{F}$ acting at a given point on the rigid body is replaced by a force $\boldsymbol{F}'$ of the same magnitude and same direction, but acting at a different point, provided that the two forces have the same line of action (Fig. 2.3); these are known as equivalent forces.

2.1.2 Addition of Concurrent Forces in Space and Equilibrium of a Particle

The resultant $\boldsymbol{R}$ of two or more forces in space is usually determined by summing their rectangular components. Graphical or trigonometric methods are generally not practical in the case of forces in space

$$\boldsymbol{R} = \sum \boldsymbol{F} = 0\,, \tag{2.5}$$

$$\begin{aligned} R_x\boldsymbol{e}_x + R_y\boldsymbol{e}_y + R_z\boldsymbol{e}_z &= R_x\boldsymbol{i} + R_y\boldsymbol{j} + R_z\boldsymbol{k} \\ &= \left(\sum F_x\right)\boldsymbol{i} + \left(\sum F_y\right)\boldsymbol{j} \\ &\quad + \left(\sum F_z\right)\boldsymbol{k} \\ &= \left(\sum F_x\right)\boldsymbol{e}_x + \left(\sum F_y\right)\boldsymbol{e}_y \\ &\quad + \left(\sum F_z\right)\boldsymbol{e}_z\,. \end{aligned} \tag{2.6}$$

From which it follows that

$$R_x = \sum F_x\,, \quad R_y = \sum F_y\,, \quad R_z = \sum F_z\,. \tag{2.7}$$

The magnitude of the resultant and the angles θ_x, θ_y, and θ_z that the resultant forms with the coordinate axes are

$$R = \sqrt{R_x^2 + R_y^2 + R_z^2}\,, \tag{2.8}$$

$$\cos\theta_x = \frac{R_x}{R}\,, \quad \cos\theta_y = \frac{R_y}{R}\,, \quad \cos\theta_z = \frac{R_z}{R}\,. \tag{2.9}$$

Statics deals primarily with the description of the force conditions necessary and sufficient to maintain the equilibrium of engineering structures. When a body is in equilibrium, the resultant of all the forces acting on it is zero. Therefore, for the equilibrium of a particle in space

$$\sum F_x = 0\,, \quad \sum F_y = 0\,, \quad \sum F_z = 0\,. \tag{2.10}$$

2.1.3 Moment and Couple

In addition to the tendency to move a body in the direction of its application, a force can also tend to rotate a body about an axis. The axis may be any line that neither intersects nor is parallel to the line of action of the force. This rotational tendency is known as the moment M of the force (Fig. 2.4a).

The moment produced by two equal, opposite, and non-collinear forces is called a couple (Fig. 2.4b).

Consider a force $\boldsymbol{F}$ acting on a rigid body as shown in Fig. 2.4a. The position vector $\boldsymbol{r}$ and the force $\boldsymbol{F}$ define the plane A. The moment $\boldsymbol{M}_O$ of $\boldsymbol{F}$ about an axis through O normal to the plane has magnitude $\boldsymbol{M}_O = Fd$, where d is the perpendicular distance from O to the line of $\boldsymbol{F}$. This

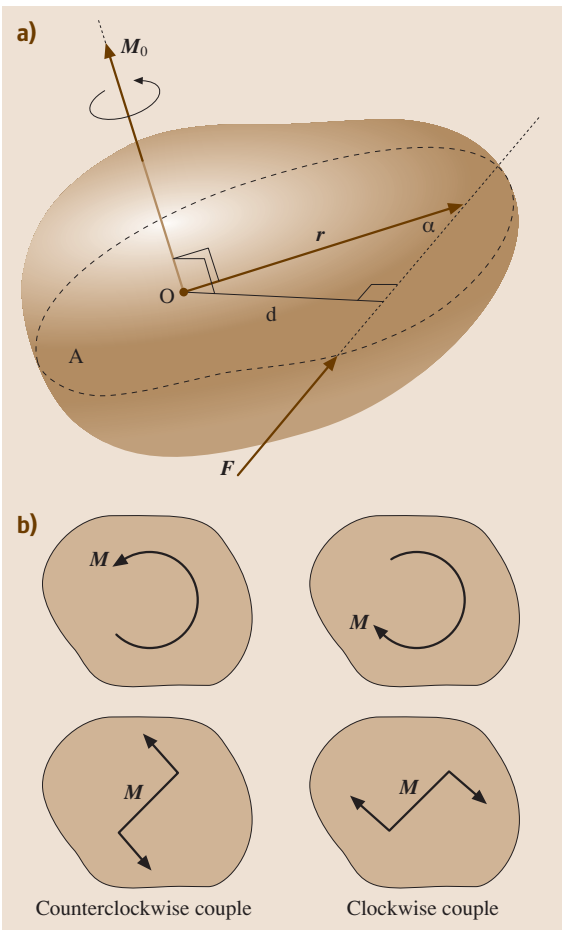

Fig. 2.4 (a) Moment of a force about a point, (b) couple

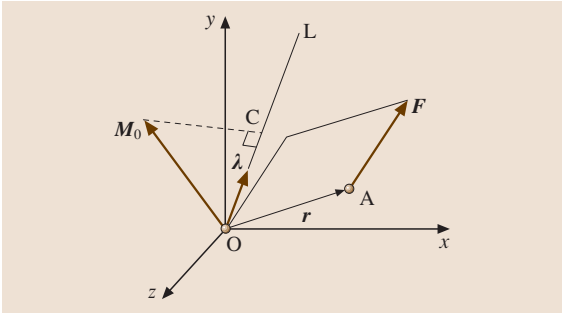

Fig. 2.5 Moment about an arbitrary axis

moment is referred to as the moment of $\boldsymbol{F}$ about the point O.

The vector form of the moment of $\boldsymbol{F}$ about point O is

$$\boldsymbol{M}_O = \boldsymbol{r}\times\boldsymbol{F} = \begin{vmatrix} \boldsymbol{i} & \boldsymbol{j} & \boldsymbol{k} \\ r_x & r_y & r_z \\ F_x & F_y & F_z \end{vmatrix} . \qquad (2.11a)$$

Expansion of the determinant gives

$$\boldsymbol{M}_O = (r_y F_z - r_z F_y)\boldsymbol{i} + (r_z F_x - r_x F_z)\boldsymbol{j} + (r_x F_y - r_y F_x)\boldsymbol{k} \qquad (2.11b)$$

The moment about an arbitrary axis can be found by considering a force $\boldsymbol{F}$ acting on a rigid body and the moment $\boldsymbol{M}_O$ of that force about O, as shown in Fig. 2.5. Let OL be an axis through O, then the moment $\boldsymbol{M}_{OL}$ of $\boldsymbol{F}$ about OL as the projection OC of the moment $\boldsymbol{M}_O$ onto the axes OL is defined as

$$\boldsymbol{M}_{OL} = \boldsymbol{\lambda}\cdot\boldsymbol{M}_O = \boldsymbol{\lambda}\cdot(\boldsymbol{r}\times\boldsymbol{F}) , \qquad (2.12a)$$

which shows that the moment $\boldsymbol{M}_{OL}$ of $\boldsymbol{F}$ about the axis OL is the scalar obtained by the triple scalar product of $\boldsymbol{\lambda}, \boldsymbol{r}$, and $\boldsymbol{F}$.

Expressing $\boldsymbol{M}_{OL}$ in the form of a determinant

$$\boldsymbol{M}_{OL} = \begin{vmatrix} \lambda_x & \lambda_y & \lambda_z \\ x & y & z \\ F_x & F_y & F_z \end{vmatrix} , \qquad (2.12b)$$

where λ_x, λ_y, and λ_z are the direction cosines of the axis OL. x, y, and z are the coordinates of the point of application of $\boldsymbol{F}$, and F_x, F_y, and F_z are the components of the force $\boldsymbol{F}$.

2.1.4 Equilibrium Conditions

When a body is in equilibrium, the resultant of all forces acting on it is zero. Thus, the resultant force $\boldsymbol{R}$ and the resultant moment $\boldsymbol{M}$ are both zero, and the equilibrium equations result

$$\boldsymbol{R} = \sum \boldsymbol{F} = 0 , \quad \boldsymbol{M} = \sum \boldsymbol{M} = \sum (\boldsymbol{r}\times\boldsymbol{F}) = 0 . \qquad (2.13)$$

These requirements are both necessary and sufficient conditions for equilibrium.

In statics, the primary concern is to study forces that act on rigid bodies at rest. In solving a problem concerning the equilibrium of a rigid body, it is essential to consider all of the forces acting on the body. Therefore, the first step in the solution of the problem should be to draw a free-body diagram of the rigid body under consideration. The free-body diagram is a diagrammatic representation of the isolated system treated as a single body. The diagram shows all forces applied to the system by mechanical contact with other bodies, which are imagined to be removed. Examples of free-body diagrams, and reactions at supports are shown in Figs. 2.6–2.8.

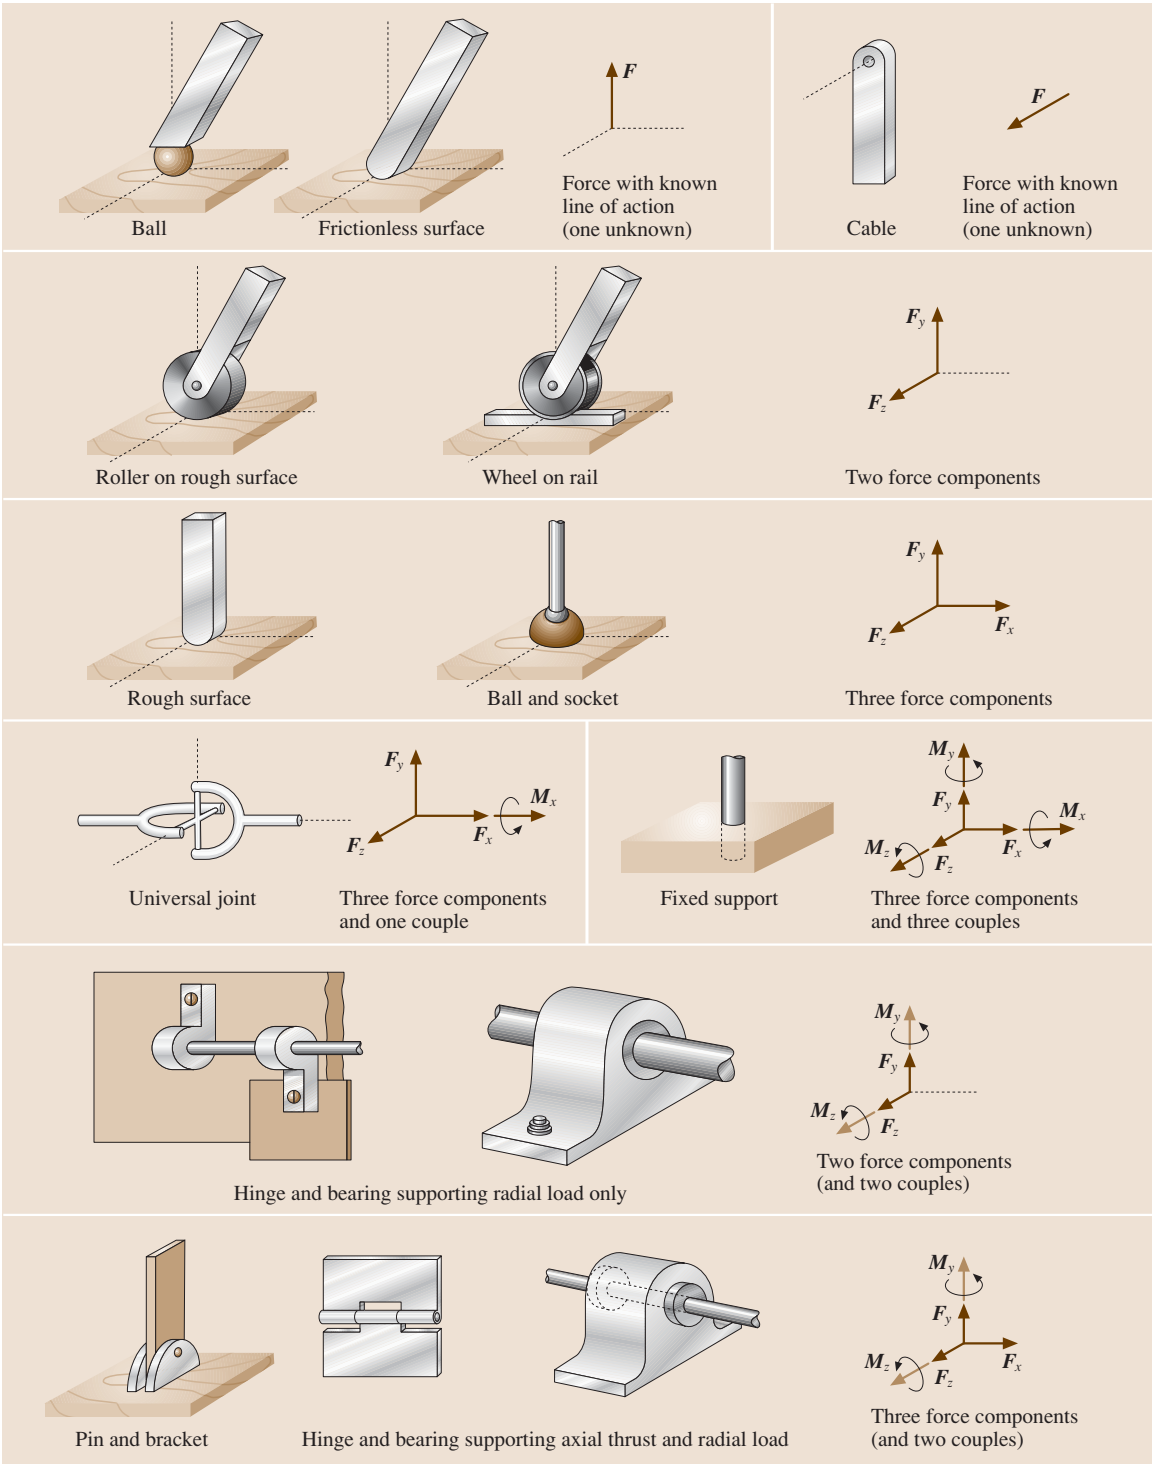

Fig. 2.8 Reactions at supports and connections for a three-dimensional structure (after [2.3])

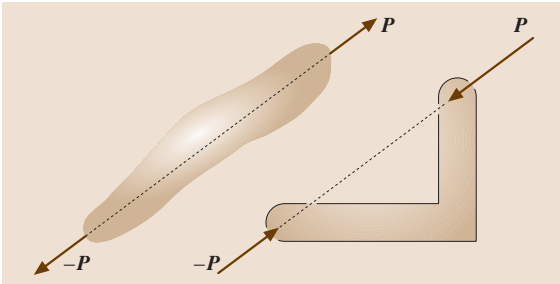

Fig. 2.9 Two-force member

There are two frequently occurring equilibrium situations: two- and three-force members. A two-force member is the equilibrium of a body under the action of two forces only, as shown in Fig. 2.9. For a two-force member to be in equilibrium, the forces must be equal, opposite and collinear. The shape of the member does not affect this simple requirement.

A three-force member is a body under the action of three forces, as shown in Fig. 2.10. For a three-force member to be in equilibrium, the lines of action of the three forces must be concurrent. The principle of the concurrency of three forces in equilibrium is of considerable use in carrying out a graphical solution of the force equations. In this case, the polygon of forces is drawn and made to close, as shown in Fig. 2.8b.

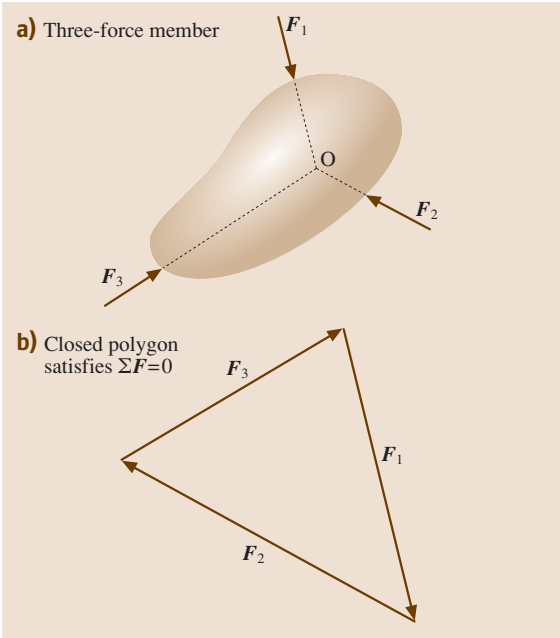

Fig. 2.10a,b Three-force member

A rigid body that possesses more external supports or constraints than are necessary to maintain an equilibrium position is called statistically indeterminate. Supports that can be removed without destroying the equilibrium condition of the body are said to be redundant. The number of redundant supporting elements corresponds to the degree of statical indeterminacy and equals the total number of unknown external forces minus the number of available independent equations of equilibrium. On the other hand, bodies supported by the minimum number of constraints necessary to ensure an equilibrium configuration are called statically determinate, and for such bodies the equilibrium equations are sufficient to determine the unknown external forces.

2.1.5 Truss Structures

A framework composed of members joined at their ends to form a rigid structure is called a truss. When the members of the truss lie essentially in a single plane, the truss is called a plane truss. The basic element of a plane truss is the triangle. Three bars joined by pins at their ends constitute a rigid truss and a larger rigid truss can be obtained by adding two new members to the first one and connecting them at a new joint as shown in Fig. 2.11. Trusses obtained by repeating this procedure are called simple trusses. One may check that, in a simple truss, the total number of members m is expected by $m = 2n - 3$, where n is the total number of joints. This expression applies to a statically determinate and stable truss, since two conditions of equilibrium exist for each joint; i. e., of the $2n - 3$ conditions of equilibrium, m unknown axial forces can be calculated. A pin-jointed truss with $m < 2n - 3$ members is statically undeterminate and kinematically unstable, and a pin-jointed truss with $m > 2n - 3$ is internally statically indeterminate.

The forces in the various members of a simple truss can be determined by the method of joints. First the reactions at the supports can be obtained by considering the entire truss as a free body. The free-body diagram of each pin is then drawn, showing the forces exerted on the pin by the members or supports it connects. Since the members are straight two-force members, the force exerted by a member on the pin is directed along that member and only the magnitude of the force is unknown. It is always possible in the case of a simple truss to draw the free-body diagrams of the pins in such an order that only two unknown forces are included in each diagram. These forces can be determined from the

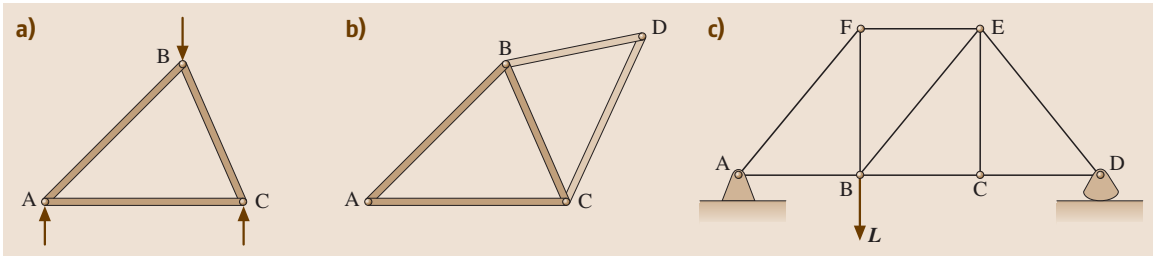

Fig. 2.11a–c Truss structure

two corresponding equilibrium equations: $\sum F_x = 0$ and $\sum F_y = 0$. If the force exerted by a member on a pin is directed toward that pin, the member is in compression; if it is directed away from the pin, the member is in tension.

The method of section is usually preferred to the method of joints when the force in only one member or very few members of a truss is desired. For example, to determine the force in member BD of the truss shown in Fig. 2.12, it is better to pass a section through members BD, BE, and CE, remove these members and use the portion ABC of the truss as a free body. Writing $\sum M_E = 0$ to determine the magnitude of the force F_{BD}, which represents the force in member BD. A positive sign indicates that the member is in tension and a negative sign indicates that it is in compression.

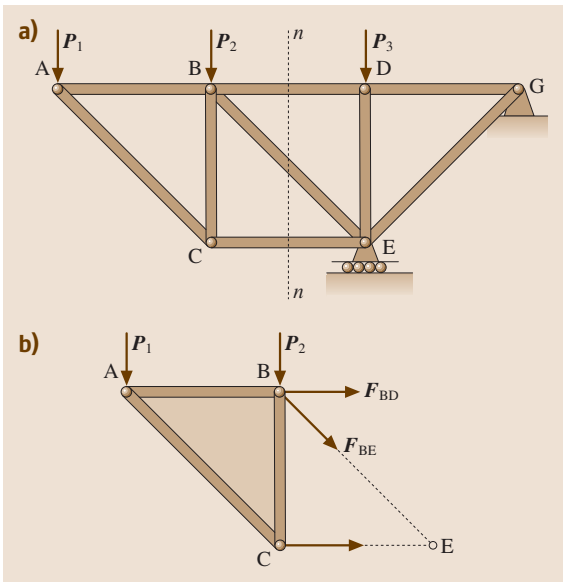

Fig. 2.12a,b Method of section

2.1.6 Distributed Forces

The mass elements of a body of mass m are affected by the forces of gravity $dF = dmg = dW$, all of which are parallel to one another. To determine the location of the center of gravity of any body mathematically, we note that the moment of the resultant gravitational force W about any axis equals the sum of the moments of the gravitational forces dW acting on all the particles treated as infinitesimal elements of the body about the same axis. The resultant of the gravitational forces acting on all elements is the weight of the body and is given by the sum $W = \int dW$. For example, as shown in Fig. 2.13, the moment about the y-axis of the elemental weight is $x\,dW$, and the sum of these moments for all elements of the body is $\int x\,dW$. This sum of moments must equal $W\overline{x}$, the moment of the sum.

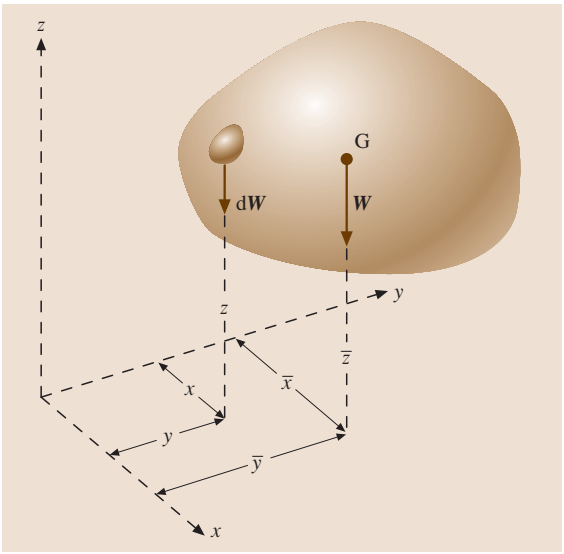

Fig. 2.13 Center of gravity

Therefore, $\overline{x}W = \int x\,\mathrm{d}W$. With similar expressions for the other two components, the coordinates of the center of gravity G are expressed as

$$\overline{x} = \frac{\int x\,\mathrm{d}W}{W}\,, \quad \overline{y} = \frac{\int y\,\mathrm{d}W}{W}\,, \quad \overline{z} = \frac{\int z\,\mathrm{d}W}{W}\,. \tag{2.14}$$

With the substitutions $W = mg$ and $\mathrm{d}W = g\,\mathrm{d}m$, the expressions for the coordinates of the center of gravity become

$$\overline{x} = \frac{\int x\,\mathrm{d}m}{m}\,, \quad \overline{y} = \frac{\int y\,\mathrm{d}m}{m}\,, \quad \overline{z} = \frac{\int z\,\mathrm{d}m}{m}\,. \tag{2.15}$$

The density ρ of a body is its mass per unit volume. Therefore, the mass of a differential element of volume $\mathrm{d}V$ becomes $\mathrm{d}m = \rho\,\mathrm{d}V$, thus, (2.15) can be written as

$$\overline{x} = \frac{\int x\rho\,\mathrm{d}V}{\int \rho\,\mathrm{d}V}\,, \quad \overline{y} = \frac{\int y\rho\,\mathrm{d}V}{\int \rho\,\mathrm{d}V}\,, \quad \overline{z} = \frac{\int z\rho\,\mathrm{d}V}{\int \rho\,\mathrm{d}V}\,. \tag{2.16}$$

Since g no longer appears in (2.15) and (2.16), a unique point that is only a function of the distribution of mass is defined in the body. This point is called the center of mass and clearly coincides with the center of gravity as long as the gravity field is treated as uniform and parallel.

The calculation of centroids falls within three distinct categories:

1. Lines: for a slender rod or wire of length L, cross-sectional area A, and density ρ, the body approximates a line segment and $\mathrm{d}m = \rho A\,\mathrm{d}L$, if ρ and A are constant over the length of the rod, the coordinates of the center of mass become the coordinates of the centroid C of the line segment, and (2.15) may be written

$$\overline{x} = \frac{\int x\,\mathrm{d}L}{L}\,, \quad \overline{y} = \frac{\int y\,\mathrm{d}L}{L}\,, \quad \overline{z} = \frac{\int z\,\mathrm{d}L}{L}\,. \tag{2.17}$$

Similarly, for area and volumes, the expressions of centroids are:

2. Areas

$$\overline{x} = \frac{\int x\,\mathrm{d}A}{A}\,, \quad \overline{y} = \frac{\int y\,\mathrm{d}A}{A}\,, \quad \overline{z} = \frac{\int z\,\mathrm{d}A}{A}\,. \tag{2.18}$$

3. Volumes

$$\overline{x} = \frac{\int x\,\mathrm{d}V}{V}\,, \quad \overline{y} = \frac{\int y\,\mathrm{d}V}{V}\,, \quad \overline{z} = \frac{\int z\,\mathrm{d}V}{V}\,, \tag{2.19}$$

where A and V represent the area and volume of the body, respectively. Some useful expressions of the centroid, area moment of inertia and mass moment of inertia for various geometric figures are listed in Tables 2.1, 2.2.

2.1.7 Friction

Consider a solid block resting on an unlubricated horizontal surface, with the application of a horizontal force $\boldsymbol{p}$ that continuously increases from zero to a value sufficient to move the block and give it an appreciable velocity (Fig. 2.14a). Note that the block does not move at first, which shows that a friction force $\boldsymbol{F}$ must have developed to balance $\boldsymbol{p}$. As the magnitude of $\boldsymbol{p}$ increases, the magnitude of $\boldsymbol{F}$ also increases until it reaches a maximum value $F_{\max} = F_{\mathrm{m}}$. If $\boldsymbol{p}$ is further increased, the block starts sliding and the magnitude of $\boldsymbol{F}$ drops from $\boldsymbol{F}_{\mathrm{m}}$ to a lower value $\boldsymbol{F}_{\mathrm{k}}$ (Fig. 2.14b). Experimental evidence shows that $\boldsymbol{F}_{\mathrm{m}}$ and $\boldsymbol{F}_{\mathrm{k}}$ are proportional to the normal component $\boldsymbol{N}$ of the reaction of

the surface. Thus

$$F_m = \mu_s N\,, \quad F_k = \mu_k N\,, \tag{2.20}$$

where μ_s and μ_k are called, respectively, the coefficients of static and kinetic friction.

It is convenient to replace the normal force $\boldsymbol{N}$ and the friction force $\boldsymbol{F}$ by their resultant $\boldsymbol{R}$, as shown in Fig. 2.15. As the friction force increases and reaches its maximum value $F_m = \mu_s N$, the angle ϕ that $\boldsymbol{R}$ forms with the normal to the surface increases and reaches a maximum value ϕ_s, called the angle of static friction. If motion actually takes place, the magnitude of $\boldsymbol{F}$ drops to $\boldsymbol{F}_k$, similarly the angle ϕ drops to a lower value ϕ_k, called the angle of kinetic friction. Thus

$$\tan\phi_s = \mu_s\,, \quad \tan\phi_k = \mu_k\,. \tag{2.21}$$

Dry friction plays an important role in a number of engineering applications such as wedges, square-threaded screws, journal bearings, thrust bearings, and disk friction. In solving a problem involving a flat belt passing over a fixed cylinder, it is important first to determine the direction in which the belt slips or is about

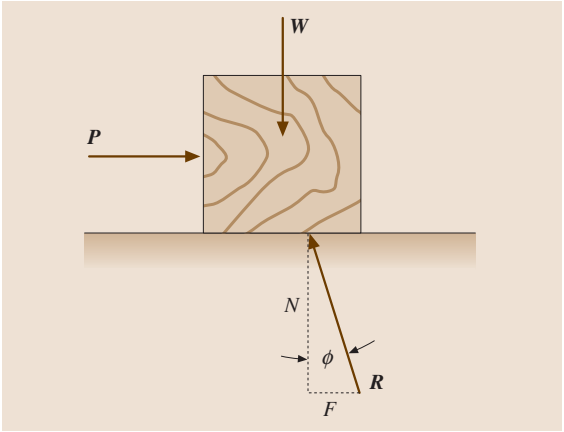

Fig. 2.15 Free-body diagram of a solid block

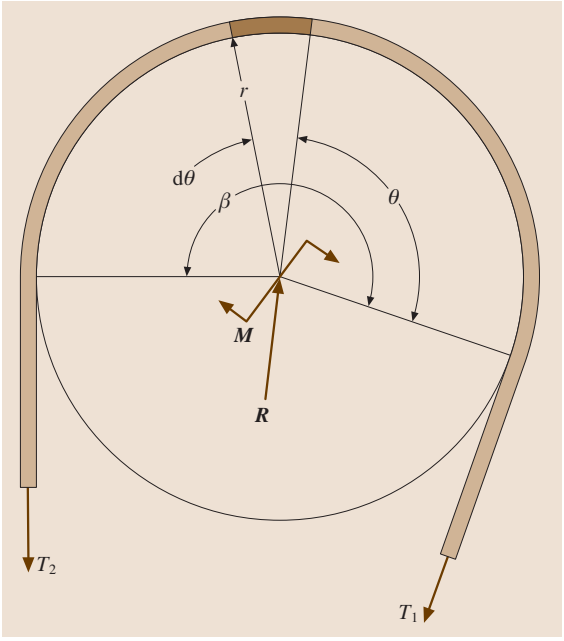

Fig. 2.16 A drum subjected to the two belt tensions T_1 and T_2 and the torque $\boldsymbol{M}$

to slip. If the drum is rotating, the motion or impending motion of the belt should be determined relative to the rotating drum. For instance, if the belt shown in Fig. 2.16 with M in the direction shown, T_2 is greater than T_1. Denoting the larger tension by T_2, the smaller tension by T_1, the coefficient of static friction by μ_s, and the angle (in radius) subtended by the belt by β, the

following formulas can be derived

$$\ln \frac{T_2}{T_1} = \mu_s \beta \,, \tag{2.22}$$

$$\frac{T_2}{T_1} = e^{\mu_s \beta} \,. \tag{2.23}$$

If the belt actually slips on the drum, the coefficient of static friction μ_s should be replaced by the coefficient of kinetic friction μ_k in both of these formulas.

It is important to note that a coefficient of friction applies to a given pair of mating surfaces. It is meaningless to speak of a coefficient of friction for a single surface. Also friction coefficients vary considerably, depending on the exact condition of the mating surfaces.

2.1.8 Principle of Virtual Work

The principle of virtual work for a particle states that *if a particle is in equilibrium, the total virtual work done by the n applied forces during any arbitrary virtual displacement of the particle is zero*. This can easily be verified as follows.

Let the virtual displacement be $\delta \boldsymbol{r}$, then the virtual work done by any force $\boldsymbol{F}_i$ $(i = 1, 2, \ldots, n)$ is the product of the virtual displacement and the component of the force in the direction of the virtual displacement, thus

$$\begin{aligned} \delta U &= \boldsymbol{F}_1 \cdot \delta \boldsymbol{r} + \boldsymbol{F}_2 \cdot \delta \boldsymbol{r} + \cdots + \boldsymbol{F}_n \cdot \delta \boldsymbol{r} \\ &= \left(\sum \boldsymbol{F} \right) \cdot \delta \boldsymbol{r} \,. \end{aligned}$$

However, the equilibrium of these static forces requires that the sum of these forces in any direction be zero, hence

$$\delta U = 0 \,.$$

That is, the total virtual work done during any virtual displacement is zero.

In the case of a rigid body, the principle of virtual work states that: *if a rigid body is in equilibrium, the total virtual work of the external forces acting on the rigid body is zero for any virtual displacement of the body*.

The principle of virtual work can be extended to the case of a system of connected rigid bodies. If the system remains connected during a virtual displacement, only the work of the forces external to the system need be considered, since the total work of the internal forces at the various connections is zero.

2.2 Dynamics

Dynamic is one of the oldest branches of physics, with its development as a science beginning with Galileo about four centuries ago. His experiments on uniformly accelerated bodies led Newton to formulate his fundamental laws of motion. The study of dynamics of particles and rigid bodies as an engineering subject is not so old, perhaps going back to after World War II as a standard course in engineering curricula. An even later addition to engineering curricula is the study of vibrations, which can be regarded as the part of dynamics concerned with the motion of elastic systems.

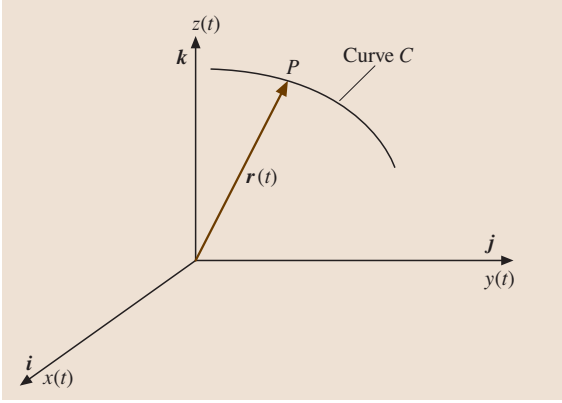

Fig. 2.17 The motion of a particle

The study of the motion of a body without regard to the forces and moments causing the motion is known as kinematics. One may think of kinematics as the geometry of motion. The material presented here is fundamental to the dynamics of systems of particles and rigid bodies [2.5–8].

2.2.1 Motion of a Particle

Motion Relative to a Fixed Frame

The position of a particle P in space is defined at any time t by the three Cartesian coordinates $x(t)$, $y(t)$, and $z(t)$. To describe the motion of a particle P along curve C in a three-dimensional space, as depicted in Fig. 2.17,

the position vector is expressed as

$$\boldsymbol{r}(t) = x(t)\boldsymbol{i} + y(t)\boldsymbol{j} + z(t)\boldsymbol{k} \,. \tag{2.24}$$

Velocity

The velocity of the particle P in space is defined as the time rate of change of the position. The velocity vector of P is written as

$$\begin{aligned}\boldsymbol{v}(t) &= \frac{\mathrm{d}\boldsymbol{r}(t)}{\mathrm{d}t} = \dot{x}(t)\boldsymbol{i} + \dot{y}(t)\boldsymbol{j} + \dot{z}(t)\boldsymbol{k} \\ &= v_x(t)\boldsymbol{i} + v_y(t)\boldsymbol{j} + v_z(t)\boldsymbol{k} \,,\end{aligned} \tag{2.25}$$

where

$$v_x(t) = \dot{x}(t) \,, \quad v_y(t) = \dot{y}(t) \,, \quad v_z(t) = \dot{z}(t) \tag{2.26}$$

are the Cartesian components of the velocity vector. From Fig. 2.17, as $\Delta t \to 0$, the increment $\Delta\boldsymbol{r}(t)$ in the position vector corresponding to the time increment aligns itself with the curve C and becomes the differential $\mathrm{d}\boldsymbol{r}(t)$. Hence, the velocity vector is tangent to the curve trajectory C at all time.

Acceleration

The acceleration of the particle P in space is defined as the time rate of change of the velocity. The acceleration vector of P is written as

$$\begin{aligned}\boldsymbol{a}(t) &= \frac{\mathrm{d}\boldsymbol{v}(t)}{\mathrm{d}t} = \dot{v}_x(t)\boldsymbol{i} + \dot{v}_y(t)\boldsymbol{j} + \dot{v}_z(t)\boldsymbol{k} \\ &= a_x(t)\boldsymbol{i} + a_y(t)\boldsymbol{j} + a_z(t)\boldsymbol{k} \,,\end{aligned} \tag{2.27}$$

where

$$\begin{aligned}&a_x(t) = \dot{v}_x(t) = \ddot{x}(t) \,, \quad a_y(t) = \dot{v}_y(t) = \ddot{y}(t) \,, \\ &a_z(t) = \dot{v}_z(t) = \ddot{z}(t)\end{aligned} \tag{2.28}$$

are the Cartesian components of the acceleration vector.

Rectilinear Motion

Rectilinear motion implies motion along a straight line. Since there is only one component of motion, we may dispense with the vector notation and describe the motion in terms of scalar quantities. Denoting the line along which the motion takes place by s and the distance of the particle P from the fixed origin 0 by $s(t)$ as depicted in Fig. 2.18, the velocity of P is written as

$$v(t) = \frac{\mathrm{d}s(t)}{\mathrm{d}t} = \dot{s}(t) \,. \tag{2.29}$$

The acceleration of P is written as

$$a(t) = \frac{\mathrm{d}v(t)}{\mathrm{d}t} = \frac{\mathrm{d}^2 s(t)}{\mathrm{d}t^2} = \ddot{s}(t) \,. \tag{2.30}$$

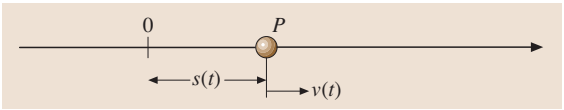

Fig. 2.18 Rectilinear motion

The distance $s(t)$, the velocity $v(t)$, the acceleration $a(t)$ are explicit function of t. However, one can derive a relation among s, v, and a in which the time t is only implicit.

Let us use the chain rule for differentiation and write

$$a = \frac{\mathrm{d}v}{\mathrm{d}t} = \frac{\mathrm{d}v}{\mathrm{d}s}\frac{\mathrm{d}s}{\mathrm{d}t} = \frac{\mathrm{d}v}{\mathrm{d}s}v \tag{2.31}$$

or

$$a\,\mathrm{d}s = v\,\mathrm{d}v \,. \tag{2.32}$$

Integrating (2.32) between the points $s = s_1$, $v = v_1$ and $s = s_2$, $v = v_2$, we obtain

$$\int_{s_1}^{s_2} a\,\mathrm{d}s = \int_{v_1}^{v_2} v\,\mathrm{d}v = \frac{1}{2}\left(v_2^2 - v_1^2\right) . \tag{2.33}$$

Uniform Motion

In this case, $v(t) = v_0$= constant. By integration, it follows that

$$s(t) = \int v\,\mathrm{d}t = v_0 t + C_1 \,. \tag{2.34}$$

With the initial condition, $s(t = t_1) = s_1$, from this $C_1 = s_1 - v_0 t_1$, therefore,

$$s(t) = v_0(t - t_1) + s_1 \,. \tag{2.35}$$

Uniform Accelerated Motion

In this case, $a(t) = a_0 =$ constant. By integration, it follows that

$$v(t) = \int a\,\mathrm{d}t = a_0 t + C_1 \tag{2.36}$$

or

$$s(t) = \int v\,\mathrm{d}t = a_0\frac{t^2}{2} + C_1 t + C_2 \,. \tag{2.37}$$

With the initial condition, $v(t = t_1) = v_1$, and $s(t = t_1) = s_1$, the constants follow: $C_1 = v_1 - a_0 t_1$ and $C_2 = s_1 - v_1 t_1 + a_0 t_1^2/2$ and therefore

$$s(t) = a_0\frac{(t - t_1)^2}{2} + v_1(t - t_1) + s_1 \,. \tag{2.38}$$

Example 2.1: A car starting from rest travels with constant acceleration a_0 for 10 s. Determine the value a_0 given that the car has reached a velocity of 108 km/h at the end of the 5 s. What is the distance traveled by the car?

$$v(t) = a_0 t$$

$$a_0 = \left.\frac{v(t)}{5}\right|_{t=5} = \frac{108(1000)/3600}{5} = 6\,\mathrm{m/s^2}$$

$$s = \frac{1}{2}a_0 t^2 = \frac{1}{2}6(5)^2 = 75\,\mathrm{m}$$

Nonuniform Accelerated Motion

In this case, $a(t) = f_0(t)$. By integration, it follows that

$$v(t) = \int a(t)\,\mathrm{d}t = \int f_0(t)\,\mathrm{d}t = f_1(t) + C_1 \qquad (2.39)$$

or

$$s(t) = \int v(t)\,\mathrm{d}t = \int [f_1(t) + C_1]\,\mathrm{d}t$$

$$= f_2(t) + C_1 t + C_2\,. \qquad (2.40)$$

The constants are determined from the initial conditions or equivalent conditions.

2.2.2 Planar Motion, Trajectories

Consider a particle traveling in the xz plane with constant acceleration (gravity) $\ddot{z} = -g$ after the initial velocity v_0 as shown in Fig. 2.19. Let v_0 be the magnitude of the initial velocity and α the angle between v_0 and the x-axis; the velocity of the particle at time t in Cartesian components is

$$\boldsymbol{v} = v_0 \cos\alpha\,\boldsymbol{i} + (v_0 \sin\alpha - gt)\boldsymbol{k}\,. \qquad (2.41)$$

The trajectory of the particle at time t in Cartesian components is

$$x = v_0 t \cos\alpha\,, \quad z = v_0 t \sin\alpha - \frac{1}{2}gt^2\,, \qquad (2.42)$$

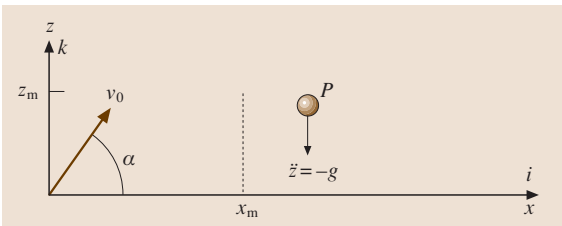

Fig. 2.19 Planar motion

from which the travel time and trajectory can then computed as

$$t = \frac{x}{v_0 \cos\alpha}\,, \quad z = x\tan\alpha - \frac{1}{2}\frac{gx^2}{v_0^2\cos^2\alpha}\,. \qquad (2.43)$$

This trajectory represents a parabola. To determine its shape, its maximum altitude is calculated by locating the point with zero slope

$$\frac{\mathrm{d}z}{\mathrm{d}x} = \tan\alpha - \frac{gx}{v_0^2\cos^2\alpha} = 0\,. \qquad (2.44)$$

Let x_m be the distance along the x-axis corresponding to the maximum altitude z_m; one obtains

$$x_m = \frac{v_0^2 \sin\alpha\cos\alpha}{g}\,. \qquad (2.45)$$

The maximum altitude z_m is

$$z_m = \frac{v_0^2}{2g}\sin^2\alpha\,. \qquad (2.46)$$

The trajectory is symmetrical with respect to the vertical through x_m, as shown in Fig. 2.19. One concludes that the particle hits the ground at $x_f = 2x_m$. The final velocity $\boldsymbol{v}_f$ in Cartesian component is

$$v_x = v_0\cos\alpha\,, \quad v_z = -v_0\sin\alpha\,. \qquad (2.47)$$

2.2.3 Polar Coordinates

Consider a particle traveling along curve C as shown in Fig. 2.20. In polar coordinates, one defines the radial axis r as the axes coinciding at all times with the direction of the radius vector $\boldsymbol{r}(t)$ from the origin O to the point P. The transverse axis θ is normal to the radial axis as shown in Fig. 2.20. The unit vectors $\boldsymbol{u}_r(t)$

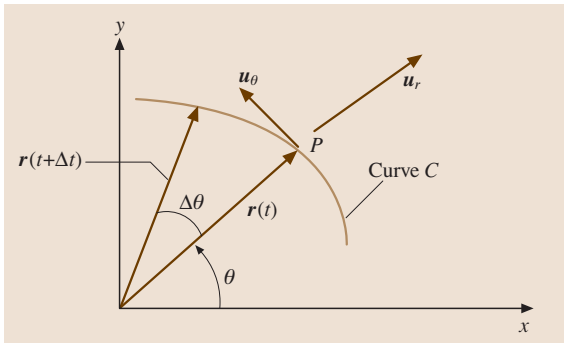

Fig. 2.20 Polar coordinates

and $\boldsymbol{u}_\theta(t)$, representing the radial and transverse directions, are functions of time. This can be explained by observing that the radius vector $\boldsymbol{r}(t)$ changes directions continuously as the particle moves along the curve C. Because the unit vector $\boldsymbol{u}_r(t)$ is aligned with $\boldsymbol{r}(t)$, $\boldsymbol{u}_r(t)$ also changes direction continuously. Because $\boldsymbol{u}_\theta(t)$ is normal to $\boldsymbol{u}_r(t)$, $\boldsymbol{u}_\theta(t)$ is also a time-dependent unit vector.

The location of the particle P is expressed as

$$\boldsymbol{r}(t) = r(t)\boldsymbol{u}_r(t) \tag{2.48}$$

and the velocity of P is

$$\boldsymbol{v}(t) = \dot{\boldsymbol{r}}(t) = \dot{r}(t)\boldsymbol{u}_r(t) + r(t)\dot{\boldsymbol{u}}_r(t)\,. \tag{2.49}$$

From Fig. 2.21, it follows that

$$\begin{aligned}\dot{\boldsymbol{u}}_r(t) &= \lim_{\Delta t\to 0}\frac{\Delta \boldsymbol{u}_r(t)}{\Delta t} = \lim_{\Delta t\to 0}\frac{\Delta\theta(t)}{\Delta t}\boldsymbol{u}_\theta(t)\\ &= \dot{\theta}(t)\boldsymbol{u}_\theta(t)\end{aligned} \tag{2.50}$$

$$\begin{aligned}\dot{\boldsymbol{u}}_\theta(t) &= \lim_{\Delta t\to 0}\frac{\Delta \boldsymbol{u}_\theta(t)}{\Delta t} = \lim_{\Delta t\to 0}\frac{\Delta\theta(t)}{\Delta t}[-\boldsymbol{u}_r(t)]\\ &= -\dot{\theta}(t)\boldsymbol{u}_r(t)\,.\end{aligned} \tag{2.51}$$

The velocity of P is rewritten as

$$\begin{aligned}\boldsymbol{v}(t) &= \dot{\boldsymbol{r}}(t) = \dot{r}(t)\boldsymbol{u}_r(t) + r(t)\dot{\boldsymbol{u}}_r(t)\\ &= v_r\boldsymbol{u}_r(t) + v_\theta\boldsymbol{u}_\theta(t)\,,\end{aligned} \tag{2.52}$$

where $v_r = \dot{r}$ and $v_\theta = r\dot{\theta}$ are the radial and transverse components of the velocity vector, respectively.

Similarly, the acceleration of point P is

$$\begin{aligned}\boldsymbol{a}(t) &= \dot{\boldsymbol{v}}(t) = \ddot{\boldsymbol{r}}(t)\\ &= \ddot{r}\boldsymbol{u}_r(t) + \dot{r}(t)\dot{\boldsymbol{u}}_r(t) + \dot{r}\dot{\theta}\boldsymbol{u}_\theta + r\ddot{\theta}\boldsymbol{u}_\theta + r\dot{\theta}\dot{\boldsymbol{u}}_\theta\\ &= (\ddot{r} - r\,\dot{\theta}^2)\boldsymbol{u}_r + (r\ddot{\theta} + 2\dot{r}\dot{\theta})\boldsymbol{u}_\theta = a_r\boldsymbol{u}_r + a_\theta\boldsymbol{u}_\theta\,,\end{aligned} \tag{2.53a}$$

where

$$a_r = \ddot{r} - r\dot{\theta}^2 \quad \text{and} \quad a_\theta = r\ddot{\theta} + 2\dot{r}\dot{\theta} \tag{2.53b}$$

are the radial and transverse components of the acceleration vector, respectively.

It should be noted that, by adding the coordinate z to the polar coordinates r and θ, one obtains the cylindrical coordinates, r, θ, z. The velocity and acceleration vectors can be expressed in terms of cylindrical coordinates as

$$\boldsymbol{v}(t) = v_r\boldsymbol{u}_r + v_\theta\boldsymbol{u}_\theta + v_z\boldsymbol{k}\,, \tag{2.54}$$

where $v_z = \dot{z}$,

$$\boldsymbol{a}(t) = a_r\boldsymbol{u}_r + a_\theta\boldsymbol{u}_\theta + a_z\boldsymbol{k}\,, \tag{2.55}$$

and $a_z = \ddot{z}$.

Example 2.2: A bicycler enters a semicircular track of radius $r = 60\,\mathrm{m}$, as shown in Fig. 2.22, with velocity $v_\mathrm{A} = 18\,\mathrm{m/s}$, decelerates at a uniform rate, and exits with velocity $v_\mathrm{C} = 12\,\mathrm{m/s}$. Find the circumferential deceleration, the time it takes to complete the semicircle, and the velocity at point B.

Denote the magnitude of the circumferential deceleration as follows

$$a_\theta = r\ddot{\theta}\,. \tag{2.56a}$$

Integrating (2.56a) with respect to time yields

$$v_\theta = r\dot{\theta} = v_\mathrm{A} + a_\theta t\,. \tag{2.56b}$$

Letting $t = t_\mathrm{f}$ and $v_\theta = v_\mathrm{C}$ in (2.56b), one can write

$$a_\theta t_\mathrm{f} = v_\mathrm{C} - v_\mathrm{A} = 12 - 18 = -6\,\mathrm{m/s}\,. \tag{2.56c}$$

Integrating (2.56b) with respect to time, one obtains

$$r\theta = v_\mathrm{A}t + \frac{1}{2}a_\theta t^2\,. \tag{2.56d}$$

Inserting $t = t_\mathrm{f}$, $a_\theta t_\mathrm{f} = -6$, and $\theta_\mathrm{f} = \pi$ in (2.56d) yields

$$t_\mathrm{f} = \frac{r\theta_\mathrm{f}}{v_\mathrm{A} + \frac{1}{2}a_\theta t_\mathrm{f}} = \frac{60(\pi)}{18 + \frac{1}{2}(-6)} = 4\pi\,\mathrm{s} \tag{2.56e}$$

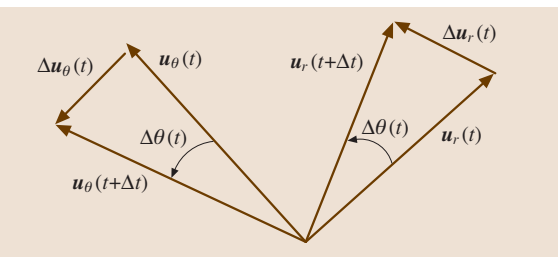

Fig. 2.21 Motion in polar coordinates

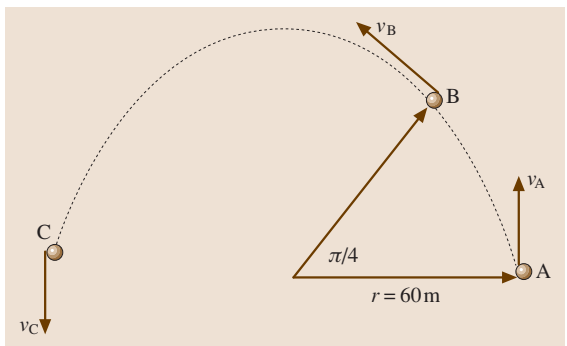

Fig. 2.22 A bicycler in the semicircular track

and

$$a_\theta = \frac{-6}{4\pi}\,\mathrm{m/s^2}\,. \tag{2.56f}$$

To obtain v_B, we use

$$a_\theta s_{AB} = \frac{1}{2}\left(v_B^2 - v_A^2\right) \tag{2.56g}$$

so that

$$v_B = \sqrt{v_A^2 + 2a_\theta s_{AB}} = \sqrt{18^2 + 2\left(\frac{-6}{4\pi}\right)\left(\frac{60\pi}{4}\right)}$$
$$= 16.7\,\mathrm{m/s}\,. \tag{2.56h}$$

2.2.4 Motion of Rigid Bodies (Moving Reference Frames)

Consider a reference frame xyz moving relative to the fixed reference frame XYZ as shown in Fig. 2.23. A point P relative to the system XYZ is expressed as

$$\boldsymbol{R} = \boldsymbol{r}_A + \boldsymbol{r}_{AP}\,. \tag{2.57}$$

The velocity of P relative to an inertial space is

$$\boldsymbol{v} = \dot{\boldsymbol{R}} = \boldsymbol{v}_A + \boldsymbol{v}_{AP}\,, \tag{2.58}$$

where

$$\boldsymbol{v}_A = \dot{\boldsymbol{r}}_A \quad \text{and} \quad \boldsymbol{v}_{AP} = \dot{\boldsymbol{r}}_{AP}\,. \tag{2.59}$$

Similarly, the acceleration of P relative to an inertial space is

$$\boldsymbol{a} = \dot{\boldsymbol{v}} = \ddot{\boldsymbol{R}} = \boldsymbol{a}_A + \boldsymbol{a}_{AP}\,, \tag{2.60}$$

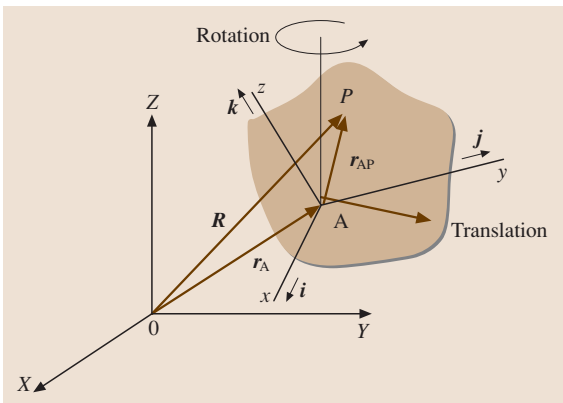

Fig. 2.23 Moving reference frame

where

$$\boldsymbol{a}_A = \dot{\boldsymbol{v}}_A = \ddot{\boldsymbol{r}}_A \quad \text{and} \quad \boldsymbol{a}_{AP} = \dot{\boldsymbol{v}}_{AP} = \ddot{\boldsymbol{r}}_{AP}\,. \tag{2.61}$$

Rotating Reference Frames

Assume that the rigid body is rotating about the axis AB, and consider a point P at a distance $d = |\boldsymbol{d}|$ from point C on axis AB, where C is the intersection between the axis AB and a plane normal to AB that contains the point P, as shown in Fig. 2.24. In the time increment Δt the vector $\boldsymbol{d}$ from C to P sweeps an angle $\Delta\theta$ in a plane normal to AB. The vector $\boldsymbol{d}$ rotates in a plane normal to the axis AB with the angular rate $\dot{\theta}$. Because the vector $\boldsymbol{d}$ is embedded in the rigid body, we say that the rigid body and the triad xyz rotate about the axis AB at the same rate $\dot{\theta}$. This angular rate is represented as a vector, ω, and is directed along the axis AB. Note that ω can be used to represent the angular velocity of the rigid body, or of the frame xyz, with units of radians per second (rad/s). We write

$$\lim_{\Delta t \to 0} \frac{\Delta\theta}{\Delta t} = \dot{\theta} = |\boldsymbol{\omega}|\,. \tag{2.62}$$

Consider the rate of change $\dot{\boldsymbol{d}}$ of the vector $\boldsymbol{d}$ due to the rotation of the body. From Fig. 2.24, we observe that the tip P of the vector $\boldsymbol{d}$ describes a circle of radius d, so that $\dot{\boldsymbol{d}}$ is tangent to the circle at P and is normal to the plane defined by the vectors $\boldsymbol{\omega}$ and $\boldsymbol{d}$. In the time increment Δt, the vector $\boldsymbol{d}$ makes the change in magnitude

$$\Delta d = d\Delta\theta \tag{2.63}$$

and

$$\dot{d} = \lim_{\Delta t \to 0} \frac{\Delta d}{\Delta t} = d\dot{\theta}\,. \tag{2.64}$$

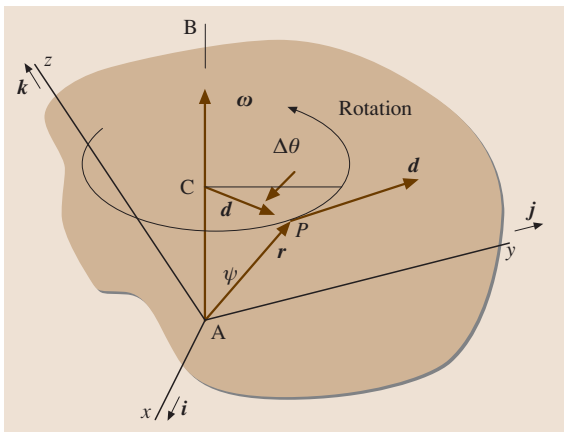

Fig. 2.24 Rotating rigid body

In vector, one has

$$\dot{\boldsymbol{d}} = \boldsymbol{\omega} \times \boldsymbol{d} \,. \tag{2.65}$$

One can generalize the above equation by observing that

$$d = r \, \sin\psi \,, \tag{2.66}$$

where r is the magnitude of the vector $\boldsymbol{r}$ and ψ is the angle between AB and $\boldsymbol{r}$. Hence the rate of change of the vector $\boldsymbol{r}$ is

$$\dot{\boldsymbol{r}} = \boldsymbol{\omega} \times \boldsymbol{r} \,. \tag{2.67}$$

The velocity of point P relative to point A is due entirely to the rotation of the frame xyz. Replacing the vector $\boldsymbol{r}$ by the radius vector $\boldsymbol{r}_{\mathrm{AP}}$, yields

$$\boldsymbol{v}_{\mathrm{AP}} = \dot{\boldsymbol{r}}_{\mathrm{AP}} = \boldsymbol{\omega} \times \boldsymbol{r}_{\mathrm{AP}} \,. \tag{2.68}$$

Because point A is at rest, $\boldsymbol{v}_{\mathrm{AP}}$ is also the absolute velocity of P, $\boldsymbol{v} = \boldsymbol{v}_{\mathrm{AP}}$. The time rate of change of $\boldsymbol{\omega}$ is referred as the angular acceleration with units of rad/s^2

$$\boldsymbol{\alpha} = \dot{\boldsymbol{\omega}} \,. \tag{2.69}$$

The acceleration of point P relative to point A is

$$\begin{aligned} \boldsymbol{a}_{\mathrm{AP}} &= \dot{\boldsymbol{v}}_{\mathrm{AP}} = \dot{\boldsymbol{\omega}} \times \boldsymbol{r}_{\mathrm{AP}} + \boldsymbol{\omega} \times \dot{\boldsymbol{r}}_{\mathrm{AP}} \\ &= \boldsymbol{\alpha} \times \boldsymbol{r}_{\mathrm{AP}} + \boldsymbol{\omega} \times (\boldsymbol{\omega} \times \boldsymbol{r}_{\mathrm{AP}}) \,. \end{aligned} \tag{2.70}$$

Because point A is at rest, $\boldsymbol{a}_{\mathrm{AP}}$ is also the absolute acceleration of P, $\boldsymbol{a} = \boldsymbol{a}_{\mathrm{AP}}$.

When the origin A of the rotating frame xyz is not fixed, but moves relative to the inertial frame XYZ with the velocity $\boldsymbol{v}_{\mathrm{A}}$ and acceleration $\boldsymbol{a}_{\mathrm{A}}$, then the absolute velocity and acceleration of P are

$$\boldsymbol{v} = \boldsymbol{v}_{\mathrm{A}} + \boldsymbol{v}_{\mathrm{AP}} = \boldsymbol{v}_{\mathrm{A}} + \boldsymbol{\omega} \times \boldsymbol{r}_{\mathrm{AP}} \,, \tag{2.71}$$

$$\boldsymbol{a} = \boldsymbol{a}_{\mathrm{A}} + \boldsymbol{a}_{\mathrm{AP}} = \boldsymbol{a}_{\mathrm{A}} + \boldsymbol{\alpha} \times \boldsymbol{r}_{\mathrm{AP}} + \boldsymbol{\omega} \times (\boldsymbol{\omega} \times \boldsymbol{r}_{\mathrm{AP}}) \,. \tag{2.72}$$

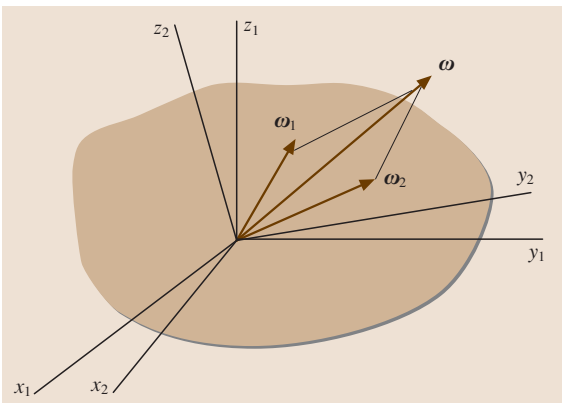

Fig. 2.25 Rotating frame

Consider the case in which the reference frame $x_1y_1z_1$ rotates with angular velocity $\boldsymbol{\omega}_1$ and the reference frame $x_2y_2z_2$ rotates relative to the frame $x_1y_1z_1$ with angular velocity $\boldsymbol{\omega}_2$, as shown in Fig. 2.25. The angular velocity of the frame $x_2y_2z_2$ is simply

$$\boldsymbol{\omega} = \boldsymbol{\omega}_1 + \boldsymbol{\omega}_2 \,. \tag{2.73}$$

Let us assume that the vector $\boldsymbol{\omega}$ is expressed in terms of components along the frame $x_1y_1z_1$; the angular acceleration then consists of two parts: the first due to the change in the component of $\boldsymbol{\omega}$ relative to the frame $x_1y_1z_1$ and the second due to the fact that $\boldsymbol{\omega}$ is expressed in terms of components along a rotating frame. Denoting the first part by $\boldsymbol{\alpha}'$ and noting that the second part can be obtained from (2.67), by replacing $\boldsymbol{r}$ by $\boldsymbol{\omega}$ and $\boldsymbol{\omega}$ by $\boldsymbol{\omega}_1$, yields

$$\boldsymbol{\alpha} = \dot{\boldsymbol{\omega}} = \boldsymbol{\alpha}' + \boldsymbol{\omega}_1 \times \boldsymbol{\omega} = \boldsymbol{\alpha}' + \boldsymbol{\omega}_1 \times \boldsymbol{\omega}_2 \,. \tag{2.74}$$

Example 2.3: A bicycle travels on a circular track of radius R with the circumferential velocity $\boldsymbol{v}_{\mathrm{A}}$ and acceleration $\boldsymbol{a}_{\mathrm{A}}$. Figure 2.26 shows one of the bicycle wheels rotating on the vertical $\boldsymbol{jk}$ plane. The radius of the wheel is r. Determine the velocity $\boldsymbol{v}$ and acceleration $\boldsymbol{a}$ of a point P on the tire when the radius from the center of the wheel at the point P makes an angle θ with respect to the horizontal plane.

Two reference frames are employed. The frame $x_1y_1z_1$ is attached to the bicycle, and the frame $x_2y_2z_2$ is attached to the wheel. The two frames coincide instantaneously, although the frame $x_2y_2z_2$ rotates relative to the frame $x_1y_1z_1$.

The velocity of the wheel center is

$$\boldsymbol{v}_{\mathrm{A}} = -v_{\mathrm{A}}\boldsymbol{j} \,. \tag{2.75a}$$

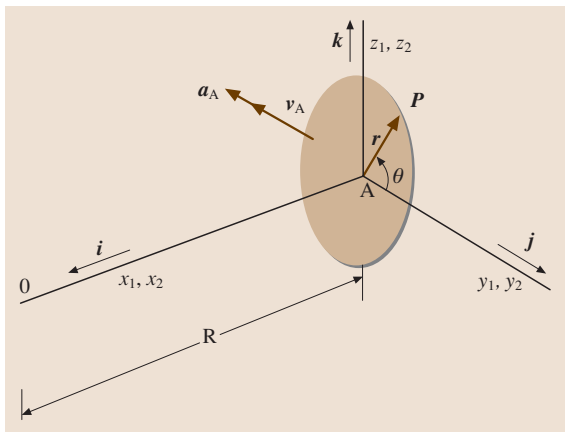

Fig. 2.26 Bicycle wheel

and the angular velocity of the frame $x_1y_1z_1$ is

$$\boldsymbol{\omega}_1 = \frac{v_A}{R}\boldsymbol{k}\,. \tag{2.75b}$$

The angular velocity of the frame $x_2y_2z_2$ relative to $x_1y_1z_1$ is

$$\boldsymbol{\omega}_2 = \frac{v_A}{r}\boldsymbol{i}\,. \tag{2.75c}$$

So, the absolute angular velocity of the frame $x_2y_2z_2$ is

$$\boldsymbol{\omega} = \boldsymbol{\omega}_1 + \boldsymbol{\omega}_2 = \frac{v_A}{R}\boldsymbol{k} + \frac{v_A}{r}\boldsymbol{i}\,. \tag{2.75d}$$

The radius vector from A to P is

$$\boldsymbol{r}_{AP} = r(\cos\theta\boldsymbol{j} + \sin\theta\boldsymbol{k})\,. \tag{2.75e}$$

The velocity of P becomes

$$\begin{aligned}\boldsymbol{v} &= v_A + \boldsymbol{\omega}\times\boldsymbol{r}_{AP}\\ &= -v_A\boldsymbol{j} + \left(\frac{v_A}{r}\boldsymbol{i} + \frac{v_A}{R}\boldsymbol{k}\right)\times r(\cos\theta\boldsymbol{j} + \sin\theta\boldsymbol{k})\\ &= -\frac{v_A r}{R}\cos\theta\boldsymbol{i} - v_A(1+\sin\theta)\boldsymbol{j} + v_A\cos\theta\boldsymbol{k}\,.\end{aligned} \tag{2.75f}$$

The acceleration of A has two components: a tangential component due to the acceleration of the bicycle along the track and a normal component due to motion along a curvilinear track. Therefore,

$$\begin{aligned}a_A &= -a_A\boldsymbol{j} + \boldsymbol{\omega}_1\times(\boldsymbol{\omega}_1\times\boldsymbol{r}_{0A})\\ &= -a_A\boldsymbol{j} + \frac{v_A}{R}\boldsymbol{k}\times\left[\frac{v_A}{R}\boldsymbol{k}\times(-R)\boldsymbol{i}\right]\\ &= \frac{v_A^2}{R}\boldsymbol{i} - a_A\boldsymbol{j}\,.\end{aligned} \tag{2.75g}$$

Using (2.74), the angular acceleration of the frame $x_2y_2z_2$ is

$$\begin{aligned}\boldsymbol{\alpha} &= \dot{\boldsymbol{\omega}}_1 + \dot{\boldsymbol{\omega}}_2 + \boldsymbol{\omega}_1\times\boldsymbol{\omega}_2\\ &= \frac{a_A}{R}\boldsymbol{k} + \frac{a_A}{r}\boldsymbol{i} + \frac{v_A}{R}\boldsymbol{k}\times\frac{v_A}{r}\boldsymbol{i}\\ &= \frac{a_A}{r}\boldsymbol{i} + \frac{v_A^2}{rR}\boldsymbol{j} + \frac{a_A}{R}\boldsymbol{k}\,.\end{aligned} \tag{2.75h}$$

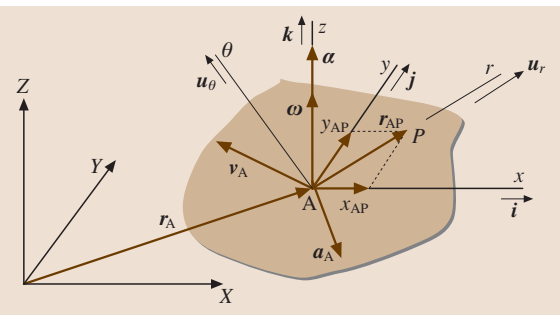

Fig. 2.27 Rigid body motion in a plane

Finally, the acceleration of P is

$$\begin{aligned}\boldsymbol{a} &= \boldsymbol{a}_A + \boldsymbol{\alpha}\times\boldsymbol{r}_{AP} + \boldsymbol{\omega}\times(\boldsymbol{\omega}\times\boldsymbol{r}_{AP})\\ &= \frac{v_A^2}{R}\boldsymbol{i} - a_A\boldsymbol{j} + \left(\frac{a_A}{r}\boldsymbol{i} + \frac{v_A^2}{rR}\boldsymbol{j} + \frac{a_A}{R}\boldsymbol{k}\right)\\ &\quad\times r(\cos\theta\boldsymbol{j} + \sin\theta\boldsymbol{k}) + \left(\frac{v_A}{r}\boldsymbol{i} + \frac{v_A}{R}\boldsymbol{k}\right)\\ &\quad\times\left[\left(\frac{v_A}{r}\boldsymbol{i} + \frac{v_A}{R}\boldsymbol{k}\right)\times r(\cos\theta\boldsymbol{j} + \sin\theta\boldsymbol{k})\right]\\ &= \left[\frac{v_A^2}{R}(1+2\sin\theta) - \frac{ra_A}{R}\cos\theta\right]\boldsymbol{i}\\ &\quad - \left[\left(\frac{1}{r} + \frac{r}{R^2}\right)v_A^2\cos\theta + a_A + a_A\sin\theta\right]\boldsymbol{j}\\ &\quad - \left(\frac{v_A^2}{r}\sin\theta - a_A\cos\theta\right)\boldsymbol{k}\,.\end{aligned} \tag{2.75i}$$

2.2.5 Planar Motion of a Rigid Body

A body has three degrees of motion in planar motion: two of translation (displacement in the x- and y-directions) and one of rotation (rotation about the z-axis) as shown in Fig. 2.27. The radius vector $\boldsymbol{r}_{AP}$ is written as

$$\boldsymbol{r}_{AP} = x_{AP}\boldsymbol{i} + y_{AP}\boldsymbol{j}\,. \tag{2.76}$$

The angular velocity and acceleration of point P are

$$\boldsymbol{\omega} = \omega\boldsymbol{k}\,, \quad \boldsymbol{\alpha} = \alpha k\,, \tag{2.77}$$

respectively. The velocity of point P is

$$\begin{aligned}\boldsymbol{v} &= \boldsymbol{v}_A + \boldsymbol{\omega}\times\boldsymbol{r}_{AP} = \boldsymbol{v}_A + \omega\boldsymbol{k}\times(x_{AP}\boldsymbol{i} + y_{AP}\boldsymbol{j})\\ &= \boldsymbol{v}_A - \omega y_{AP}\boldsymbol{i} + \omega x_{AP}\boldsymbol{j}\,.\end{aligned} \tag{2.78}$$

and the acceleration of point P is

$$\begin{aligned}\boldsymbol{a} &= \boldsymbol{a}_A + \alpha\times\boldsymbol{r}_{AP} + \boldsymbol{\omega}\times(\boldsymbol{\omega}\times\boldsymbol{r}_{AP})\\ &= a_A + \alpha\boldsymbol{k}\times(x_{AP}\boldsymbol{i} + y_{AP}\boldsymbol{j})\\ &\quad + \omega\boldsymbol{k}\times[\omega\boldsymbol{k}\times(x_{AP}\boldsymbol{i} + y_{AP}\boldsymbol{j})]\\ &= \boldsymbol{a}_A - \alpha(y_{AP}\boldsymbol{i} - x_{AP}\boldsymbol{j}) - \omega^2\boldsymbol{r}_{AP}\,.\end{aligned} \tag{2.79}$$

The motion can also be expressed in terms of radial and transverse components. The radius vector is

$$\boldsymbol{r}_{AP} = r_{AP}\boldsymbol{u}_r\,, \tag{2.80}$$

where $\boldsymbol{u}_r$ is the unit vector in the radial direction. The velocity of point P is

$$\boldsymbol{v} = \boldsymbol{v}_A + \omega r_{AP}\boldsymbol{u}_\theta\,, \tag{2.81}$$

where $\boldsymbol{u}_\theta$ is the unit vector in the transverse direction. The acceleration of point P is

$$\begin{aligned}\boldsymbol{a} &= \boldsymbol{a}_\mathrm{A} + \alpha r_\mathrm{AP}\boldsymbol{u}_\theta - \omega^2 \boldsymbol{r}_\mathrm{AP} \\ &= \boldsymbol{a}_\mathrm{A} + \alpha r_\mathrm{AP}\boldsymbol{u}_\theta - \omega^2 r_\mathrm{AP}\boldsymbol{u}_\mathrm{r} \,. \end{aligned} \tag{2.82}$$

Equation (2.78) consists of two terms. The first term represents the velocity of translation of a reference point A. The second term represents the velocity due to rotation about A. There exists a point C such that the velocity of P can be regarded instantaneously as due entirely to rotation about C. It follows that the point C is instantaneously at rest. The point C is the *instantaneously center of rotation*. Point C may lie inside or outside the body. If both the magnitude and direction of the velocity vector are known, and the angular velocity is also given, then the instantaneously center can be determined by a graphical approach. Figure 2.28 depicts the rigid body and the velocity at point P. The velocity vector can be written

$$\boldsymbol{v} = \boldsymbol{\omega}\times\boldsymbol{r} = \omega\boldsymbol{k}\times r\boldsymbol{u}_r = \omega r\boldsymbol{u}_\theta = v\boldsymbol{u}_\theta \,. \tag{2.83}$$

The radius vector $\boldsymbol{r}$ is normal to the velocity vector $\boldsymbol{v}$, and the angular velocity ω is in the counterclockwise direction as shown in Fig. 2.28. The magnitude of the radius vector is

$$r = \frac{v}{\omega} \,. \tag{2.84}$$

The instantaneously center of rotation describes the *space centrode* during motion in relation to a coordinate system fixed in space and in relation to a fixed-body coordinate system of the *body centrode*. During motion, the body centrode rolls on the space centrode.

Example 2.4: A slipping bar of length $L = 20\,\mathrm{m}$ is depicted in Fig. 2.29. The velocity of the point A has magnitude $v_\mathrm{A} = 40\,\mathrm{m/s}$ when the angle between the bar and the wall is $\theta = 30°$; determine the angular velocity of the bar and the velocity of the point B and plot the body and space centrodes.

The instantaneously center of rotation lies at the intersection of the normal to the wall at A and the normal to the floor at the point B. From Fig. 2.29, one has

$$\begin{aligned} r_\mathrm{A} &= L\sin\theta = 10\,\mathrm{m} \,, \\ r_\mathrm{B} &= L\cos\theta = 17.32\,\mathrm{m} \,. \end{aligned} \tag{2.85}$$

The velocity vector $\boldsymbol{v}_\mathrm{A}$ is in the negative y-direction and the angular velocity in the counterclockwise direction is

$$\omega = \frac{v_\mathrm{A}}{r_\mathrm{A}} = 4\,\mathrm{rad/s} \,. \tag{2.86}$$

The velocity vector $\boldsymbol{v}_\mathrm{B}$ is in the x-direction and its magnitude is

$$v_\mathrm{B} = \omega r_\mathrm{B} = 69.28\,\mathrm{m/s} \,. \tag{2.87}$$

The points A, 0, B, and C are the corners of a rectangular with diagonals equal to L, as shown in Fig. 2.29. Point C is always at a distance L from 0. Therefore, the space centrode is one quarter of a circle with radius L and the center at 0, as depicted by the solid line in Fig. 2.29. At the same time, the velocity vectors $\boldsymbol{v}_\mathrm{A}$ and $\boldsymbol{v}_\mathrm{B}$ make a 90° angle at C. The body centrode is the

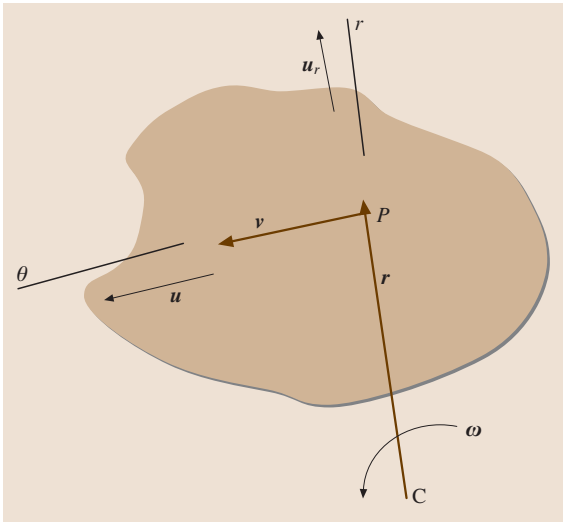

Fig. 2.28 Rigid body and the velocity vector

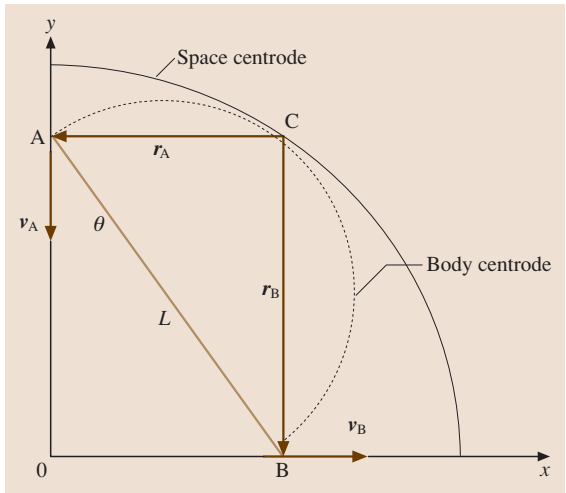

Fig. 2.29 A sliding rod

locus of the point C that is a semicircle as depicted by the dashed line in Fig. 2.29. As the bar slides, the body centrode rolls on the space centrode.

2.2.6 General Case of Motion

Consider the case that the particle P is no longer at rest relative to the moving frame xyz, but can move relative to that frame as depicted in Fig. 2.30. Given an arbitrary vector $\boldsymbol{r}$

$$\boldsymbol{r} = x\boldsymbol{i} + y\boldsymbol{j} + z\boldsymbol{k} \,, \tag{2.88}$$

where x, y, and z are the Cartesian components of the vector and $\boldsymbol{i}$, $\boldsymbol{j}$, and $\boldsymbol{k}$ are the unit vectors along these axes. The unit vectors $\boldsymbol{i}$, $\boldsymbol{j}$, and $\boldsymbol{k}$ rotate with the same angular velocity ω as the moving frame. Hence, from (2.67), we have

$$\begin{aligned}\dot{\boldsymbol{r}} &= \dot{x}\boldsymbol{i} + \dot{y}\boldsymbol{j} + \dot{z}\boldsymbol{k} + x\dot{\boldsymbol{i}} + y\dot{\boldsymbol{j}} + z\dot{\boldsymbol{k}} \\ &= \dot{x}\boldsymbol{i} + \dot{y}\boldsymbol{j} + \dot{z}\boldsymbol{k} + \boldsymbol{\omega}\times(x\boldsymbol{i} + y\boldsymbol{j} + z\boldsymbol{k}) \\ &= \dot{\boldsymbol{r}}' + \boldsymbol{\omega}\times\boldsymbol{r} \,,\end{aligned} \tag{2.89}$$

where

$$\dot{\boldsymbol{r}}' = \dot{x}\boldsymbol{i} + \dot{y}\boldsymbol{j} + \dot{z}\boldsymbol{k} \tag{2.90}$$

is the time rate of change of $\boldsymbol{r}$ regarding the reference frame xyz as inertial.

The position vector of point P as depicted in Fig. 2.30 is

$$\boldsymbol{R} = \boldsymbol{r}_\mathrm{A} + \boldsymbol{r}_\mathrm{AP} \,. \tag{2.91}$$

The absolute velocity of P is

$$\boldsymbol{v} = \dot{\boldsymbol{R}} = \dot{\boldsymbol{r}}_\mathrm{A} + \dot{\boldsymbol{r}}_\mathrm{AP} = \boldsymbol{v}_\mathrm{A} + \boldsymbol{v}'_\mathrm{AP} + \boldsymbol{\omega}\times\boldsymbol{r}_\mathrm{AP} \,, \tag{2.92}$$

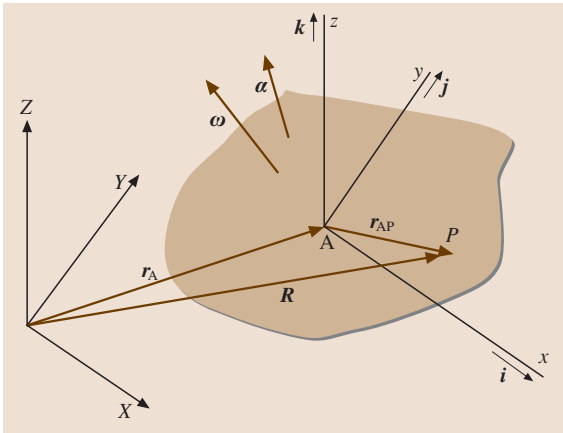

Fig. 2.30 General motion

where $\boldsymbol{v}_\mathrm{A}$ is the velocity of point A relative to the inertial space, and

$$\boldsymbol{v}'_\mathrm{AP} = \dot{x}_\mathrm{AP}\boldsymbol{i} + \dot{y}_\mathrm{AP}\boldsymbol{j} + \dot{z}_\mathrm{AP}\boldsymbol{k} \tag{2.93}$$

is the velocity of P relative to the moving frame xyz, where x_AP, y_AP, and z_AP are the Cartesian components of $\boldsymbol{r}_\mathrm{AP}$, and $\omega\times\boldsymbol{r}_\mathrm{AP}$ is the velocity of P entirely due to the rotation of the frame xyz. Similarly, the absolute acceleration of P is

$$\begin{aligned}\boldsymbol{a} = \dot{\boldsymbol{v}} &= \dot{\boldsymbol{v}}_\mathrm{A} + \frac{\mathrm{d}}{\mathrm{d}t}\boldsymbol{v}'_\mathrm{AP} + \dot{\boldsymbol{\omega}}\times\boldsymbol{r}_\mathrm{AP} + \boldsymbol{\omega}\times\dot{\boldsymbol{r}}_\mathrm{AP} \\ &= \boldsymbol{a}_\mathrm{A} + \boldsymbol{a}'_\mathrm{AP} + \boldsymbol{\omega}\times\boldsymbol{v}'_\mathrm{AP} + \boldsymbol{\alpha}\times\boldsymbol{r}_\mathrm{AP} + \boldsymbol{\omega}\times\boldsymbol{v}'_\mathrm{AP} \\ &\quad + \boldsymbol{\omega}\times(\boldsymbol{\omega}\times\boldsymbol{r}_\mathrm{AP}) \\ &= a_\mathrm{A} + a'_\mathrm{AP} + 2\boldsymbol{\omega}\times\boldsymbol{v}'_\mathrm{AP} + \boldsymbol{\alpha}\times\boldsymbol{r}_\mathrm{AP} \\ &\quad + \boldsymbol{\omega}\times(\boldsymbol{\omega}\times\boldsymbol{r}_\mathrm{AP}) \,,\end{aligned} \tag{2.94}$$

where

$$\boldsymbol{a}'_\mathrm{AP} = \ddot{x}_\mathrm{AP}\boldsymbol{i} + \ddot{y}_\mathrm{AP}\boldsymbol{j} + \ddot{z}_\mathrm{AP}\boldsymbol{k} \tag{2.95}$$

is the acceleration of P relative to the moving frame xyz, $2\boldsymbol{\omega}\times\boldsymbol{v}'_\mathrm{AP}$ is the Coriolis acceleration, and $\boldsymbol{\alpha}\times\boldsymbol{r}_\mathrm{AP} + \boldsymbol{\omega}\times(\boldsymbol{\omega}\times\boldsymbol{r}_\mathrm{AP})$ is the acceleration of P entirely due to the rotation of the frame xyz, where $\boldsymbol{\alpha} = \dot{\boldsymbol{\omega}}$ is the angular acceleration of the frame xyz.

2.2.7 Dynamics

Dynamics of a Particle

Particle Dynamics. Dynamics describes the motion of mass particles, mass particle systems, bodies and body systems, in terms of the forces and moments, under the laws of kinematics [2.5–9].

Newton's Law of Motion. Newton's law of motion can be applied to systems of particles and rigid bodies. Newton suggested the concept of inertial systems of reference, i. e., systems of reference that are either at rest or moving with uniform velocity relative to a fixed reference frame. The motion of any particle is measured relative to such an inertial system and is said to be *absolute*. The linear momentum vector $\boldsymbol{p}$ is defined as the product of the mass m of the particle and the absolute velocity $\boldsymbol{v}$, or $\boldsymbol{p} = m\boldsymbol{v}$. The second law is

$$\boldsymbol{F} = \frac{\mathrm{d}\boldsymbol{p}}{\mathrm{d}t} = \frac{\mathrm{d}}{\mathrm{d}t}m\boldsymbol{v} \,. \tag{2.96}$$

In SI units, the unit of mass is the kilogram (kg) and the unit of force is Newton (N). If the mass m is constant, then

$$\boldsymbol{F} = m\frac{\mathrm{d}\boldsymbol{v}}{\mathrm{d}t} = m\boldsymbol{a} \,, \tag{2.97}$$

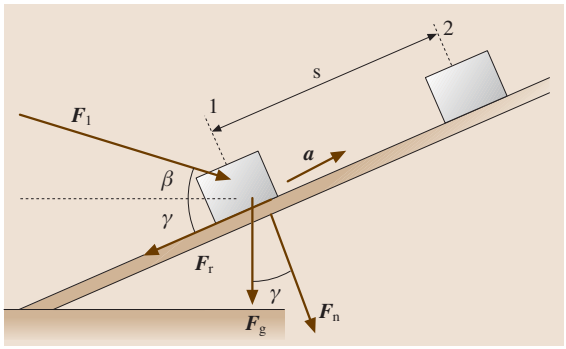

Fig. 2.31 Point mass on an inclined plane

where $\boldsymbol{a} = \mathrm{d}\boldsymbol{v}/\mathrm{d}t$ is the absolute acceleration of m. Equation (2.97) is the equation of motion of a particle.

Example 2.5: The mass $m = 5\,\mathrm{kg}$ is moved from the position of rest 1 by the force $F_1 = 100\,\mathrm{N}$ with $\beta = 15°$ onto the inclined plane with $\gamma = 25°$ as depicted in Fig. 2.31. The friction coefficient is $\mu = 0.3$. Determine the acceleration, velocity, and time upon arrival at position 2 after traveling $s = 8\,\mathrm{m}$.

$$\begin{aligned} \boldsymbol{F}_n &= m\boldsymbol{g}\cos\gamma + \boldsymbol{F}_1 \sin(\beta+\gamma) = 108.7\,\mathrm{N} \\ m\boldsymbol{a} &= \sum \boldsymbol{F} = \boldsymbol{F}_1\cos(\beta+\gamma) - \boldsymbol{F}_g \sin\gamma - \mu \boldsymbol{F}_n \\ &= 23.3\,\mathrm{N}\,. \end{aligned} \tag{2.98a}$$

In scalar notation, we have

$$\begin{aligned} a &= \frac{ma}{m} = 4.66\,\mathrm{m/s^2} \quad t = \sqrt{2s/a} = 1.85\,\mathrm{s}\,, \\ v &= \sqrt{2as} = 8.63\,\mathrm{m/s}\,. \end{aligned} \tag{2.98b}$$

Basic Concepts of Energy, Work, and Power.

Work. From Fig. 2.32, the increment of work $\mathrm{d}W$, a scalar, is defined as the dot product (scalar product) of the force vector and the increment of distance vector

$$\mathrm{d}W = \boldsymbol{F}\cdot\mathrm{d}\boldsymbol{r} = F\cos\beta\,\mathrm{d}r = F_1\,\mathrm{d}r\,. \tag{2.99}$$

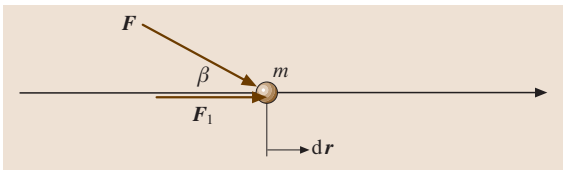

Fig. 2.32 Basic concept of work

From Newton's second law, $\boldsymbol{F} = m\ddot{\boldsymbol{r}}$, and $\mathrm{d}\boldsymbol{r} = \dot{\boldsymbol{r}}\,\mathrm{d}t$, we obtain

$$\begin{aligned} \mathrm{d}W &= m\ddot{\boldsymbol{r}}\cdot\dot{\boldsymbol{r}}\,\mathrm{d}t = m\frac{\mathrm{d}\dot{\boldsymbol{r}}}{\mathrm{d}t}\cdot\dot{\boldsymbol{r}}\,\mathrm{d}t \\ &= m\dot{\boldsymbol{r}}\cdot d\dot{\boldsymbol{r}} = \mathrm{d}\left(\frac{1}{2}m\dot{\boldsymbol{r}}\cdot\dot{\boldsymbol{r}}\right)\,. \end{aligned} \tag{2.100}$$

The kinetic energy T, a scalar, is defined as

$$T = \frac{1}{2}m\dot{\boldsymbol{r}}\cdot\dot{\boldsymbol{r}}\,. \tag{2.101}$$

Consider the work performed by force $\boldsymbol{F}$ in moving the particle m from position $\boldsymbol{r}_1$ to position $\boldsymbol{r}_2$ along curve S as depicted in Fig. 2.33, one has

$$W_{1-2} = \int_{r_1}^{r_2} \boldsymbol{F}\cdot\mathrm{d}\boldsymbol{r} = \int_{T_1}^{T_2} \mathrm{d}T = T_2 - T_1\,. \tag{2.102}$$

If forces have a potential as below

$$\boldsymbol{F} = -\mathbf{grad}\,U = -\frac{\partial U}{\partial x}\boldsymbol{i} - \frac{\partial U}{\partial y}\boldsymbol{j} - \frac{\partial U}{\partial z}\boldsymbol{k}\,, \tag{2.103}$$

then it follows that

$$\begin{aligned} W &= -\int_{P_1}^{P_2}\left(\frac{\partial U}{\partial x}\mathrm{d}x + \frac{\partial U}{\partial y}dy + \frac{\partial U}{\partial z}\mathrm{d}z\right) \\ &= -\int_{P_1}^{P_2}\mathrm{d}U = U_1 - U_2\,. \end{aligned} \tag{2.104}$$

In this case, work is independent of the integration distance and equal to the difference of the potential between the initial point P_1 and the final point P_2, as depicted in Fig. 2.34a. Forces with potential are forces of gravity and spring forces.

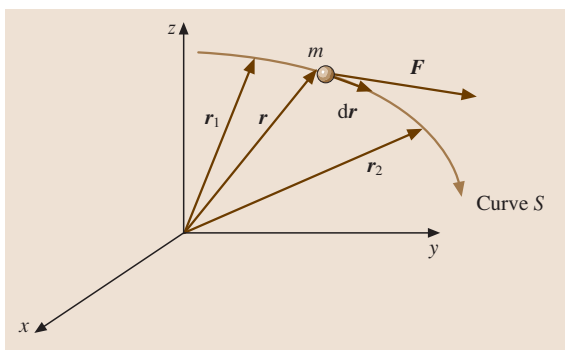

Fig. 2.33 Work of a force

Special Work Examples.

1. Force of gravity. The potential energy $U = F_g z$ and the work is

$$W_g = -\int_{U_1}^{U_2} dU = U_1 - U_2 = F_g(z_1 - z_2) \,. \tag{2.105}$$

2. Spring force (Fig. 2.34b). Potential spring energy $U = cs^2/2$ with spring constant c. The spring force is $\boldsymbol{F}_c = -\nabla U = -\partial U/\partial s\boldsymbol{i} = -cs\boldsymbol{i}$ and the work is

$$W_c = \int_{s_1}^{s_2} cs\, ds = \frac{c\left(s_2^2 - s_1^2\right)}{2} \,. \tag{2.106}$$

3. Frictional force (Fig. 2.34c). There is no potential since frictional work is lost in the form of heat

$$W_r = \int_{s_1}^{s_2} \boldsymbol{F}_r \cdot d\boldsymbol{r} = \int_{s_1}^{s_2} F_r \cos\pi\, ds = -\int_{s_1}^{s_2} F_r\, ds \,. \tag{2.107}$$

4. Torque (Fig. 2.34d). Only the moment components M_t parallel to the axis of rotation perform work

$$W_M = \int_{\phi_1}^{\phi_2} M(\phi) \cdot d\phi = \int_{\phi_1}^{\phi_2} M(\phi) \cos\gamma\, d\phi$$
$$= \int_{\phi_1}^{\phi_2} M_t(\phi)\, d\phi \,. \tag{2.108}$$

Total Work. If forces and moments are at work on a body simultaneously, then

$$W = \int_{s_1}^{s_2} \sum \boldsymbol{F}_i\, d\boldsymbol{r}_i + \int_{\phi_1}^{\phi_2} \sum \boldsymbol{M}_i\, d\phi_i \,. \tag{2.109}$$

Power. Power is defined as work per unit time

$$P(t) = \frac{dW}{dt} = \sum \boldsymbol{F}_i \boldsymbol{v}_i + \sum \boldsymbol{M}_i \boldsymbol{\omega}_i \,. \tag{2.110}$$

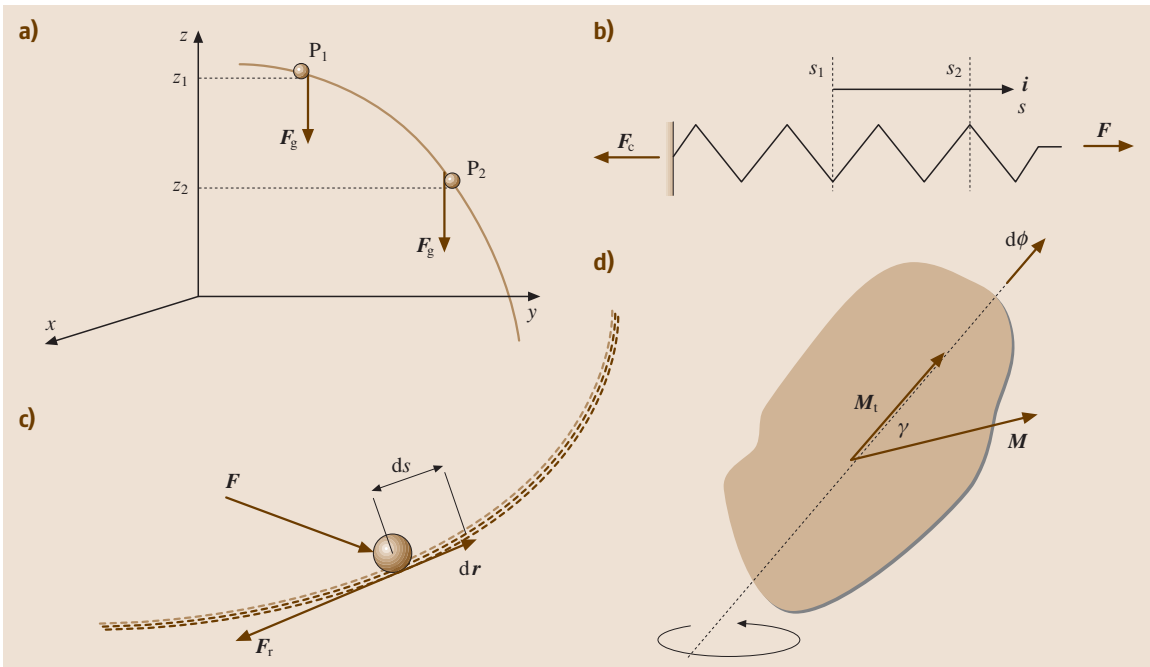

Fig. 2.34a–d Examples of work: (a) gravity, (b) spring force, (c) friction, (d) torque

Mean Power.

$$P_{\mathrm{m}} = \frac{\int_{t_1}^{t_2} P(t)\,\mathrm{d}t}{t_2 - t_1} = \frac{W}{t_2 - t_1} \,. \tag{2.111}$$

2.2.8 Straight-Line Motion of Particles and Rigid Bodies

Momentum Equation

From (2.96), for constant mass, we have

$$\boldsymbol{P}_{1,2} = \int_{t_1}^{t_2} \boldsymbol{F}\,\mathrm{d}t = \int_{v_1}^{v_2} m\,\mathrm{d}\boldsymbol{v} = m\boldsymbol{v}_2 - m\boldsymbol{v}_1 = \boldsymbol{p}_2 - \boldsymbol{p}_1 \,. \tag{2.112}$$

The time integral of the force, known as the *linear impulse vector*, is equal to the difference in momentum.

Angular Momentum Equation

Consider a particle of mass m moving under the action of a force $\boldsymbol{F}$. From Fig. 2.35, it shows the position of m relative to the origin 0 of the inertial frame xyz by $\boldsymbol{r}$ and the absolute velocity of m by $\boldsymbol{v}$. The moment of momentum or angular momentum of m with respect to point 0 is defined as the moment of the linear momentum $\boldsymbol{p}$ about 0 and is represented by the cross product of the vectors $\boldsymbol{r}$ and $\boldsymbol{p}$. The angular momentum of m about point 0 is

$$\boldsymbol{H}_0 = \boldsymbol{r} \times \boldsymbol{p} = \boldsymbol{r} \times m\boldsymbol{v} = \boldsymbol{r} \times m\dot{\boldsymbol{r}} \,. \tag{2.113}$$

Assuming that m is a constant, we have

$$\dot{\boldsymbol{H}}_0 = \dot{\boldsymbol{r}} \times m\dot{\boldsymbol{r}} + \boldsymbol{r} \times m\ddot{\boldsymbol{r}} = \boldsymbol{r} \times m\ddot{\boldsymbol{r}} = \boldsymbol{r} \times \boldsymbol{F} = \boldsymbol{M}_0 \,. \tag{2.114}$$

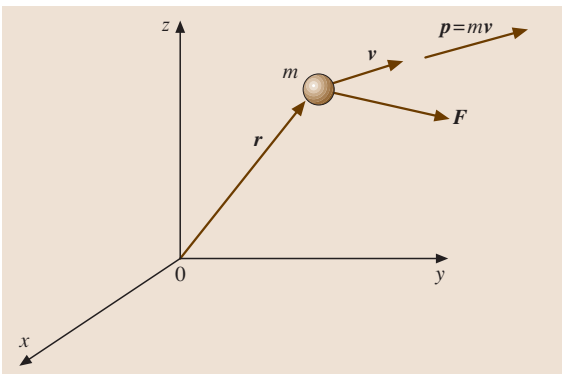

Fig. 2.35 Angular momentum of a particle

Note that $\dot{\boldsymbol{r}} \times m\dot{\boldsymbol{r}} = m(\dot{\boldsymbol{r}} \times \dot{\boldsymbol{r}}) = 0$ and $\boldsymbol{r} \times \boldsymbol{F} = \boldsymbol{M}_0$ is the moment of the force about 0. Therefore, the moment of a force about 0 is equal to the time rate of change of the moment of momentum about 0.

The angular impulse vector about 0 between the times t_1 and t_2 is

$$\hat{\boldsymbol{M}}_0 = \int_{t_1}^{t_2} \boldsymbol{M}_0\,\mathrm{d}t = \int_{t_1}^{t_2} \frac{\mathrm{d}\boldsymbol{H}_0}{\mathrm{d}t}\,\mathrm{d}t = \boldsymbol{H}_0(t_2) - \boldsymbol{H}_0(t_1) = \Delta\boldsymbol{H}_0 \,. \tag{2.115}$$

Therefore, the angular impulse vector about 0 between the times t_1 and t_2 is equal to the change in the angular momentum vector about 0 between the same two instants.

2.2.9 Dynamics of Systems of Particles

A system of particles is a group of n particles as shown in Fig. 2.36. The external and internal forces are denoted by $\boldsymbol{F}_i$ and $\boldsymbol{f}_i$, respectively. The internal force is the resultant of the interaction forces $\boldsymbol{f}_{ij}$ exerted by the particles $m_j (j = 1, 2, \ldots, n,\ j \neq i)$ on particle $m_i (i = 1, 2, \ldots, n)$. The equation of motion of the system of particles is

$$\sum_{i=1}^{n} \boldsymbol{F}_i + \sum_{j=1}^{n}\sum_{i=1}^{n} \boldsymbol{f}_{ij} = \sum_{i=1}^{n} \boldsymbol{F}_i = \sum_{i=1}^{n} m_i \ddot{\boldsymbol{r}}_i = \sum_{i=1}^{n} m_i \boldsymbol{a}_i \,. \tag{2.116}$$

By Newton's third law, $\boldsymbol{f}_{ij} = -\boldsymbol{f}_{ji}$. Hence $\sum_{j=1}^{n} \sum_{i=1}^{n} \boldsymbol{f}_{ij} = 0$.

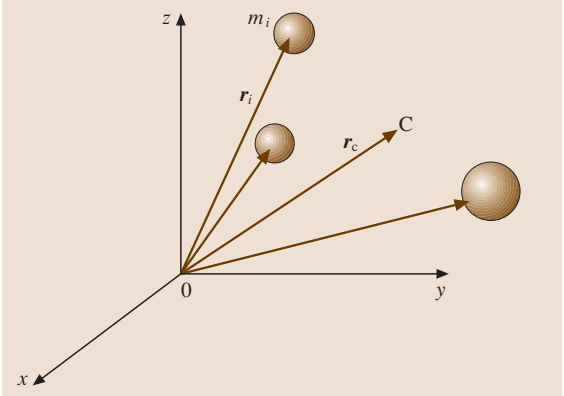

Fig. 2.36 A group of particles

The center of mass C of the system is a point in space representing a weighted average position of the system. The weighting factor is the mass of the particle. We have

$$\boldsymbol{F} = m\boldsymbol{a}_\mathrm{c} \,, \tag{2.117}$$

where

$$\boldsymbol{F} = \sum_{i=1}^{n} \boldsymbol{F}_i m = \sum_{i=1}^{n} m_i \boldsymbol{a}_\mathrm{c} = \frac{1}{m} \sum_{i=1}^{n} m_i \ddot{\boldsymbol{r}}_i \,. \tag{2.118}$$

2.2.10 Momentum Equation

From Fig. 2.36, the linear momentum of m_i is

$$\boldsymbol{p}_i = m_i \boldsymbol{v}_i \,. \tag{2.119}$$

The linear momentum of the system is

$$\boldsymbol{p} = \sum_{i=1}^{n} \boldsymbol{p}_i = \sum_{i=1}^{n} m_i \boldsymbol{v}_i = m\boldsymbol{v}_\mathrm{c} \,. \tag{2.120}$$

The resultant of the external forces acting on the system is

$$\boldsymbol{F} = \dot{\boldsymbol{p}} = m\dot{\boldsymbol{v}}_\mathrm{c} = m\boldsymbol{a}_\mathrm{c} \,. \tag{2.121}$$

If $\boldsymbol{F} = 0$, then $\boldsymbol{p} =$ constant. This is the conservation of linear momentum of a system of particles.

The angular momentum of the particle m_i about 0 is

$$\boldsymbol{H}_{0i} = \boldsymbol{r}_i \times \boldsymbol{p}_i = \boldsymbol{r}_i \times m_i \boldsymbol{v}_i \,. \tag{2.122}$$

The angular momentum of the system about 0 is

$$\boldsymbol{H}_0 = \sum_{i=1}^{n} \boldsymbol{H}_{0i} = \sum_{i=1}^{n} \boldsymbol{r}_i \times m_i \boldsymbol{v}_i \,. \tag{2.123}$$

Hence

$$\begin{aligned} \dot{\boldsymbol{H}}_0 &= \sum_{i=1}^{n} \dot{\boldsymbol{r}}_i \times m_i \boldsymbol{v}_i + \sum_{i=1}^{n} \boldsymbol{r}_i \times m_i \dot{\boldsymbol{v}}_i \\ &= \sum_{i=1}^{n} \boldsymbol{r}_i \times m_i \boldsymbol{a}_i = \sum_{i=1}^{n} \boldsymbol{r}_i \times \boldsymbol{F}_i \,. \end{aligned} \tag{2.124}$$

Since $\boldsymbol{M}_0 = \sum_{i=1}^{n} \boldsymbol{r}_i \times \boldsymbol{F}_i$, we have

$$\boldsymbol{M}_0 = \dot{\boldsymbol{H}}_0 \,. \tag{2.125}$$

If $\boldsymbol{M}_0 = 0$, then $\boldsymbol{H}_0 =$ constant. This states that, in the absence of external torques about 0, the angular momentum of the system about 0 is a constant. This is the conservation of angular momentum of the system about a fixed point. It can be extended to the conservation of angular momentum about the mass center.

Energy Equation

The kinetic energy of particle m_i is

$$T_i = \frac{1}{2} m_i \dot{\boldsymbol{r}}_i \cdot \dot{\boldsymbol{r}}_i \,. \tag{2.126}$$

and the kinetic energy of the system is

$$T = \sum_{i=1}^{n} T_i = \frac{1}{2} \sum_{i=1}^{n} m_i \dot{\boldsymbol{r}}_i \cdot \dot{\boldsymbol{r}}_i \,. \tag{2.127}$$

Example 2.6: A spring with spring constant c, which is pre-stressed by the value s, thrusts the masses m_1 and m_2 apart from rest as depicted in Fig. 2.37. Disregarding the friction forces during the relaxation process of the spring, there is no external force. Determine the velocities of m_1 and m_2.

From the conservation of momentum of a system of particles, we have $m_1 v_1 - m_2 v_2 = 0$.

The energy equation is

$$\frac{1}{2} c s^2 = \frac{1}{2} \left(m_1 v_1^2 + m_2 v_2^2 \right) . \tag{2.128a}$$

It follows that

$$v_1 = \sqrt{\frac{c s^2}{(m_1 + m_1^2/m_2)}} \,, \quad v_2 = \sqrt{\frac{c s^2}{(m_2 + m_2^2/m_1)}} \,. \tag{2.128b}$$

Example 2.7: Two masses, connected by an inextensible chain, are drawn out of the position of rest by the force $\boldsymbol{F}$ as depicted in Fig. 2.38. Mass m_1 moves along the inclined surface. Determine the velocity after traveling a distance s_1.

The friction force on masses m_1 and m_2 are $F_{\mathrm{r}1} = \mu_1 (F_{\mathrm{g}1} \cos\gamma_1 - F \sin\gamma_1)$ and $F_{\mathrm{r}2} = \mu_2 F_{\mathrm{g}2} \cos\gamma_2$, respectively. As a precondition for the mass m_1 not being lifted, we must have $F \le F_{\mathrm{g}1} \cot\gamma_1$.

The energy equation is

$$\begin{aligned} &F \cos\gamma_1 s_1 + F_{\mathrm{g}1} h_1 - F_{\mathrm{r}1} s_1 - F_{\mathrm{g}2} h_2 - F_{\mathrm{r}2} s_2 \\ &= \frac{1}{2} \left(m_1 v_1^2 + m_2 v_2^2 \right) . \end{aligned} \tag{2.129a}$$

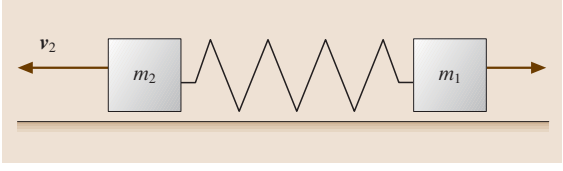

Fig. 2.37 Spring–mass system

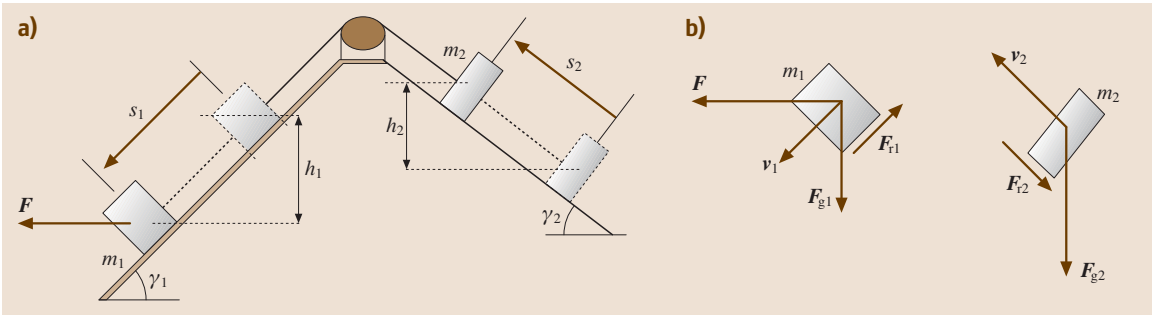

Fig. 2.38 (a) Two-mass system, (b) forces on each mass

Because $s_1 = s_2$, $v_1 = v_2$, $h_1 = s_1 \sin\gamma_1$, and $h_2 = s_2 \sin\gamma_2$, it follows that

$$v_1 = \sqrt{\frac{2s_1(F\cos\gamma_1 + F_{g1}\sin\gamma_1 - F_{r1} - F_{g2}\sin\gamma_2 - F_{r2})}{m_1 + m_2}} \,. \qquad (2.129b)$$

2.2.11 D'Alembert's Principle, Constrained Motion

From Newton's law we know that $\boldsymbol{F} - m\boldsymbol{a} = 0$, i. e., the external forces and forces of inertia of a particle form a *state of equilibrium*. In the event of a system of particles m_i $(i = 1, 2, \ldots, n)$, Newton's equations of motion are

$$\boldsymbol{F}_i + \boldsymbol{f}_i - m_i\ddot{\boldsymbol{r}}_i = 0 \,, \quad i = 1, 2, \ldots, n \,, \qquad (2.130)$$

where $\boldsymbol{F}_i$ are the applied forces, $\boldsymbol{f}_i$ are the constraint forces, and $-m_i\ddot{\boldsymbol{r}}_i$ are the inertial forces. Equation (2.130) is the dynamic equilibrium of the system of particles. The sum of virtual work for the entire system is

$$\sum_{i=1}^{n} (\boldsymbol{F}_i + \boldsymbol{f}_i - m_i\ddot{\boldsymbol{r}}_i)\cdot\delta\boldsymbol{r}_i = 0 \,. \qquad (2.131)$$

However, the virtual work performed by the constraint forces over virtual displacements is zero. Hence, it follows that

$$\sum_{i=1}^{n} (\boldsymbol{F}_i - m_i\ddot{\boldsymbol{r}}_i)\cdot\delta\boldsymbol{r}_i = 0 \,. \qquad (2.132a)$$

Equation (2.132a) is D'Alembert's principle for a system of particles. It can also be applied to a system of rigid bodies. If the motion is planar, the D'Alembert's principle for a system of rigid bodies is

$$\sum_{i=1}^{n} (\boldsymbol{F}_i - m_i\ddot{\boldsymbol{r}}_{Ci})\cdot\delta\boldsymbol{r}_{Ci} + (M_{Ci} - I_{Ci}\ddot{\theta}_i)\delta\theta_i = 0 \,, \qquad (2.132b)$$

where r_{Ci} is the position of the mass center of the i-th rigid body, M_{Ci} is the moment of the mass center of the i-th rigid body, and I_{Ci} is the mass moment of inertia about an axis normal to the plane of motion that passes through C.

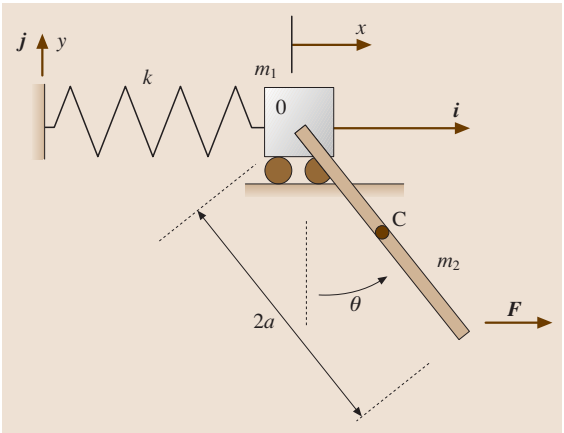

Fig. 2.39 Spring–mass and rod system

Example 2.8: Derive the equation of motion of the system shown in Fig. 2.39 by using D'Alembert's principle. Use θ and x as independent coordinates.

There are two rigid bodies in Fig. 2.39. m_1 can be considered as a particle that is subjected to no moments and no moment of inertia. m_2 is a rigid body. Equation (2.131) becomes

$$(\boldsymbol{F}_1 - m_1\ddot{\boldsymbol{r}}_{C1})\cdot\delta\boldsymbol{r}_{C1} + (\boldsymbol{F}_2 - m_2\ddot{\boldsymbol{r}}_{C2})\cdot\delta\boldsymbol{r}_{C2} + (M_{C2} - I_{C2}\ddot{\theta}_2)\delta\theta_2 = 0 \,. \qquad (2.133a)$$

From Fig. 2.39, we have

$$\boldsymbol{F}_1 = -kx\boldsymbol{i} - m_1 g\boldsymbol{j}\ , \quad \boldsymbol{F}_2 = F\boldsymbol{i} - m_2 g\boldsymbol{j}\ ,$$
$$M_{C2} = Fa\cos\theta\ , \quad I_{C2} = \frac{1}{3}m_2 a^2 \qquad (2.133b)$$

and

$$\boldsymbol{r}_{C1} = (L+x)\boldsymbol{i}\ ,$$
$$\boldsymbol{r}_{C2} = (L+x+a\sin\theta)\boldsymbol{i} - a\cos\theta\boldsymbol{j}\ ,$$
$$\delta\boldsymbol{r}_{C1} = \delta x\boldsymbol{i}$$
$$\delta\boldsymbol{r}_{C2} = (\delta x + a\cos\theta\delta\theta)\boldsymbol{i} + a\sin\theta\delta\theta\boldsymbol{j}\ , \qquad (2.133c)$$

where $\theta = \theta_2 \delta\theta = \delta\theta_2$, and L is the fixed length of the spring before moving. The accelerations are

$$\ddot{\boldsymbol{r}}_{C1} = \ddot{x}\boldsymbol{i}\ ,$$
$$\ddot{\boldsymbol{r}}_{C2} = (\ddot{x} + a\ddot{\theta}\cos\theta - a\dot{\theta}^2\sin\theta)\boldsymbol{i}$$
$$+ a(\ddot{\theta}\sin\theta + \dot{\theta}^2\cos\theta)\boldsymbol{j}\ . \qquad (2.133d)$$

Substituting (2.133b)–(2.133d) into (2.133a) and setting each of the coefficients of $\delta\theta$ and δx equal to zero, the equations of motion are

$$(m_1+m_2)\ddot{x} + m_2 a(\ddot{\theta}\cos\theta - \dot{\theta}^2\sin\theta) + kx = F\ ,$$
$$m_2\cos\theta\ddot{x} + \frac{4}{3}m_2 a\ddot{\theta} + m_2 g\sin\theta = 2F\cos\theta\ . \qquad (2.133e)$$

2.2.12 Lagrange's Equations

Lagrange provided the equations of motion for a system by a differentiation process related to the dynamic (kinetic and potential) energy. Considering an n-degree-of-freedom system, Lagrange's equations read

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial L}{\partial \dot{q}_i}\right) - \frac{\partial L}{\partial q_i} = Q_i \quad i = 1, 2, \ldots, n\ , \qquad (2.134)$$

where the Lagrangian $L = T - V$, in which T is the kinetic energy, V is the potential energy, q_i are the generalized coordinates of the system, and Q_i are the generalized forces. The Lagrangian approach is very efficient for deriving the equations of motion for both linear and nonlinear systems.

Example 2.9: Derive the equation of motion of the system of Fig. 2.39 using Lagrange's equations.

Suppose $q_1 = x$ and $q_2 = \theta$. First, we need to calculate the virtual work with the nonconservative force $\boldsymbol{F}$. Denoting the point of application of the force by B, the position vector of B is

$$\boldsymbol{r}_B = (L + x + 2a\sin\theta)\boldsymbol{i} - 2a\cos\theta\boldsymbol{j}\ . \qquad (2.135a)$$

The virtual displacement of B is

$$\delta\boldsymbol{r}_B = (\delta x + 2a\cos\theta\delta\theta)\boldsymbol{i} + 2a\sin\theta\delta\theta\boldsymbol{j}\ . \qquad (2.135b)$$

The force $\boldsymbol{F}$ is

$$\boldsymbol{F} = F\boldsymbol{i}\ . \qquad (2.135c)$$

The nonconservative virtual work is

$$\boldsymbol{F}\cdot\delta\boldsymbol{r}_B = F(\delta x + 2a\cos\theta\delta\theta)\ . \qquad (2.135d)$$

The coefficients of $\delta\theta$ and δx are the nonconservative generalized forces, or

$$X = F\ , \quad \Theta = 2Fa\cos\theta\ . \qquad (2.135e)$$

The kinetic energy is

$$T = \frac{1}{2}m_1\boldsymbol{v}_1\cdot\boldsymbol{v}_1 + \frac{1}{2}m_2\boldsymbol{v}_2\cdot\boldsymbol{v}_2 + \frac{1}{2}I_C\dot{\theta}^2$$
$$= \frac{1}{2}m_1\dot{x}^2 + \frac{1}{2}m_2\left[(\dot{x} + a\dot{\theta}\cos\theta)^2\right.$$
$$\left. + (a\dot{\theta}\sin\theta)^2\right] + \frac{1}{2}\frac{1}{12}m_2(2a)^2\dot{\theta}^2$$
$$= \frac{1}{2}(m_1+m_2)\dot{x}^2 + m_2 a\dot{x}\dot{\theta}\cos\theta + \frac{2}{3}m_2 a^2\dot{\theta}^2\ . \qquad (2.135f)$$

The potential energy is

$$V = \frac{1}{2}kx^2 + m_2 ga(1-\cos\theta)\ . \qquad (2.135g)$$

Hence,

$$L = T - V$$
$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial L}{\partial \dot{x}}\right) = (m_1+m_2)\ddot{x} + m_2 a(\ddot{\theta}\cos\theta - \dot{\theta}^2\sin\theta)$$
$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial L}{\partial \dot{\theta}}\right) = m_2 a(\ddot{x}\cos\theta - \dot{x}\dot{\theta}\sin\theta) + \frac{4}{3}m_2 a^2\ddot{\theta}$$
$$\frac{\partial L}{\partial x} = -kx\ , \quad \frac{\partial L}{\partial \theta} = -m_2 a\sin\theta(\dot{x}\dot{\theta} + g)\ . \qquad (2.135h)$$

From (2.134), the equations of motion are

$$(m_1+m_2)\ddot{x} + m_2 a(\ddot{\theta}\cos\theta - \dot{\theta}^2\sin\theta) + kx = F\ ,$$
$$m_2\ddot{x}\cos\theta + \frac{4}{3}m_2 a\ddot{\theta} + m_2 g\sin\theta = 2F\cos\theta\ . \qquad (2.135i)$$

2.2.13 Dynamics of Rigid Bodies

Rigid bodies can be viewed as a special type of systems of particles, where the distances between any two

particles are rigidly constrained to be constant. The velocity of a point in the rigid body relative to another is due only to the angular velocity of the rigid body.

Linear and Angular Momentum

The angular momentum of a rigid body rotating with the angular velocity $\boldsymbol{\omega}$ about the fixed point 0 is defined as

$$H_0 = \int_m \boldsymbol{r} \times \boldsymbol{v}\, \mathrm{d}m \,. \tag{2.136}$$

From Fig. 2.40, because the velocity $\boldsymbol{v}$ of any point in the body is due entirely to the rotation about 0, (2.136) becomes

$$H_0 = \int_m \boldsymbol{r} \times (\boldsymbol{\omega} \times \boldsymbol{r})\, \mathrm{d}m = \int_m (\boldsymbol{r} \cdot \boldsymbol{r})\boldsymbol{\omega} - (\boldsymbol{r} \cdot \boldsymbol{\omega})\boldsymbol{r}\, \mathrm{d}m \,. \tag{2.137}$$

Note that $\boldsymbol{A} \times (\boldsymbol{B} \times \boldsymbol{C}) = (\boldsymbol{A} \cdot \boldsymbol{C})\boldsymbol{B} - (\boldsymbol{A} \cdot \boldsymbol{B})\boldsymbol{C}$ in vector analysis.

Let

$$\boldsymbol{r} = x\boldsymbol{i} + y\boldsymbol{j} + z\boldsymbol{k} \quad \text{and} \quad \boldsymbol{\omega} = \omega_x \boldsymbol{i} + \omega_y \boldsymbol{j} + \omega_z \boldsymbol{k} \,. \tag{2.138}$$

Substituting (2.138) into (2.136), we have

$$\begin{aligned} \boldsymbol{H}_0 = {} & (I_{xx}\omega_x - I_{xy}\omega_y - I_{xz}\omega_z)\,\boldsymbol{i} \\ & + (-I_{xy}\omega_x + I_{yy}\omega_y - I_{yz}\omega_z)\,\boldsymbol{j} \\ & + (-I_{xz}\omega_x - I_{yz}\omega_y + I_{zz}\omega_z)\,\boldsymbol{k} \,, \end{aligned} \tag{2.139}$$

where

$$I_{xx} = \int_m (y^2 + z^2)\, \mathrm{d}m \,, \quad I_{yy} = \int_m (x^2 + z^2)\, \mathrm{d}m \,,$$
$$I_{zz} = \int_m (x^2 + y^2)\, \mathrm{d}m \tag{2.140}$$

are mass moments of inertia about the body axes xyz, and

$$I_{xy} = I_{yx} = \int_m xy\, \mathrm{d}m \,, \; I_{xz} = I_{zx} = \int_m xz\, \mathrm{d}m \,,$$
$$I_{yz} = I_{zy} = \int_m yz\, \mathrm{d}m \tag{2.141}$$

are mass product of inertia about the same axes.

Note that the moment of inertia can be represented as the moment of inertia tensor shown below

$$\boldsymbol{I} = \begin{pmatrix} I_{xx} & -I_{xy} & -I_{xz} \\ -I_{yx} & I_{yy} & -I_{yz} \\ -I_{zx} & -I_{zy} & I_{zz} \end{pmatrix} \,. \tag{2.142}$$

For a pure rotation about a fixed point 0, the moment equation of motion is

$$\boldsymbol{M}_0 = \dot{\boldsymbol{H}}_0 \,. \tag{2.143}$$

If we choose the axes x, y, and z be the principal axes, this results in $I_{xy} = I_{yz} = I_{zx} = 0$. Then the moment equation of motion becomes

$$\begin{aligned} \boldsymbol{M}_0 &= M_x \boldsymbol{i} + M_y \boldsymbol{j} + M_z \boldsymbol{k} \,, \\ M_x &= I_{xx}\dot{\omega}_x + (I_{zz} - I_{yy})\omega_y \omega_z \,, \\ M_y &= I_{yy}\dot{\omega}_y + (I_{xx} - I_{zz})\omega_x \omega_z \,, \\ M_z &= I_{zz}\dot{\omega}_z + (I_{yy} - I_{xx})\omega_x \omega_y \,, \end{aligned} \tag{2.144}$$

which are called Euler's moment equations.

2.2.14 Planar Motion of a Rigid Body

Assuming that the motion takes place in the xy plane, we have $v_z = a_z = 0$, $\omega_x = \dot{\omega}_x = \omega_y = \dot{\omega}_y = 0$, $\omega_z = \omega$, and $I_{xz} = I_{yz} = 0$ due to the small dimension of the body in the z-direction.

For pure translation, i. e., $\omega = \dot{\omega} = 0$, we have

$$F_x = m a_{\mathrm{C}x} \quad \text{and} \quad F_y = m a_{\mathrm{C}y} \,. \tag{2.145}$$

The only moment equation is about the z-axis. The moment equation about the mass center C is $M_{\mathrm{C}z} = 0$.

The kinetic energy is

$$T = \frac{1}{2} m \boldsymbol{v}_{\mathrm{C}} \cdot \boldsymbol{v}_{\mathrm{C}} = \frac{1}{2} m \left(v_{\mathrm{C}x}^2 + v_{\mathrm{C}y}^2 \right) \,, \tag{2.146}$$

where $v_{\mathrm{C}x}$ and $v_{\mathrm{C}y}$ are the Cartesian components of the velocity vector of the mass center.

For pure rotation about a fixed point 0, we have the scalar angular momentum and scalar equation of motion as follows

$$H_0 = I_{zz}\omega \quad \text{and} \quad M_0 = I_{zz}\dot{\omega} \,, \tag{2.147}$$

and the kinetic energy is

$$T = \frac{1}{2} I_{zz} \omega^2 \,. \tag{2.148}$$

Example 2.10: A horizontal bar with a total mass m is hinged at point 0, as depicted in Fig. 2.41. The bar is released from rest. Determine the angular acceleration immediately after release, the reaction force at point 0 at the same time, and the angular velocity of the bar when it passes through the vertical position.

Let us consider the counterclockwise moments and angular motion as positive. From (2.114) and (2.147), we have

$$M_0 = I_{zz}\dot{\omega} = -\frac{1}{6} L m g \,. \tag{2.149a}$$

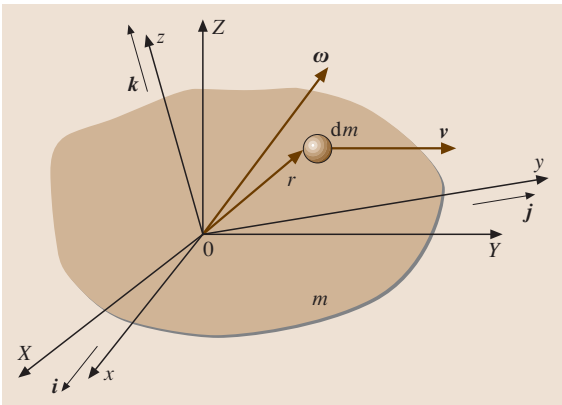

Fig. 2.40 A rotating rigid body

The mass moment of inertia of the bar about point 0 is obtained as

$$I_{zz} = \int_m x^2 \,\mathrm{d}m = \frac{m}{L} \int_{-L/3}^{2L/3} x^2 \,\mathrm{d}x = \frac{1}{9} L^2 m \,. \quad (2.149b)$$

Hence, the angular acceleration immediately after release is

$$\alpha = \dot{\omega} = -\frac{3g}{2L} \,. \quad (2.149c)$$

From (2.53b) and (2.145), we have the reaction force in the y-axis direction only as follows

$$F_y = R - mg = ma_{Cy} = m\frac{1}{6} L\alpha = \frac{-1}{4} mg \,. \quad (2.149d)$$

The reaction force R at point 0 is then obtained as

$$R = \frac{3}{4} mg \,. \quad (2.149e)$$

Both the potential and kinetic energy of the bar at horizontal position are zero. At vertical position, the potential energy becomes $V = -1/6Lmg$. The kinetic energy becomes $T = 1/2 I_{zz}\omega^2 = 1/18 mL^2\omega^2$. By applying the law of conservation of energy, we have

$$T + V = 0 \quad \text{and} \quad \omega = -\sqrt{\frac{3g}{L}} \,, \quad (2.149f)$$

where te negative sign indicates an angular velocity in the clockwise direction.

2.2.15 General Case of Planar Motion

By using the mass center C, the moment equation has the scalar form $M_c = I_c\alpha$, where I_c is the mass moment

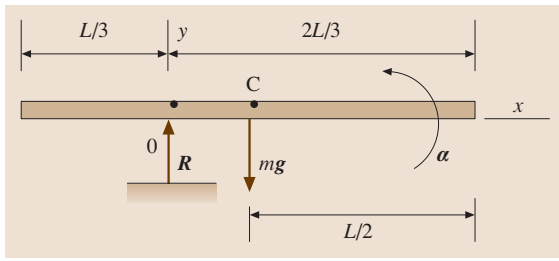

Fig. 2.41 A uniform bar

of inertia about an axis normal to the plane of motion that passing through C. The kinetic energy consists of the translation of C and rotation about C as follows

$$T = \frac{1}{2} m\left(v_{Cx}^2 + v_{Cy}^2\right) + \frac{1}{2} I_C \omega^2 \,. \quad (2.150)$$

Let us consider the system shown in Fig. 2.42 and write a moment about the arbitrary point A as

$$\boldsymbol{M}_A = \int \boldsymbol{\rho}_A \times \mathrm{d}\boldsymbol{F} = \int (\boldsymbol{\rho}_{AC} + \boldsymbol{\rho}) \times \mathrm{d}\boldsymbol{F} = \boldsymbol{\rho}_{AC} \times \boldsymbol{F} + \boldsymbol{M}_C \,, \quad (2.151)$$

or

$$\boldsymbol{M}_A = \boldsymbol{\rho}_{AC} \times m\boldsymbol{a}_C + \boldsymbol{M}_C \quad \text{and} \quad \boldsymbol{M}_C = I_C\boldsymbol{\alpha} \,. \quad (2.152)$$

The acceleration at the mass center C can be written as

$$\boldsymbol{a}_C = \boldsymbol{a}_A + \boldsymbol{a}_{C/A} \,. \quad (2.153)$$

From (2.82), the acceleration reduces to

$$\boldsymbol{a}_C = \boldsymbol{a}_A - \omega^2 \boldsymbol{\rho}_{AC} + \boldsymbol{\alpha} \times \boldsymbol{\rho}_{AC} \,. \quad (2.154)$$

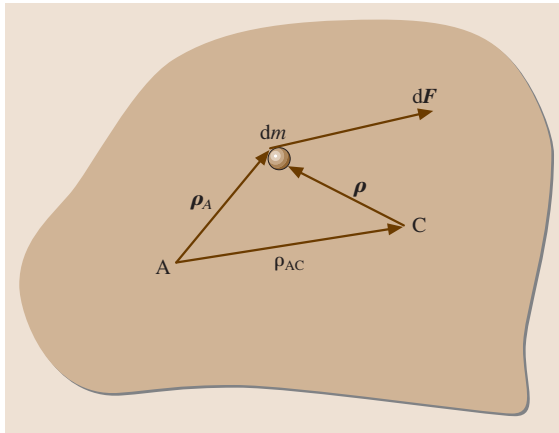

Fig. 2.42 Rigid-body planar motion

Substituting (2.154) into (2.152) we have

$$\boldsymbol{M}_A = \boldsymbol{\rho}_{AC} \times m\boldsymbol{a}_C + I_A \boldsymbol{\alpha} \,. \tag{2.155}$$

where $I_A = (I_C + m\rho_{AC}^2)$ is the mass moment of inertia of the body about point A.

Example 2.11: A disk of radius R is originally at rest at point 1. It rolls without slipping down to point 2 as depicted in Fig. 2.43. Calculate the velocity at point 2.

The kinetic energy at point 2 is

$$T_2 = \frac{1}{2} m v_2^2 + \frac{1}{2} I_C \omega_2^2 \,. \tag{2.156a}$$

Since $v_2 = -R\omega_2$ and $I_C = mR^2/2$, we have

$$T_2 = \frac{3}{4} m v_2^2 \,. \tag{2.156b}$$

Conservation of energy then yields

$$V_2 + T_2 = -mgh + \frac{3}{4} m v_2^2 = 0 \quad \text{and}$$
$$v_2 = \sqrt{4gh/3} \,. \tag{2.156c}$$

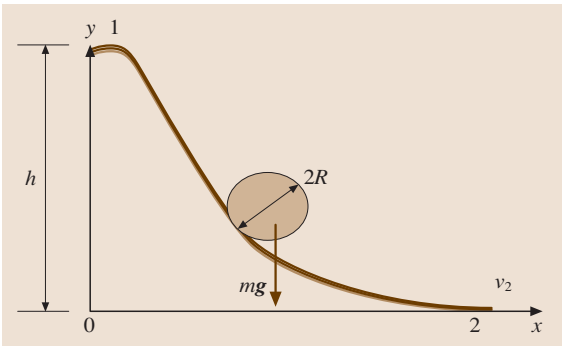

Fig. 2.43 A rolling ball

2.2.16 Rotation About a Fixed Axis

Let us consider the rigid body of Fig. 2.40 and assume that the only motion takes place about the fixed z-axis, i. e., $\omega_x = \dot{\omega}_x = \omega_y = \dot{\omega}_y = 0$, $\omega_z = \omega$. The fixed origin 0 is also on the fixed axis. The moment equations become

$$\begin{aligned} M_x &= -I_{xz}\dot{\omega} + I_{yz}\omega^2 \,, \\ M_y &= -I_{yz}\dot{\omega} - I_{xz}\omega^2 \,, \\ M_z &= I_{zz}\dot{\omega} \,. \end{aligned} \tag{2.157}$$

Example 2.12: A thin disk with radius R and mass m is shown in Fig. 2.44. The normal to the disk makes an angle β with respect to the shaft. The disk rotates with $\omega_z = \omega = \text{const}$. Determine the bearing forces at points A and B.

From Fig. 2.44a, axes XYZ are inertial and axes xyz are body axes, where z is along the shaft and x is embedded in the disk. Fig. 2.44b depicts the body axes, xyz and the principle axes, $x'y'z'$. The relationship between these two set of axes are

$$\begin{aligned} &x = x' \,, \quad y = y' \cos\beta + z' \sin\beta \,, \\ &z = -y' \sin\beta + z' \cos\beta \,. \end{aligned} \tag{2.158a}$$

The inertia products I_{xz} and I_{yz} of the axes xyz are

$$\begin{aligned} I_{xz} &= \int_m xz \, \mathrm{d}m = \int_m x'(-y' \sin\beta + z' \cos\beta) \, \mathrm{d}m \\ &= -\sin\beta I_{x'y'} + \cos\beta I_{x'z'} = 0 \end{aligned} \tag{2.158b}$$

and

$$\begin{aligned} I_{yz} &= \int_m yz \, \mathrm{d}m \\ &= \int_m (y' \cos\beta + z' \sin\beta) \\ &\quad \times (-y' \sin\beta + z' \cos\beta) \, \mathrm{d}m \\ &= \sin\beta \cos\beta (I_{y'y'} - I_{z'z'}) \\ &\quad + (\cos^2\beta - \sin^2\beta) I_{y'z'} \,. \end{aligned} \tag{2.158c}$$

Note that because $x'y'z'$ are the principle axes, the products of inertia are zero. The moments of inertia of the disk are

$$I_{x'x'} = I_{y'y'} = \frac{1}{4} m R^2 \,, \quad I_{z'z'} = \frac{1}{2} m R^2 \,. \tag{2.158d}$$

Hence,

$$I_{yz} = -\frac{1}{4} m R^2 \sin\beta \cos\beta \,. \tag{2.158e}$$

Substituting (2.158b) and (2.158e) into (2.157), we obtain

$$M_x = -\frac{1}{4} m R^2 \omega^2 \sin\beta \cos\beta \,, \quad M_y = 0, \quad M_z = 0 \,. \tag{2.158f}$$

The moment components along the X- and Y-axes are

$$M_X = M_x \cos\gamma \quad \text{and} \quad M_Y = M_x \sin\gamma \,. \tag{2.158g}$$

Since the acceleration of the mass center is zero, the force equations along the X- and Y-axes are

$$\begin{aligned} &F_X = R_{AX} + R_{BX} = 0 \quad \text{and} \\ &F_Y = R_{AY} + R_{BY} - mg = 0 \,. \end{aligned} \tag{2.158h}$$

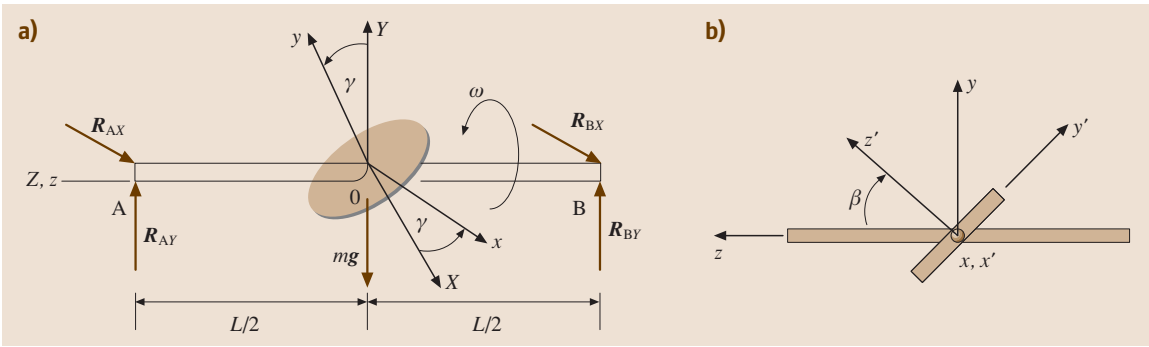

Fig. 2.44a,b A rotating disk: (a) the axes XYZ are inertial, (b) the axes xyz are body axes

From the reaction forces, the moment equations about 0 yield

$$M_X = \frac{L}{2}(R_{BY} - R_{AY}) = -\frac{1}{4}mR^2\omega^2 \sin\beta\cos\beta\cos\gamma\,,$$
$$M_Y = \frac{L}{2}(R_{AX} - R_{BX}) = -\frac{1}{4}mR^2\omega^2 \sin\beta\cos\beta\sin\gamma\,. \qquad (2.158i)$$

Because $\gamma = \omega t$, (2.158h) and (2.158i) yield

$$R_{BX} = -R_{AX} = \frac{1}{4L}mR^2\omega^2 \sin\beta\cos\beta\sin\omega t\,,$$
$$R_{AY} = \frac{mg}{2} + \frac{1}{4L}mR^2\omega^2 \sin\beta\cos\beta\cos\omega t\,,$$
$$R_{BY} = \frac{mg}{2} - \frac{1}{4L}mR^2\omega^2 \sin\beta\cos\beta\cos\omega t\,. \qquad (2.158j)$$

Therefore, in addition to the static bearing forces equal to half the weight, there are dynamic bearing forces that vary harmonically with a frequency equal to the spin frequency ω. These dynamic bearing forces will wear out the bearing.

2.2.17 Lagrange's Equations of Motion for Linear Systems

Lagrange's equations can be applied to the derivation of the equations of motion for a linear n-degree-of-freedom dynamic system. By extending the concept of Sect. 2.2.12, (2.134) can be rewritten as follows

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial T}{\partial \dot{q}_i}\right) - \frac{\partial T}{\partial q_i} + \frac{\partial D}{\partial \dot{q}_i} + \frac{\partial V}{\partial q_i} = Q_i\,, \quad i = 1, 2, \ldots, n\,, \qquad (2.159)$$

where D, the dissipation function due to the damping force of viscous type, is defined as

$$D = \frac{1}{2}\sum_{i=1}^{n}\sum_{j=1}^{n} c_{ij}\dot{q}_i\dot{q}_j \quad \text{and}$$
$$\frac{\partial D}{\partial \dot{q}_i} = \sum_{j=1}^{n} c_{ij}\dot{q}_j\,, \qquad (2.160)$$

where the c_{ij} are known as the damping coefficients.

Equation (2.159) can be rewritten in a compact matrix form as

$$M\ddot{\boldsymbol{q}}(t) + C\dot{\boldsymbol{q}}(t) + K\boldsymbol{q}(t) = \boldsymbol{Q}(t)\,, \qquad (2.161)$$

where M is the mass matrix, C is the damping matrix, and K is the stiffness matrix. All three are $n \times n$ symmetric matrices.

$$\boldsymbol{q}(t) = [q_1(t)q_2(t), \ldots, q_n(t)]^{\mathrm{T}} \quad \text{and}$$
$$\boldsymbol{Q}(t) = [Q_1(t), Q_2(t), \ldots, Q_n(t)]^{\mathrm{T}} \qquad (2.162)$$

Equation (2.162) defines the n-dimensional generalized displacement vector and generalized force vector.

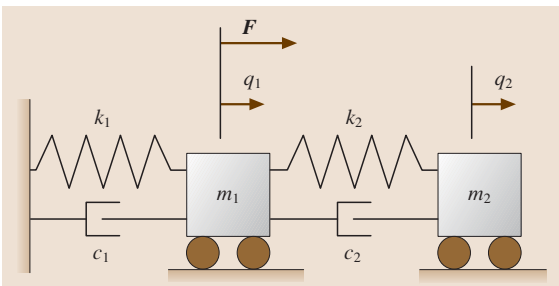

Fig. 2.45 Spring–mass–damping system

The kinetic energy T, dissipation function D, and the potential energy V can be expressed as

$$T = \frac{1}{2}\dot{\boldsymbol{q}}^{\mathrm{T}}(t)M\dot{\boldsymbol{q}}(t)$$
$$D = \frac{1}{2}\dot{\boldsymbol{q}}^{\mathrm{T}}(t)C\dot{\boldsymbol{q}}(t)$$
$$V = \frac{1}{2}\boldsymbol{q}^{\mathrm{T}}(t)K\boldsymbol{q}(t)\,. \qquad (2.163)$$

Example 2.13: Derive the equation of motion of the system shown in Fig. 2.45. Use q_1 and q_2 as independent coordinates.

The kinetic energy T, dissipation function D, and the potential energy V are

$$T = \frac{1}{2}\left(m_1\dot{q}_1^2 + m_2\dot{q}_2^2\right)$$
$$= \frac{1}{2}\begin{pmatrix}\dot{q}_1\\ \dot{q}_2\end{pmatrix}^{\mathrm{T}}\begin{pmatrix}m_1 & 0\\ 0 & m_2\end{pmatrix}\begin{pmatrix}\dot{q}_1\\ \dot{q}_2\end{pmatrix},$$
$$D = \frac{1}{2}\left[c_1\dot{q}_1^2 + c_2(\dot{q}_2 - \dot{q}_1)^2\right]$$
$$= \frac{1}{2}\begin{pmatrix}\dot{q}_1\\ \dot{q}_2\end{pmatrix}^{\mathrm{T}}\begin{pmatrix}c_1 + c_2 & -c_2\\ -c_2 & c_2\end{pmatrix}\begin{pmatrix}\dot{q}_1\\ \dot{q}_2\end{pmatrix},$$
$$V = \frac{1}{2}\left[k_1 q_1^2 + k_2(q_2 - q_1)^2\right]$$
$$= \frac{1}{2}\begin{pmatrix}q_1\\ q_2\end{pmatrix}^{\mathrm{T}}\begin{pmatrix}k_1 + k_2 & -k_2\\ -k_2 & k_2\end{pmatrix}\begin{pmatrix}q_1\\ q_2\end{pmatrix}. \qquad (2.164a)$$

The equation of motion of the two-degree-of-freedom dynamic system is obtained as follows

$$\begin{pmatrix}m_1 & 0\\ 0 & m_2\end{pmatrix}\begin{pmatrix}\ddot{q}_1\\ \ddot{q}_2\end{pmatrix} + \begin{pmatrix}c_1 + c_2 & -c_2\\ -c_2 & c_2\end{pmatrix}\begin{pmatrix}\dot{q}_1\\ \dot{q}_2\end{pmatrix} + \begin{pmatrix}k_1 + k_2 & -k_2\\ -k_2 & k_2\end{pmatrix}\begin{pmatrix}q_1\\ q_2\end{pmatrix} = \begin{pmatrix}F\\ 0\end{pmatrix}. \qquad (2.164b)$$

This second-order differential equation can be solved and time- and frequency-domain responses can be obtained. Furthermore, this type of problem can be treated as a spring–mass-damping vibration system. Additionally, modern control theory can be introduced to this type of dynamic systems with feedback loops to obtain the desired time- or frequency-domain response.

3. Materials Science and Engineering

Jens Freudenberger, Joachim Göllner, Martin Heilmaier, Gerhard Mook, Holger Saage, Vivek Srivastava, Ulrich Wendt

The chapter is structured into the following main parts. After a short introduction which addresses the term *materials* as it is used in mechanical engineering and sorts out other matters for the sake of space, the first main section, Sect. 3.1, describes the fundamentals of *atomic structure and microstructure* of materials (as defined in the introduction). The following Sects. 3.3, 3.4, 3.5, 3.6 deal with the most important *properties and testing methods* of materials from the viewpoint of mechanical engineers. The last and largest Sect. 3.7 is devoted to the most commonly used *materials in mechanical engineering*.

Materials science and technology is still a relatively young scientific discipline with its roots dating back about half a century. Emerging from the schools in metal physics in Cambridge, Göttingen, Oxford, and Stuttgart amongst others, it is, in essence, a truly interdisciplinary field where people with a classical education in natural sciences, e.g., in (solid-state) physics and (physical) chemistry to mention a few, but also with a solid engineering background, e.g., in chemical or mechanical engineering, come together to develop new materials with improved properties for the ever-increasing demand of our society. Bearing this in mind, the present chapter is not intended to address all these aspects and recent developments in depth; thus, it is

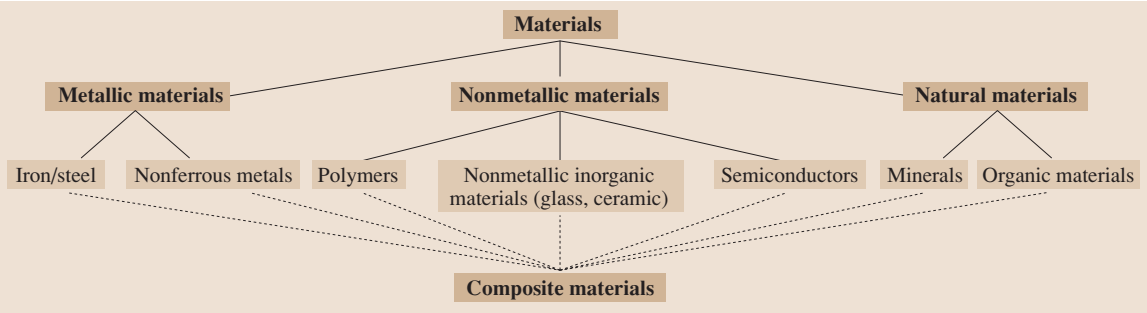

Fig. 3.1 Scheme for the classification of materials

far from being complete. Rather, the authors wanted to give both the novice and the expert a broad but up-to-date overview of those topics of *materials science and technology* that are relevant to the field of *mechanical engineering*.

Though liquids and gases are frequently used in mechanical engineering, e.g., lubricants to reduce friction in tribological applications (Chap. 5) or oils in combustion engines (Chap. 10) the most commonly used definition of materials in mechanical engineering focuses on those in the solid state during their technical application. Still, this broad spectrum requires a further classification, as illustrated in Fig. 3.1, which takes into account the traditional special role of *metallic materials* in mechanical engineering. The term *metallic materials* is used here not only for pure metals, i. e., the metallic elements of the periodic table, but also for *alloys*, which can be created by solving other chemical elements within the crystallographic structure of the base (matrix) element (Sect. 3.2). Metals contrast with *nonmetallic materials* (the second group in Fig. 3.1, in essence comprising *polymers*, *ceramics* and *glasses*, and semiconductors) because of their particular physical properties (see Sect. 3.2.2 for an overview and [3.1] for details). Most importantly, their electrical conductivity is usually several orders of magnitudes larger than in nonmetallic materials while characteristically decreasing with increasing temperature. Further typical metallic properties are their high thermal conductivity, nontransparency to visible light (in bulk form), and a shiny surface, all of which stem from the special electronic structure, i. e., from the *metallic bonding*. For details regarding the peculiarities of the different types of bonding (i. e., *ionic*, *covalent*, and *van der Waals* types) the interested reader should refer to textbooks on solid-state physics or physical chemistry [3.2, 3]. The scheme in Fig. 3.1 is completed with *natural materials*, which can be further subdivided into *minerals* and *organic (natural) materials*. Representatives of the former group are, e.g., *stone* (including *precious stones* such as *diamond*) and *asbestos*, while the latter is essentially comprises *wood* and *rubber*. However, due to their limited importance for mechanical engineering in general, natural materials will not be addressed in the remainder of this chapter.

The group of metallic materials is usually divided into *iron and steel* and *nonferrous metals*. Iron and steel – in essence an alloy of Fe and C – are still the most important structural materials by far to deal with in mechanical engineering. The reason for this importance lies mainly in the availability of raw materials, the sophisticated processing, and the possibility of tuning the mechanical properties within an extremely wide spectrum. Steels will be highlighted in Sect. 3.3.1. However, nonferrous metals are gaining increasing importance in mechanical engineering mainly due to specific properties stemming from their chemistry. Some of the more important ones which will be discussed in more detail later are *light metals* and alloys of aluminum (Sect. 3.3.2), magnesium (Sect. 3.3), titanium (Sect. 3.4), *nickel-based alloys* for high-temperature applications (Sect. 3.5), and *copper* and its alloys for conducting applications (Sect. 3.6). For precious metals (Ag, Au, Pt, Pd) and refractory metals (Mo, W, Nb, Ta) and their properties and fields of applications the interested reader is referred to [3.1].

Of the nonmetallic materials polymers is becoming increasingly important in mechanical engineering, mainly because of its low specific weight and ease of manufacturing. They will be treated in Sect. 3.7.7. Nonmetallic anorganic materials, i. e., glasses and ceramics, are described in Sect. 3.7.9. Finally, combining two or more of the subclasses described before and in Fig. 3.1 leads to the emerging field of *composite materials*. These will be highlighted in a few examples in Sect. 3.3.

3.1 Atomic Structure and Microstructure

3.1.1 Atomic Order in Solid State

While many physical and/or chemical problems should be considered on the atomic level, it may be satisfactory for mechanical engineers to remain on the microstructural level. Therefore, we will discuss in this section the different possibilities of (ideal) atomic arrangements, whereas we introduce the so-called *lattice defects* in the subsequent section. Then, three main categories of atomic arrangement can be distinguished (Fig. 3.2):

- No order (or disordered state), which is the case for inert gases such as argon (Fig. 3.2a), where the interaction between the single atoms is essentially limited to random collisions. Since we focus on materials in the solid state, this will be disregarded in the following.
- Short-range order (SRO) over only a few atomic distances, which can be observed for polar molecules such as water (Fig. 3.2b), but also in polymers (e.g., polyethylene) and glasses; e.g., silica is built of chains of tetrahedrons with a (central) Si atom surrounded by four oxygen atoms (Fig. 3.2c). These materials are, thus, called *amorphous solids* or, in view of the similarity to polar liquids, *undercooled liquids*.
- Long-range order (LRO) requires the atoms to be arranged on a periodic *crystal lattice* (*crystallos* is Greek for *ice*) with – in principle – infinite extension in three-dimensional space where the atoms sit on certain lattice points in such a way that the next neighbor situation is the same for every atom under consideration. An example of a *primitive cubic lattice* is shown in Fig. 3.2d. Such an ideal atomic arrangement is also called *single crystal*. Then, the smallest possible three-dimensional geometrical unit able to reproduce the lattice structure is called the *unit cell* of the corresponding crystal structure with the three unit vectors being the *lattice constants* of the crystal structure. This equilibrium distance of two atoms can then be considered as the result of a superposition of an attractive and a repulsive potential between these atoms.

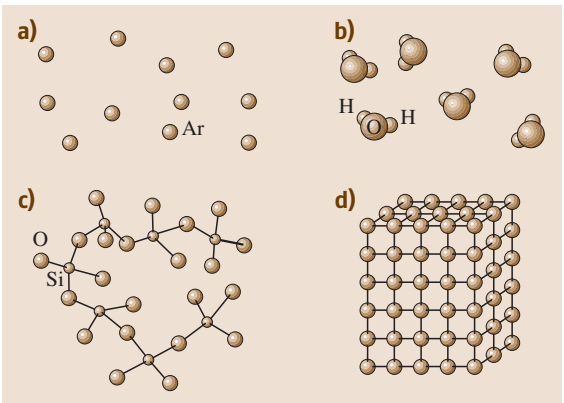

Fig. 3.2a–d Categories of atomic arrangement in materials: **(a)** inert gases have no order, **(b)** and **(c)** polar liquids and amorphous solids show short-range order, **(d)** crystalline materials possess long-range order (of infinite extension)

Amorphous Structures

As pointed out in the previous subsection two important classes of materials, namely glasses and many polymers, exist in the solid state without possessing a long-periodic crystallographic lattice structure: they are amorphous solids, thus, having SRO. Figure 3.3 elucidates how these structures may form upon cooling

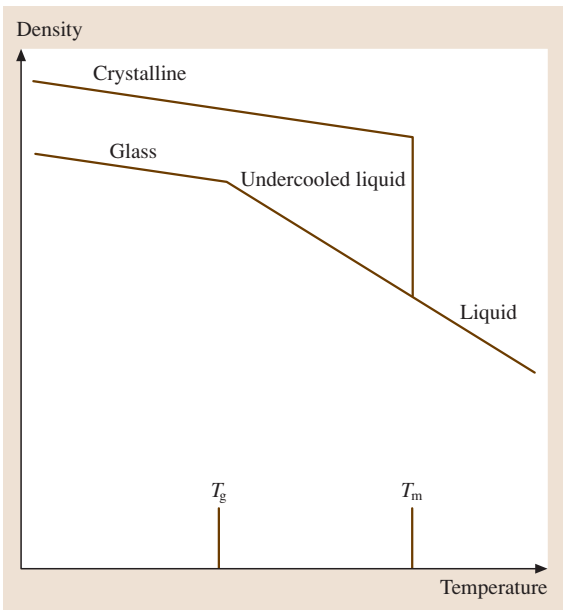

Fig. 3.3 Cooling of a silica melt: crystallization at T_m leads to an abrupt increase in density; if crystallization is suppressed, however, the undercooled melt transforms into a glassy state at T_g and the density–temperature curve shows a bend

from the melt: usually, a liquid starts to form a crystalline solid when it is cooled below the melting point T_m of the material due to crystal nucleation and growth (see Sect. 3.2.3 for details). The crystallization event is accompanied with an abrupt jump in density. If, however, the kinetics for this transition into solid state is too sluggish or the cooling rate is too high, crystallization may be completely suppressed and an undercooled liquid is formed, which eventually transforms below the glass-transition temperature T_g into a glassy state. Note, that the transition from the undercooled liquid into a glassy state (with both structures being *amorphous* and possessing SRO) is a second-order thermodynamic reaction. This expresses itself in Fig. 3.3 as a bend of the curve such that both the crystalline and the glassy state show an identical temperature dependence of density.

An important conclusion can be drawn from Fig. 3.3. Since the glassy state exhibits the lower density, it is in a thermodynamically metastable state (of higher free energy G, Sect. 3.2.3) and will eventually transform into the crystalline structure, i. e., into the thermodynamically stable state (of minimal free energy G_{min}).

Like glasses and polymers some metals can also be solidified into an amorphous structure. However, while simple binary and ternary systems can be produced only in the form of thin metallic ribbons via rapid solidification (requiring cooling rates of up to 10^6 K/s; see [3.4] for a review), multicomponent metallic glassy alloys in bulk form produced by slow cooling from the melt have attracted widespread interest ranging from scientific curiosity about their structure and resulting properties to technological aspects of their preparation and potential applications. Readers interested in the outstanding properties of these new emerging class of advanced metallic materials may be referred to relevant literature [3.5–8].

Crystal Structures

As early as the 19th century the French scientist *Bravais* demonstrated that in three-dimensional space the seven major crystallographic unit cells may be better classified into 14 *Bravais lattices* (Fig. 3.4). The resulting geometric relations between the crystal axes are tabulated in Table 3.1. However, of those listed, most metallic materials used in mechanical engineering crystallize in hexagonal or in cubic form, i. e., in crystal lattice structures with high symmetry.

The most important characteristics of these crystal structures are summarized in Table 3.2. In essence they

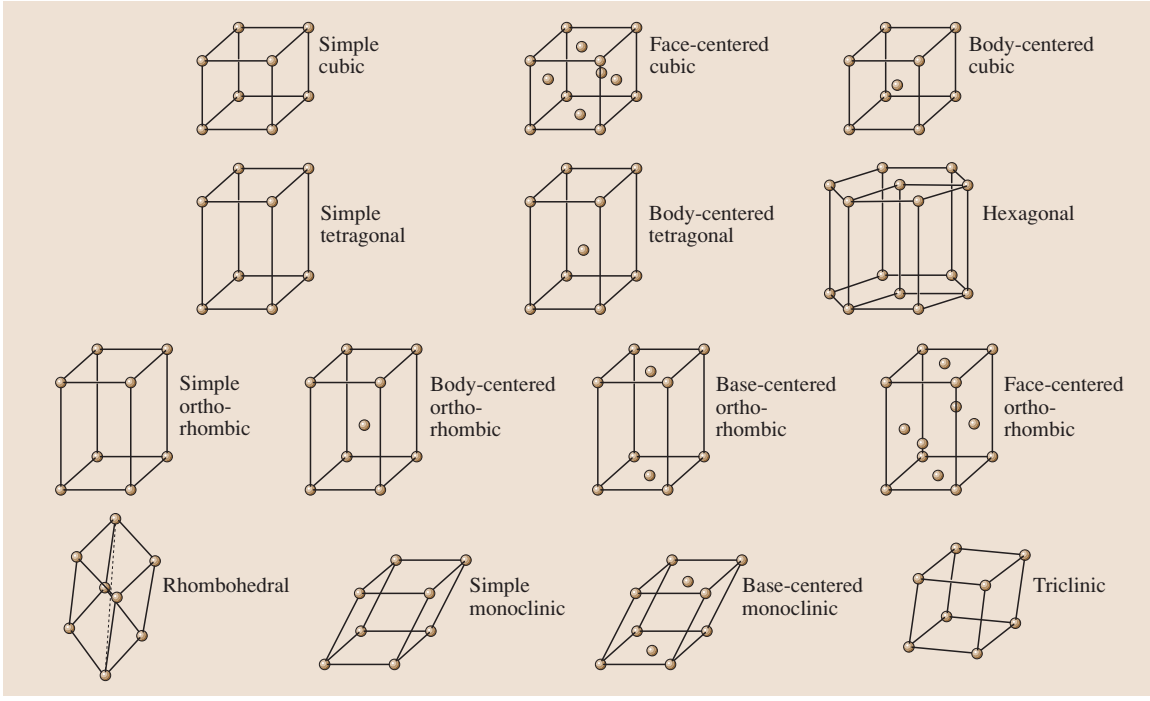

Fig. 3.4 The seven crystal systems and the 14 types of unit cells (Bravais lattices)

Table 3.1 Characteristic relations between crystallographic axes (lattice constants) and angles within the seven crystal systems

Structure	Lattice constants	Angles between axes
Cubic	$a = b = c$	All angles equal 90°
Tetragonal	$a = b \neq c$	All angles equal 90°
Orthorombic	$a \neq b \neq c$	All angles equal 90°
Hexagonal	$a = b \neq c$	Two angles equal 90°. One angle equals 120°
Rhombohedric	$a = b = c$	All angles are equal and none equals 90°
Monoclinic	$a \neq b \neq c$	Two angles equal 90°. One angle (β) is not equal to 90°
Triclinic	$a \neq b \neq c$	All angles are different and none equals 90°

can be distinguished by the number of atoms per unit cell (NA), the coordination number (i. e., the number of nearest neighbors, CN) and the packing density (PD). The latter is defined as $\mathrm{PD} = \mathrm{NA}/V_{\mathrm{uc}}$ (with V_{uc} being the volume of the unit cell) and ranges between 0 and 1.

A comparison of the different crystal structures in Table 3.2 yields that:

1. For the cubic systems, both the coordination number and the packing density increase with increasing number of atoms in the unit cell.
2. CN and PD are identical for face-centered cubic (fcc) and hexagonal crystals, if the ratio of the c- and the a-axis in the hexagonal system is 1.633 (which is nearly the case for the metallic elements Ti, Mg, and Co).

Then, these systems are called *hexagonally closed packed* (hcp) and they can be distinguished from the fcc structures only by the different stacking sequence, which is ABAB... for hcp along the c-axis and ABCABC... for fcc along the space diagonal ⟨111⟩ (in crystallography it is convenient to use the Miller indices for describing lattice vectors and planes; in cubic systems the space diagonal is a ⟨111⟩ direction [3.3]).

Table 3.2 Characteristics of cubic and hexagonal unit cells. NA is the number of atoms per unit cell on regular lattice points, CN is the coordination number, PD is the packing density

Structure	NA	CN	PD
Simple cubic	1	6	0.52
Body-centered cubic (bcc)	2	8	0.68
Face-centered cubic (fcc)	3	12	0.74
Hexagonal	6	12	0.74 (if $c/a = 1.633$)

It is obvious from the comparison in Table 3.2 that even the closed packed crystal structures with space filling of 74% are still far from being fully dense. The open spaces left between regular lattice sites are called *interstitial sites*. They may be filled by atomic species that are significantly smaller than the matrix atoms which build the regular crystal lattice. For cubic systems three different interstitial sites can be distinguished depending on the crystal structure and on the ratio of the radii of the (foreign) interstitial atom r_{ia} and the matrix atom r_{m}, respectively (Fig. 3.5). For relatively large interstitial atoms and $r_{\mathrm{ia}}/r_{\mathrm{m}} = 0.732\ldots1$ these interstitials will likely occupy *cubic interstitial lattice sites* with $\mathrm{CN} = 8$. *Octahedral interstitial sites* with $\mathrm{CN} = 6$ may be filled when $r_{\mathrm{ia}}/r_{\mathrm{m}} = 0.414\ldots0.732$. *Tetrahedral interstitial sites* with $\mathrm{CN} = 4$ provide the least free space and, hence, $r_{\mathrm{ia}}/r_{\mathrm{m}} = 0.225\ldots0.414$. This is technically most relevant since the interstitial carbon atom in the Fe – C alloy system (i. e., *steel*) obeys these empirical rules and favors octahedral sites (largest holes) in the fcc structure, whereas it occupies tetrahedral sites in the body-centered cubic (bcc) structure. The incorporation of carbon atoms at interstitial sites leads to significant elastic lattice distortion and, thus, readily explains the increased strength of steels as compared with pure iron.

Polymorphism

If materials exist in more than one crystal structure depending on temperature and/or pressure they are called *polymorphic*. A more specific term applicable for pure elements is *allotropy*. Two prominent representatives for metallic materials show polymorphism:

1. Iron and steel transforms from the low-T *ferritic* bcc structure into a higher-temperature *austenitic* fcc structure and back to a bcc structure called *δ-ferrite* close to the melting point.
2. Titanium undergoes a transformation from α-hcp structure at low T to a β-bcc structure at high T.

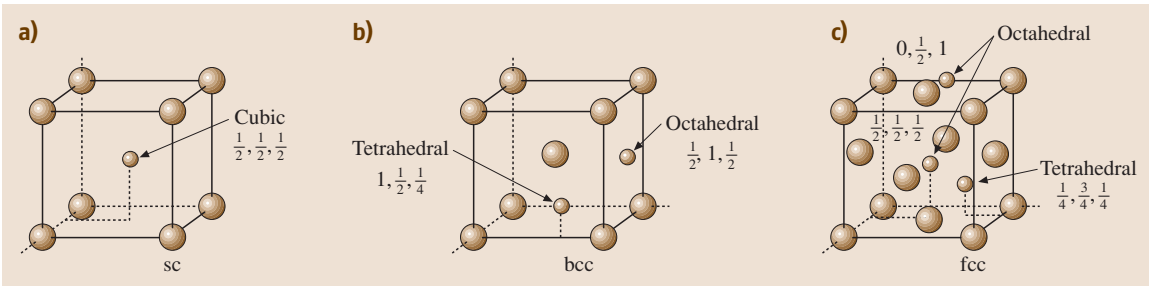

Fig. 3.5a–c Locations of interstitial sites within cubic unit cells: **(a)** simple cubic, **(b)** body-centered cubic (bcc), **(c)** face-centered cubic. The numbers denote the lattice positions of the interstitial sites

Both transformation reactions form the basis for the heat treatment of steels and titanium alloys and, thus, the potential for widely adjusting the properties of these alloy systems; see Sect. 3.3.1 and Sect. 3.7.4, respectively. A further example of polymorphism is the covalently bonded element carbon, which exists in a hexagonal structure of two-dimensional layers called *graphite*, as *diamond* with the open diamond cubic crystal structure (with a PD of only 0.34) and, as recently discovered, in the form of a hollow C_{60} *spherical molecule* called *fullerenes* or bucky balls (the scientists R. F. Curl, H. W. Kroto, and R. E. Smalley received the Noble prize in chemistry in 1996 for this discovery).

Crystal Structures with More Than One Atomic Species

In most cases, technically relevant materials consist of more than one atomic species. Depending on how the different elements mixed with each other, one can classify them into:

1. *Solid solutions*, where the different atomic elements are randomly mixed and placed on the lattice points of the crystal structure. Two subcases may be distinguished:

- Substitutional solid solutions, where the atomic species occupy regular lattice points in a random manner (see also Fig. 3.7c,d). According to *Hume-Rothery* [3.3, 10] this occurs when the elements (e.g., A and B) have comparable atomic radii ($\delta = (r_B - r_A)/r_A < 15\%$) and crystallize in the same structure. A prominent example is the binary alloy system Cu – Ni, which exhibits unlimited mutual solubility.
- Interstitial solid solution, where the smaller atomic species occupy interstitial sites because of the too large a difference in atomic radii between them and the matrix atoms ($\delta > 15\%$) (Fig. 3.7b). The most prominent example is again C in Fe, but this can be generalized for gaseous impurities such as H, O, and N in metals. In contrast to the former case the maximum solubility is much smaller, typically less than 1 at.%, which means that in the case of a bcc lattice only about every 50th unit cell hosts one interstitially solved atom:

2. *Ordered* crystal structures, where the ratio between the atomic species is fixed to small integer numbers. This is called *stoichiometry*. Two categories may be

distinguished here depending on the way how these structures are formed:

- An ordered *superlattice structure* with the same basic crystal structure type may form upon cooling a disordered solid solution. The following example elucidates this scenario: a Cu alloy containing 25 at. % Au has a simple fcc crystal structure temperatures. Upon cooling it transforms into an ordered fcc $L1_2$ crystal structure of type Cu_3Au, where the gold atoms occupy the corner lattice points of the unit cell and the copper atoms sit on the faces of the cube.
- An intermetallic compound made up by two or more elements, producing a new phase with its own composition, crystal structure, and properties substantially different from those of its constituents, namely higher hardness, strength, and melting point but almost always at the expense of a lack of ductility. A recent, technically relevant example are the titanium aluminides (Fig. 3.6) considered for a variety of high-temperature applications, such as automotive valves and turbocharger wheels, and turbine blades and vanes in aerospace engines, as structural materials, mainly because of their attractive combination of high melting point and strength together with low density.

A final point should be noted here: many superlattice structures and intermetallic compounds have a range of compositions (*stoichiometry range*) in which they appear in the same crystal structure as compared with the fixed stoichiometric composition. This is, e.g., the case for both of the TiAl-based intermetallic compounds shown in Fig. 3.6, thus, making alloy property improvement and fine-tuning through addition of further alloying elements more feasible. This *nonstoichiometry* can lead to partial disordering of the atomic arrangement within the unit cell.

3.1.2 Microstructure

The crystal structure introduced in the previous section describes the ideal arrangement of atoms within a solid material and, hence determines several *intrinsic* material properties (e.g., elastic stiffness and compliance constants). However, lattice imperfections, which destroy the infinite extension of the periodic atomic structure, are decisive for many *extrinsic* properties (e.g., the mechanical properties discussed in Sect. 3.2.1). As a result, a real structure containing crystalline areas and a variety of lattice imperfections is called *microstructure*. Lattice imperfections are created and can be controlled during the processing and manufacturing of materials. They can be classified through their dimensionality as follows.

Point Defects

Figure 3.7 provides an overview of the various types of point defects (of zero dimensionality) in materials. Foreign atoms, either solved substitutionally on regular lattice sites (Fig. 3.7c,d) or interstitially (Fig. 3.7b), have already been treated in the previous section. If a lattice site is without an atom, we get a *vacancy* in the

lattice (Fig. 3.7a). From thermodynamics calculations we know that a certain (small) number of vacancies exists in thermal equilibrium. A more detailed treatment [3.11] yields

$$x_V^e = \exp\frac{-\Delta G_V}{RT} = \exp\frac{-(\Delta H_V - T\Delta S_V)}{RT}\,, \quad (3.1)$$

where x_V^e is the equilibrium concentration of vacancies, which follows an Arrhenius-type increase with increasing temperature. At the melting point of the material $x_V^e = 10^{-4}$–10^{-3}, whereas at absolute zero, i. e., 0 K, $x_V^e \equiv 0$. From the above it becomes obvious that vacancies will very likely be introduced into materials upon solidification from the melt. Figure 3.7b–d represents the various types of alloying elements in solid solution which were already treated in the previous section. Two special types of point defects are displayed in Fig. 3.7e and f: *Frenkel defects*, consisting of pairs of vacancy and interstitial atom, can be created upon neutron irradiation (Fig. 3.7e), while *Schottky defects* exist only in ionic crystals as pairs of vacancies formed in the cationic and anionic partial lattice, respectively (Fig. 3.7f).

Solid Solution Strengthening. It has been well known for a long time that introduction of alloying elements into a pure metal increases its hardness. When the difference in size and electronegativity of the alloying element is less than a critical value, the alloying element forms a solution with the matrix. The alloy atoms occupy either lattice sites, leading to a *substitutional solid solution*, or the interstitial voids in the lattice, i. e., *interstitial solid solutions*. Carbon, nitrogen, oxygen, hydrogen, and boron are elements that commonly occupy interstitial sites. Solute atoms interact with dislocations in a number of ways:

- *Par-elastic interaction* due to overlapping strain energy of solute atom and dislocation core. The interaction energy is directly proportional to the size difference between the solute and matrix atoms.
- *Modulus interaction* due to a local change of modulus, thereby affecting elastic energy of the dislocation. This is also called *Di-elastic interaction* in the literature [3.10]. The interaction energy is directly proportional to the difference in shear modulus between the solute and matrix atoms.
- *Stacking-fault interaction* or *Suzuki hardening* due to preferential segregation of solutes to the stacking fault of extended dislocations.
- *Electrical interactions* due to localization of electron cloud, leading to interaction with dislocations with electrical dipoles. This effect is usually smaller than the above mechanisms.

All these interactions require extra energy to be expended to overcome the solute atom, requiring higher stresses for dislocation motion and, hence, give rise to *solid solution hardening*. It may be pointed out that the presence of vacancies, introduced due to rapid quenching or high-energy radiations, also leads to considerable strengthening by some of the above mechanisms. For further details see [3.10].

Dislocations

Independently from each other Orowan, Polanyi, and Taylor introduced the term *dislocations* in 1934 in order to explain the observed strength values and the plastic deformability of materials on a theoretical basis. It should be emphasized here that the existence of these one-dimensional lattice imperfections was proven experimentally more than a decade later with the advent of the first transmission electron microscopes in materials science. To motivate why dislocations are essential in explaining the deformation behavior of materials we first consider the theoretical (shear) strength of materials shown in Fig. 3.8, in which A and B represent sites of stable equilibrium for the atoms within the hexagonal plane. Then a is the displacement required to shift any atom to another stable position, hence, the potential connected with a displacement x of any atom is

$$U(x) = U_0\left(1 - \cos\frac{2\pi x}{a}\right). \quad (3.2)$$

From (3.2) one can obtain the necessary force by differentiating with respect to x

$$F(x) = \frac{\partial U(x)}{\partial x} = U_0\frac{2\pi}{a}\sin\frac{2\pi x}{a}\,. \quad (3.3)$$

The shear stress is simply $\tau = F(x)/A$. For $x \ll a$ and since the sin function is point-symmetric about the origin, one gets from (3.3)

$$\tau \approx \tau_{max}\frac{2\pi x}{a} \quad (3.4)$$

with $\tau_{max} = U_0(2\pi x/aA)$. On the other hand, Hooke's law for simple shear is

$$\tau = G\gamma = G\frac{x}{d}\,. \quad (3.5)$$

Setting (3.4) and (3.5) equal, one obtains for the maximum shear stress

$$\tau_{max} = \frac{G\,a}{2\pi d} = \frac{G\,a}{2\pi\sqrt{3}} \approx \frac{G}{10}\,. \quad (3.6)$$

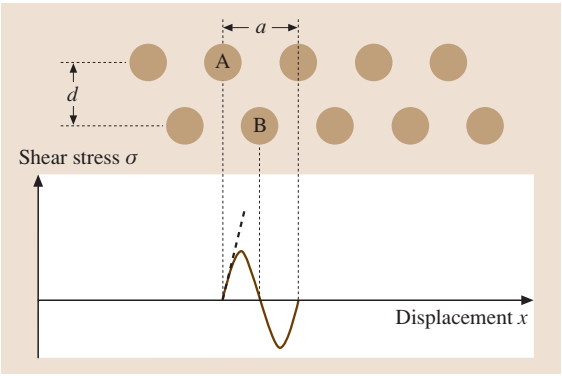

Fig. 3.8 The theoretical strength of crystalline materials: the shear displacement x between two neighboring lattice planes of interplanar spacing d causes a sinusoidal shear stress fluctuation σ. A and B are regular lattice sites, respectively, a is the lattice constant within the hexagonal plane

Thus, the theoretical shear strength τ_{max} is only dependent on the elastic properties of a material, i. e., the shear modulus G. As an example, for pure copper with $G \approx 45\,\text{GPa}$ one gets $\tau_{max} = 4500\,\text{MPa}$. However, in experiments one observes for pure copper single crystals that plastic shearing occurs already at shear stresses below 10 MPa [3.10] (Fig. 3.12). This obvious discrepancy by about three orders of magnitude can be rationalized only when assuming the existence of dislocations which enables plastic shearing by moving this dislocation in a direction $\boldsymbol{r}$ perpendicular to its line (the dislocation line is represented by the vector $\boldsymbol{s}$) through the lattice.

We can identify two basic types of dislocations:

1. *Screw dislocations*, which can be illustrated by cutting halfway through a perfect crystal (Fig. 3.9a) and subsequently skewing the crystal one atomic spacing (Fig. 3.9b,c). If one follows a crystallographic plane one revolution around the axis on which the crystal was skewed, starting at point x and moving an equal number of atomic spacings in each of the four planar directions one ends up one lattice site below the starting point (point y). The vector required to close the loop is called the *Burgers vector* $\boldsymbol{b}$ and represents the unit of plastic shearing of the crystal through the moving of the dislocation line (from

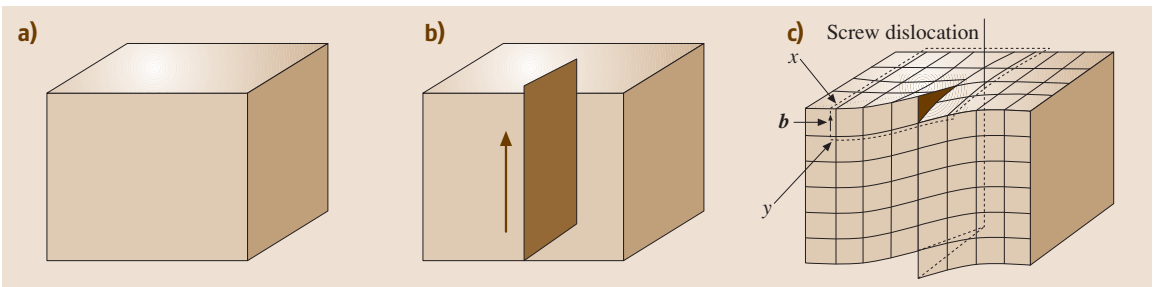

Fig. 3.9a–c A perfect crystal (a) is cut and (b) and (c) sheared by one atomic spacing. The line along which shearing is carried out is a screw dislocation with its Burgers vector $\boldsymbol{b}$ closing a loop of equal atomic spacings around itself

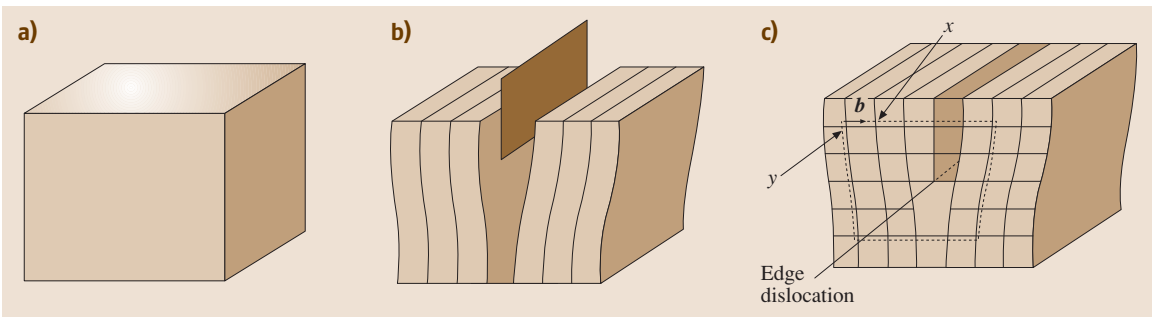

Fig. 3.10a–c A perfect crystal (a) is cut and an extra (half) plane of atoms is inserted (b). The bottom edge of the extra plane is an edge dislocation with its Burgers vector $\boldsymbol{b}$ closing a loop of equal atomic spacings around itself

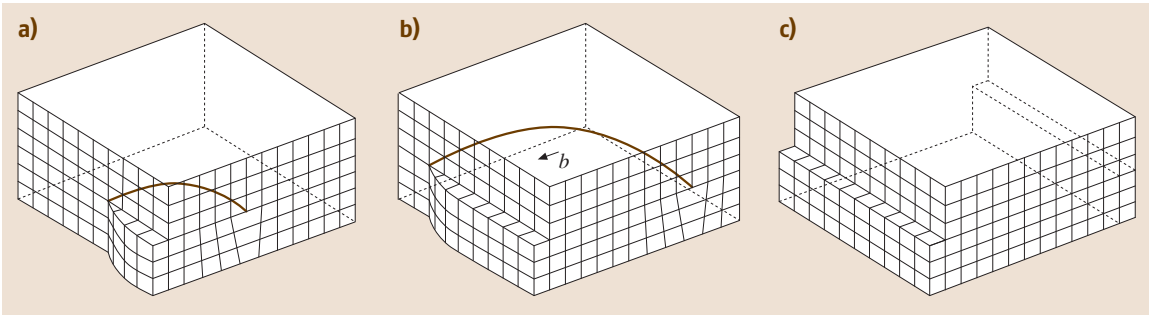

Fig. 3.11a–c Movement of a mixed dislocation through a simple cubic lattice: **(a)** and **(b)** the dislocation character is purely screw-type on the left side and purely edge-type on the right side of the crystal; **(c)** after completion of the movement the dislocation has disappeared and has left a slip step of height b

the front to the back in Fig. 3.9c). Hence, in screw dislocations $\boldsymbol{b} \parallel \boldsymbol{s} \perp \boldsymbol{r}$.

2. *Edge dislocations*, which can be illustrated by slicing halfway through a perfect crystal (Fig. 3.10a), tearing the crystal apart and inserting an extra (half) plane of atoms into the cut (Fig. 3.10b). The bottom edge of this inserted plane represents the edge dislocation (Fig. 3.10c). A clockwise loop, starting at point x and going an equal number of lattice sites into each direction within the plane finishes at point y, hence leaving the required Burgers vector $\boldsymbol{b}$ to close the loop in Fig. 3.10c. For edge dislocations $\boldsymbol{r} \parallel \boldsymbol{b} \perp \boldsymbol{s}$.

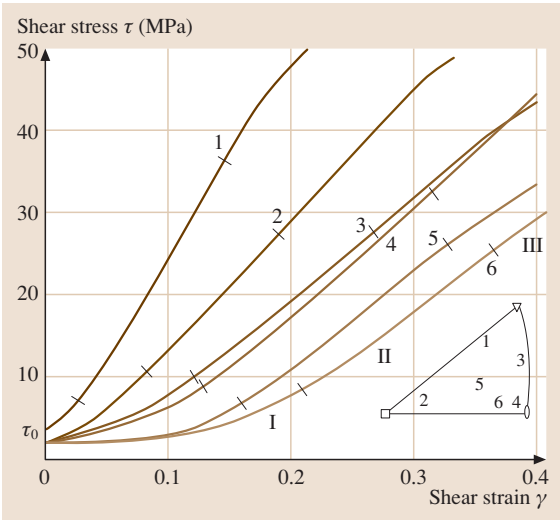

Fig. 3.12 Shear stress versus shear strain curves for differently oriented copper single crystals at room temperature. Samples 1–6 are oriented within the standard orientation triangle as depicted

The more general case of a dislocation with *mixed* character when $\boldsymbol{b}$ is neither parallel nor perpendicular to $\boldsymbol{s}$ is plotted in Fig. 3.11. Likewise, one notes from Fig. 3.11 that pure screw or edge configurations can be considered the extremal cases of the general mixed configuration for either $\boldsymbol{b} \parallel \boldsymbol{s}$ or $\boldsymbol{b} \perp \boldsymbol{s}$.

From the above the following important conclusions can be drawn:

- The dislocation line is the border between the undeformed and the slipped area of the crystal plane.
- Dislocations cannot end within a crystal: they either have to form a loop or penetrate an internal (e.g., grain or phase boundaries, see below) or external surface.
- Dislocations exhibit a long-range three-dimensional stress field within the crystal lattice, allowing them to interact with all kinds of other lattice imperfections. This feature is the basis for the various approaches of strengthening materials in metallurgy.
- Dislocations are the carrier of plastic (i. e., irreversible) deformation in crystalline materials.
- The slip system of a dislocation in crystalline materials is composed of:

1. A close packed slip plane
2. A close packed slip direction which is identical with $\boldsymbol{b}$

The Burgers vector must be contained within the slip plane. Both, slip plane and slip direction depend on the lattice structure of the material.

Similarly as for the grain boundaries explained below, dislocations are created in crystals during solidification due to thermal stresses arising from the density mismatch between the liquid phase and the solid phases.

Hence, the creation of a dislocation within a crystal increases the (total) free energy of the system. A satisfactory approximation for the dislocation line energy is

$$E_\rho = \frac{1}{2} G b^2 \,. \tag{3.7}$$

Equation (3.7) reveals that the dislocation line energy is an *intrinsic* materials property, depending only on crystal lattice parameters. Experimentally, dislocations can be detected either via optical microscopy as *etch pits* stemming from the penetration points of the dislocation lines through the crystal surface or via transmission electron microscopy (TEM), where the slight lattice distortions caused by the dislocations gives rise to a contrast visible in the TEM; see [3.12] for details. For explaining the strength and deformability of materials it is useful to introduce the dislocation density for the number of dislocation per unit volume as

$$\rho = \frac{\text{dislocation line length}}{\text{unit volume}}$$

$$= \frac{\text{number of dislocations}}{\text{unit area}} \,. \tag{3.8}$$

As an example for well-annealed metals $\rho = 10^9 - 10^{11}\,\mathrm{m}^{-2}$, whereas for ceramics and semiconductors $\rho = 10^4 - 10^{10}\,\mathrm{m}^{-2}$.

Strain Hardening. Strain hardening is caused by interaction of dislocations with each other. During plastic deformation, e.g., cold working, the number of dislocations increases with increasing strain to values of $\rho = 10^{14} - 10^{16}\,\mathrm{m}^{-2}$. Similarly, an increase of dislocation density is connected with tensile straining. An example for the stress–strain behavior of Cu single crystals with different crystallographic orientations with respect to the loading axis is depicted in Fig. 3.12. The *flow curve* comprises three stages:

1. Stage I or *easy glide*
2. Stage II or *dislocation pile-ups*
3. Stage III or *dynamic recovery*

Stage I is observed only in well-annealed crystals oriented such that only one slip system is operative, cf. curves 5 and 6 in Fig. 3.12. Stage II dominates the flow curve of most engineering polycrystalline alloys and measurements over a wide range show that

$$\sigma_\rho = \sigma_\mathrm{i} + \alpha G b \sqrt{\rho} \,, \tag{3.9}$$

where α is a numeric constant (typically ≈ 0.3). Equation (3.9) is also referred to as Taylor's relation and originates from the interaction of the stress fields of dislocations (long-range interaction) or from dislocations cutting due to intersecting slip systems. The strain hardening rate during stage II is fairly insensitive to temperature and/or impurities. On the other hand, the region of dominance of stage III, *dynamic recovery*, is strongly temperature dependent. For further details see, e.g., [3.13].

Grain Boundaries

Grain boundaries are two-dimensional lattice faults. Like vacancies and dislocations they are created during manufacturing of materials, as can be exemplified with metallic materials upon solidification from the amorphous (or disordered) melt (Fig. 3.13a). When decreasing the temperature of the melt below the liquidus temperature (Sect. 3.1.2) nuclei that have the crystal structure of the solid are formed within the liquid and

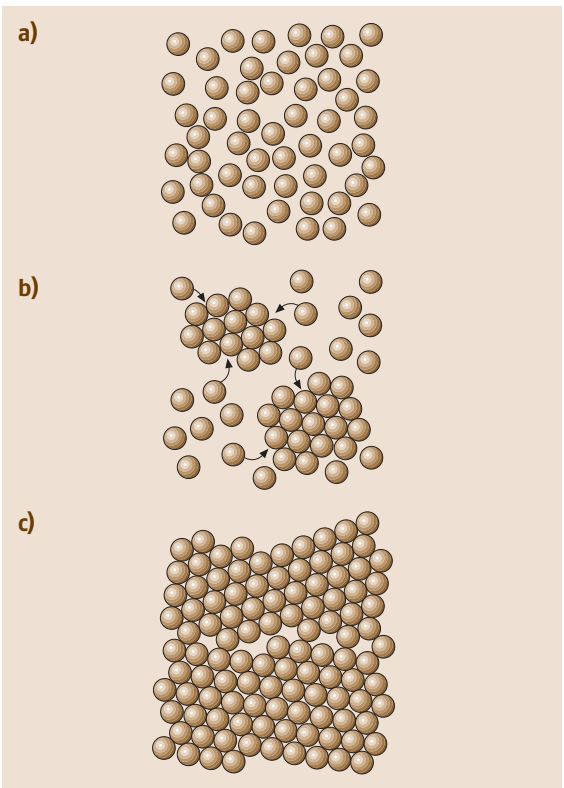

Fig. 3.13a–c The development of grains and grain boundaries upon solidification from the melt: **(a)** amorphous melt, **(b)** two crystals begin to nucleate within the liquid melt, **(c)** a grain boundary has been created between the two crystallites of different crystallographic orientation

grow with continuing time and cooling (Fig. 3.13b). When T falls below the solidus temperature the material has solidified completely and adjacent grains with the same crystal lattice but different crystallographic orientation (Fig. 3.13c) do not fit perfectly to each other. The narrow zone where the atoms are not properly spaced is called a *grain boundary*. Typically, $d_{gb} = 0.5$ nm is a good estimate for the grain boundary thickness.

Fine Grain Strengthening. One important method of controlling the properties of a material is to adjust the grain size. By reducing the grain size, the number of grains and hence the fraction of grain boundaries is increased. If mechanical properties are concerned, any dislocation that moves within a grain is stopped when it encounters a grain boundary. The mean free path of dislocations is, thus, limited by the grain size and the strength of the metal is increased. The famous Hall–Petch relation relates the grain size to the yield strength at room temperature [3.15, 16]

$$\sigma_y = \sigma_0 + K_y d_{gb}^{-1/2} , \qquad (3.10)$$

where σ_y is the yield strength (Sect. 3.2.1), $d_{gb}^{-1/2}$ is the inverse square root of grain size, preferentially measured as mean intercept length (3.44) in Sect. 3.2.3, and σ_0 and K_y are constants for material (σ_0 is often related to the *Peierls stress* in crystallographic slip [3.10]). Figure 3.14 shows the relationship according to (3.10) for some steels.

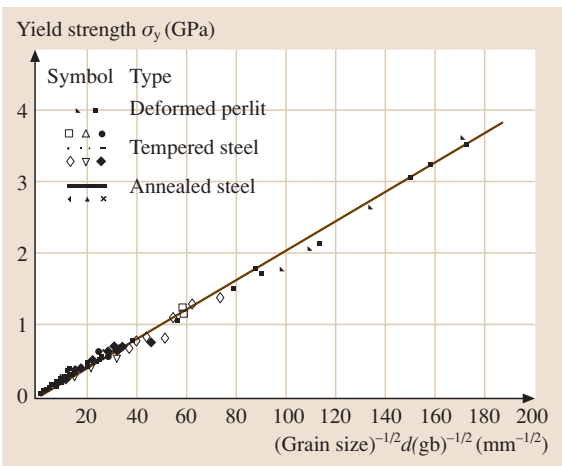

Fig. 3.14 Dependence of yield strength σ_y on the inverse root of the grain size, $d_{gb}^{-1/2}$, in steel (after [3.14])

Optical or scanning electron microscopy (SEM) can be used to reveal microstructural features such as grain boundaries (Sect. 3.2.3) and to assess the grain size of materials quantitatively.

Dispersoids and Precipitates

When the solubility of a material is exceeded for any alloying element, a second phase forms in the volume and a two-phase alloy is produced. Hence, second-phase particles such as *dispersoids* or *precipitates* are classified as three-dimensional lattice imperfections. The continuous phase that surrounds the particles and is usually present in a larger fraction, is called the *matrix*. The boundary between the two phases is an internal surface or *interface* at which, as for the grain boundaries in the previous section, the atomic arrangement is not perfect. Again, this boundary impedes the slip of dislocations and, thus, strengthens the material.

Dispersion and Precipitation Strengthening. Two types of second-phase particles can be distinguished. In *dispersion strengthening*, hard particles are introduced into the matrix using powder metallurgical techniques or through solid reactions. These particles are in essence insoluble in and *incoherent* (Fig. 3.15a) with the matrix. *Precipitation strengthening* or *age hardening* is produced through a series of heat treatments that exploit the decrease in solubility of a given solute with decreasing temperature. This requirement for elevated temperature solubility places a limitation on the number of useful precipitate-strengthened alloy systems. Due to their insolubility within the metallic matrix, dispersion-hardened alloys are stable up to temperatures relatively close to the melting point of the matrix, in contrast to precipitate-strengthened alloys which are degraded upon prolonged exposure to high temperature due to *precipitate coarsening*, i. e., *Ostwald ripening*. Nevertheless, precipitation hardening due to very small *coherent* particles (2–10 nm, Fig. 3.15b) is a very efficient strengthening mechanism. Fine particles can act as barriers to dislocation motion either by requiring the dislocations to shear them or by acting as strong impenetrable particles, forcing dislocations to bypass them. When the particles are small and/or soft they get sheared and the following mechanisms contribute to the strength increment:

- *Coherency strain*, arising from the strain field resulting from mismatch between particle and the matrix.
- *Stacking fault energy* variation between matrix and particles, which leads to local variation in the stacking fault width.

- If the precipitates have an *ordered structure*, as in many Ni-based superalloys (Sect. 3.7.5), motion of dislocation through them introduces antiphase boundaries (APB).
- A difference in *local modulus* of the particle and matrix alters the energy of the dislocation passing through the particle. Likewise, voids counterintuitively can contribute significantly to strength through this mechanism.
- As dislocations pass through a precipitate a step, which is one Burgers vector high, is produced. This raises the particle–matrix *interfacial energy*, contributing to strengthening.
- Finally, there is a strengthening contribution due to difference in lattice friction stress or Peierls stress in particle and matrix.

For larger (incoherent) precipitates or dispersion strengthened alloys, Orowan proposed a mechanism for particle overcoming, as illustrated in Fig. 3.16. In essence, the strength increase is related to the increase of dislocation line length when the dislocation deposits a loop around the particle after bypassing it (Fig. 3.16d). The critical situation for bypassing is reached when the dislocation line possesses its maximum curvature around the particle, i. e., the half-circle. According to Fig. 3.17 one obtains for the critical configuration for dislocation bypassing ($\theta \to 0°$)

$$F = \frac{\tau b}{l} = 2E_\rho = Gb^2 \,. \tag{3.11}$$

Solving (3.11) for τ one obtains the strength increase due to Orowan bypassing

$$\tau_{OR} = \frac{Gb}{l} \,. \tag{3.12}$$

Since the particle spacing l is not directly extractable from microstructure analysis (Sect. 3.2) the following more useful expression has been established for the strength increment from Orowan bypassing which also takes into account the conversion of the shear stress τ into a normal stress σ via the Taylor factor $M = \sigma/\tau$

$$\sigma_{\mathrm{OR}} = 0.8MGb\frac{\sqrt{f}}{r} \,, \tag{3.13}$$

where f is the volume fraction of particles present in the material and r is the (directly measurable) particle radius. For a detailed review on the various types of particle strengthening sketched above see [3.17].

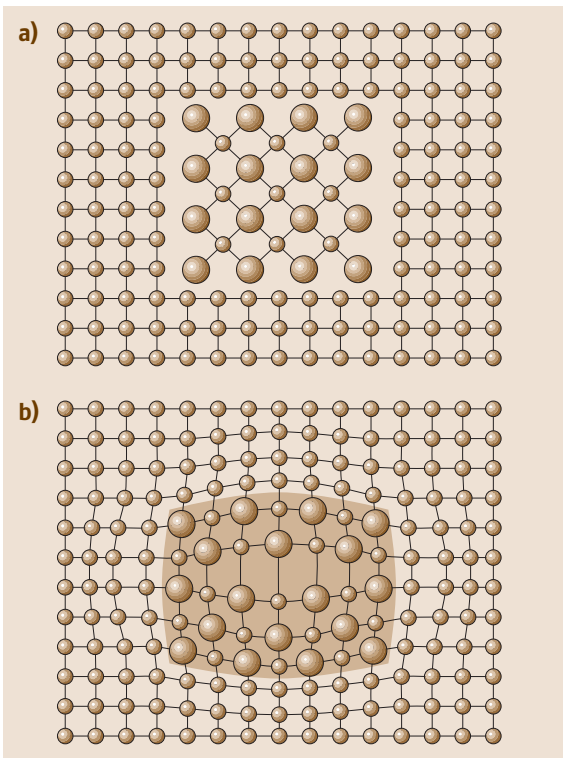

Fig. 3.15 **(a)** An incoherent second-phase particle has no crystallographic relationship with the structure of the surrounding matrix; **(b)** coherent precipitates show a definite crystallographic relationship with the matrix

3.1.3 Atomic Movement in Materials

The movement of atoms (or molecules) within materials (or liquids) is called *diffusion*. It is emphasized here

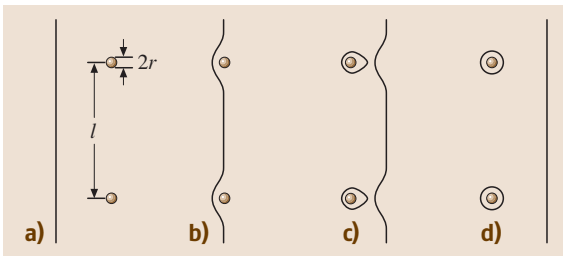

Fig. 3.16a–d Scheme of dislocation bypassing of fine nonshearable particles by Orowan bowing: driven by shear stress τ, a dislocation approaches an array of (two) particles with radius r separated by a distance l **(a)**. It bows out between the particles **(b)**, until it deposits loops around them **(c)**. After by-passing the dislocation line remains unchanged **(d)**

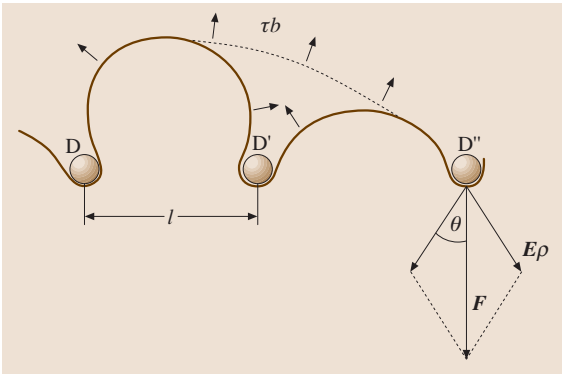

Fig. 3.17 Bowing out of a dislocation line between an array of impenetrable incoherent particles (designated D, D′, D″) with spacing l due to a shear force (per unit length of dislocation) τb. The obstacle force acting against bypassing is F

that diffusion can take place without a superimposed mechanical stress just by random movement of atoms, provided that enough thermal energy is introduced into the system. Vice versa, as for the concentration of vacancies, (3.1) in Sect. 3.1.2, atoms in crystalline solids are at rest only at absolute zero. The driving force behind this movement is usually a gradient in concentration of atoms according to

$$j_D = -D\,\mathbf{grad}\,c = -D\frac{\partial c}{\partial x}\,, \qquad (3.14)$$

where the latter fraction is the *concentration gradient* in the simplified case for one-dimensional atom movement. Equation (3.14) is called *Fick's first law* and is visualized in Fig. 3.18. j_D is the flux of atoms through a plane of unit area per unit time, and D is the *diffusion coefficient* (m^2/s).

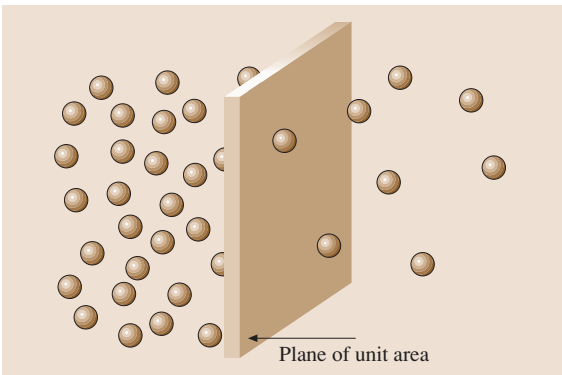

Fig. 3.18 The flux j_D during diffusion is defined as the number of atoms passing through a plane of unit area per unit time

Consider now a sheet of nickel and copper bonded to each other (Fig. 3.19a) the steep concentration gradient at the contact surface will cause continuous mutual diffusion of both atomic species to either side (Fig. 3.19b) until eventually an equilibrium concentration is attained (Fig. 3.19c). The kinetics, i. e., the velocity of this interdiffusion process is triggered by the absolute temperature T according to an Arrhenius law

$$D = D_0 \exp\left(-\frac{Q}{RT}\right). \qquad (3.15)$$

D_0 is a constant prefactor and – in essence – an intrinsic material parameter, $R = 8.314\,\mathrm{J mol^{-1} K^{-1}}$ is the gas constant and Q is the activation energy required for the atom to carry out a single jump event. In crystalline solids, as pointed out in Sect. 3.1.2, two mechanisms of atom movement are conceivable depending on the size ratio δ of solute and matrix atom (Sect. 3.1.1):

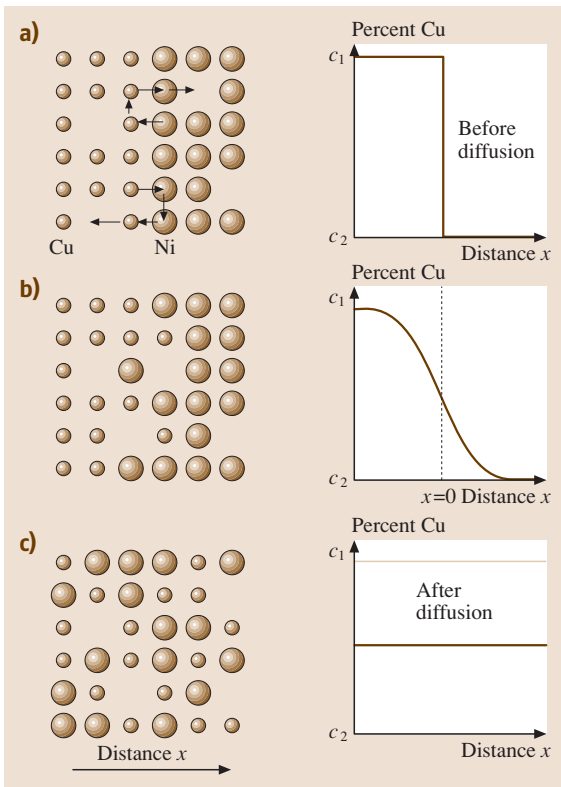

Fig. 3.19a–c Mutual diffusion of copper and nickel atoms into each other through a vacancy mechanism: **(a)** $t = 0$, **(b)** $t > 0$, intermediate time, **(c)** $t \to \infty$

- $\delta < 0.15$: this is the case for self-diffusion and diffusion of substitutionally solved atoms and requires the presence of a vacancy next to the lattice site of the moving atom (see the upper part of Fig. 3.20). After the jump the atom has created a new vacancy at the original lattice site, hence, one observes a countercurrent flow of atoms and vacancies. Consequently, this mechanism is also called *vacancy diffusion*. Since this diffusion mechanism requires the presence of vacancies, its activation energy Q_v is composed of two terms, namely one for the formation of vacancies, Q_f, and one for their migration, Q_m, hence $Q_v = Q_f + Q_m$ replaces Q in (3.15) for self-diffusion or vacancy diffusion.
- $\delta > 0.15$: this is the case for (small) interstitial atoms moving from one interstitial site to another. No vacancies are required for this mechanism and the activation energy for *interstitial diffusion*, Q_i, accounts for the migration of interstitials and is therefore smaller than its counterpart for vacancy diffusion Q_v (Fig. 3.20). For interstitial diffusion Q_i substitutes for Q in (3.15).

Examples for the temperature dependence of the diffusion coefficient according to (3.15) are given in Fig. 3.21 in the form of an Arrhenius-type plot of ln D versus the reciprocal temperature $1/T$. One notes the following characteristic features:

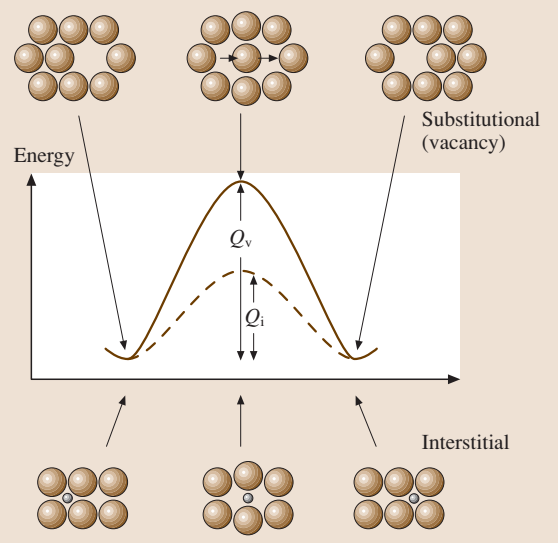

Fig. 3.20 Visualization of diffusion mechanisms in crystalline solids: *top* vacancy diffusion with activation energy Q_v, *below* interstitial diffusion with activation energy Q_i

1. The slope of the curves is a measure for the activation energy Q, with a steeper slope indicating a higher value of Q.
2. As anticipated from Fig. 3.20, interstitial diffusion is considerably faster than vacancy diffusion, cf. the curves for Fe self-diffusion with those of carbon and hydrogen diffusion in iron.
3. The lower packing density (PD) of the bcc crystal structure as compared with the fcc or hcp structure (Table 3.2) gives rise to a higher diffusivity D.

This holds for Fe as well as for Ti, which undergoes an allotropic transformation from hcp α-Ti to bcc β-Ti at 882 °C.

The scenario depicted in Fig. 3.19 is typical for many engineering applications of diffusional processes such as heat treatment of materials for equilibrating concentration inhomogeneities stemming from alloy solidification, joining operations. Figure 3.19 can be considered as an exemplification of diffusional bonding, or consolidation of metallic and/or ceramic powder particles through solid-state sintering (*powder metallurgy*). Fick's first law (3.14) is unable to describe the local and temporal distribution of atoms during different time stages of diffusion, e.g., the concentration profile shown in Fig. 3.19b. However, as the number of atomic species in the system remains constant

$$\frac{\partial c}{\partial t} + \operatorname{div} j_D = 0 \tag{3.16}$$

and with (3.14) one obtains finally after some manipulations (see [3.11] for a detailed derivation) Fick's second law (in its one-dimensional form)

$$\frac{\partial c}{\partial t} = D\frac{\partial^2 c}{\partial x^2}\,, \tag{3.17}$$

whose solution depends on the specific boundary conditions of the diffusion problem. For the scenario depicted in Fig. 3.19 (*diffusion bonding* of two semi-infinite rods of different metals) one obtains

$$\frac{c(x,t) - c_1}{c_2 - c_1} = \frac{1}{2}\left[1 + \operatorname{erf}\left(\frac{x}{2\sqrt{Dt}}\right)\right] \tag{3.18}$$

with erf(ξ) being the *error function* (also called the *Gaussian probability integral*), which can be solved only numerically. Note that the error function is point-symmetric with respect to the origin and $-1 \le \operatorname{erf}(\xi) \le 1$ for $-\infty \le \xi \le \infty$. Equation (3.18) reveals that, for obtaining a certain given concentration c_0 at depth x_0 both, temperature (via D) and time t can be varied independently to design an optimum heat treat-

ment in view of the availability of appropriate furnaces as well as cost of operation. The most prominent application of diffusional problems is the carburization of steels, for which solutions similar to (3.18) are available in literature [3.11].

3.1.4 Transformation into Solid State

In Sect. 3.1.2 we have already noted that the solidification process of materials critically influences the microstructure in general, and the amount of dislocations and grain boundaries in particular. While physical (PVD) and chemical (CVD) vapor deposition techniques on (cold) surfaces become increasingly important in thin-film technologies, the main and most important phase transformation in metallic materials, semiconductors, and glasses in terms of both mass production and annual turnover is still by far solidification from the melt (*cast metallurgy*). This phase transformation can be quantitatively treated by applying the principles of thermodynamics. Hence, in this section we will introduce the basic thermodynamic concepts focusing on the behavior of pure materials, in other words a single-component *system*, a material that can exist as a mixture of one or more phases. A *phase* can then be defined as apportion of the system whose properties and composition are homogeneous and which is physically different from other parts of the system. The *components* are the different (chemical) elements which make up a system, and the composition of a phase or the system can be described by giving the relative amounts of each component.

Consequently, the subsequent sections show how solidification occurs in alloys and multiple-*phase* systems and the main species of binary phase diagrams are derived.

The reason why a transformation occurs at all is because the initial state of the material is unstable relative to the final state. This scenario can be expressed by thermodynamics principles (at constant temperature and pressure p) through the Gibbs free energy G of the system

$$G = H - TS\,, \tag{3.19}$$

where H is the enthalpy, i. e., the heat content arising (to a good approximation for condensed matter) from the total kinetic and potential energies of the atoms, and S is the entropy, i. e., a measure of the randomness of the system.

A system is in *equilibrium* when it is in its most stable state. This translates (3.21) for a closed system (of fixed mass and composition) at constant T and p

into

$$dG = 0\,. \tag{3.20}$$

From (3.19, 3.20) one can intuitively conclude that the state with the highest stability will be the one with the best compromise between a low value of H and a high entropy. Thus, at low temperatures, solid phases are most stable since they have the strongest atomic binding and, hence, lowest enthalpy. At higher temperatures, however, the $-TS$ term in (3.19) dominates over H and phases with increasingly larger degree of atom movement become stable: first liquids and then gases. This is elucidated in Fig. 3.22 where the intersection of the curves with the ordinate is a measure of the enthalpy of the respective phases and the slope of the curves represent the entropy.

Homogeneous Nucleation

Undercooling a liquid below its equilibrium temperature T_m yields a driving force for solidification $\Delta G = (G_S - G_L) < 0$, so one might expect the melt to solidify spontaneously. However, this is not the case and liquids can be supercooled by more than a hundred Kelvin below T_m without crystallization [3.5–8] when a nucleus of solid matter has to be formed within the homogeneous liquid. The change in free energy of the system ΔG_{cryst} when producing a solid sphere of radius r within the liquid for a given undercooling ΔT consists of two terms

$$\Delta G_{cryst} = -\frac{4}{3} r^3 \pi \Delta G + 4r^2 \pi \gamma_{SL}, \tag{3.21}$$

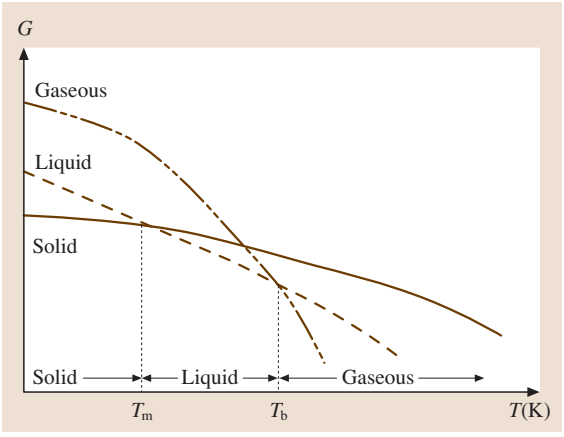

Fig. 3.22 Differences in molar free energy ΔG between solids, liquids, and gases in a single-component system (pure material). T_m and T_b denote the melting and boiling point, respectively

of which the first term, ΔG_V, is the gain in energy due to the formation of a spherical volume of crystalline solid and the second term, ΔG_O, is the expenditure of energy due to the formation of the interface of specific interfacial energy γ_{SL} between the liquid and solid phases. The individual terms ΔG_V and ΔG_O are plotted together with the sum curve ΔG_{cryst} as a function of crystal radius r in Fig. 3.23.

The critical radius $r*$ of a stable nucleus of crystalline solid is reached when further growth of the nucleus leads to a gain in ΔG_{cryst}. Mathematically, this is obtained for the first derivative of ΔG_{cryst} in (3.21) with respect to r

$$\frac{\partial \Delta G_{cryst}}{\partial r} = 0 = -4r^{*2}\pi \Delta G + 8r^* \pi \gamma_{SL}\,. \tag{3.22}$$

Solving (3.22) yields for the critical radius

$$r^* = \frac{2\gamma_{SL}}{\Delta G} \tag{3.23}$$

and for the excess free energy

$$\Delta G^* = \frac{16\pi \gamma_{SL}^3}{3(\Delta G)^2}\,. \tag{3.24}$$

Since ΔG is proportional to the undercooling ΔT, (3.23, 3.24) straightforwardly demonstrate that small undercoolings require a large amount of ΔG^* and the

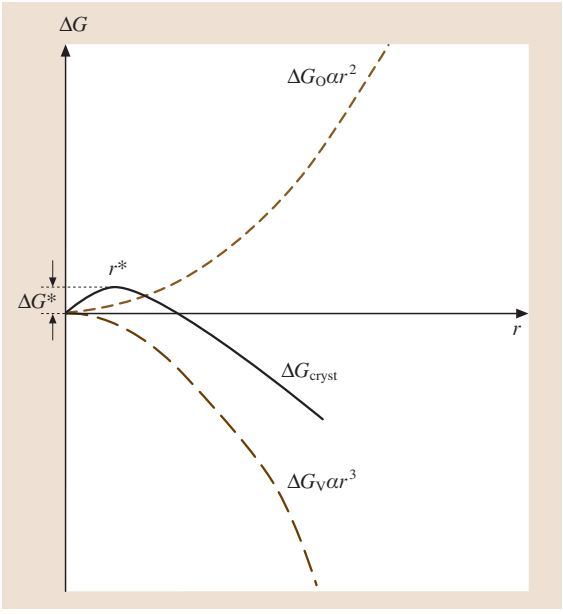

Fig. 3.23 Free-energy change associated with homogeneous nucleation of a sphere of radius r

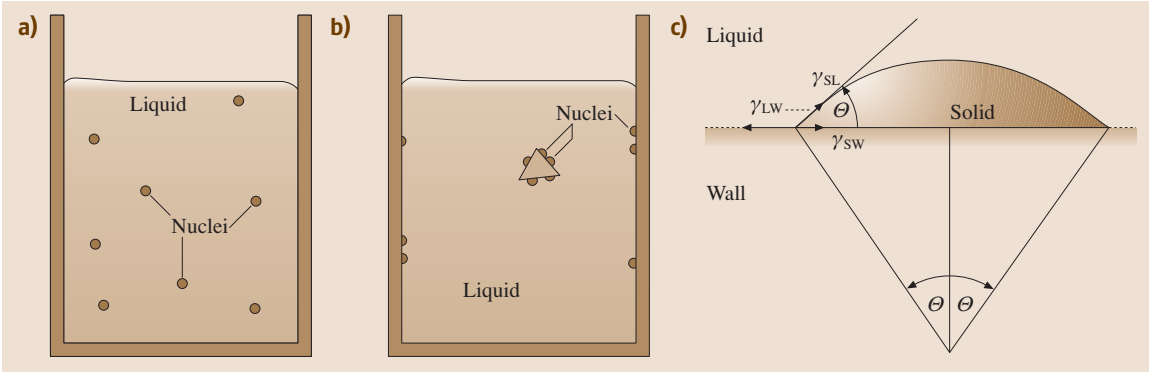

Fig. 3.24a–c Homogeneous (a) versus heterogeneous nucleation ((b), (c)): a spherical cap of a solid needs fewer atoms to become a stable nucleus than a sphere, see text

formation of large cluster of atoms for a stable nucleus. Vice versa, for large undercoolings, nuclei with a small critical radius are already stable within the melt and can grow.

Heterogeneous Nucleation

From (3.26) for ΔG^* it is obvious that nucleation can become easier if the interfacial energy term is reduced. This is effectively achieved if the nuclei form in contact with the mould wall (or likewise, impurities within the melt). Consider a solid embryo in contact with a perfectly flat mould wall (Fig. 3.26b,c). For a given volume of solid the total interfacial energy of the system can be minimized if the condition

$$\gamma_{LW} = \gamma_{SW} + \gamma_{SL} \cos \Theta \qquad (3.25)$$

is fulfilled in the plane of the mould wall. The embryo has the shape of a spherical cap with radius r and a wetting angle Θ. *Porter* and *Easterling* [3.11] compared this situation with that ofa sphere with same radius r which undergoes homogeneous nucleation (Fig. 3.24a) and derived the following relation for the energy barrier for heterogeneous nucleation

$$\Delta G^*_{het} = \frac{16\pi\gamma_{SL}^3}{3(\Delta G)^2} S(\Theta) , \qquad (3.26)$$

where

$$S(\Theta) = \frac{(2+\cos\Theta)(1-\cos\Theta)^2}{4} . \qquad (3.27)$$

Except for the shape factor $S(\Theta)$, (3.26) is the same as the relation obtained for homogeneous nucleation (3.24). Since $S(\Theta) \leq 1$ and the critical radius $r*$ is unaffected, heterogeneous nucleation is always energetically favored over homogeneous nucleation and, thus, also the rate of heterogeneous nucleation becomes faster [3.11]. If, for example, $\Theta = 10°$, $S(\Theta) \approx 10^{-4}$ and the energy barrier for heterogeneous nucleation becomes dramatically smaller than that for homogeneous nucleation. Even for the upper limit $\Theta = 90°$ (half sphere), $S(\Theta) = 0.5$.

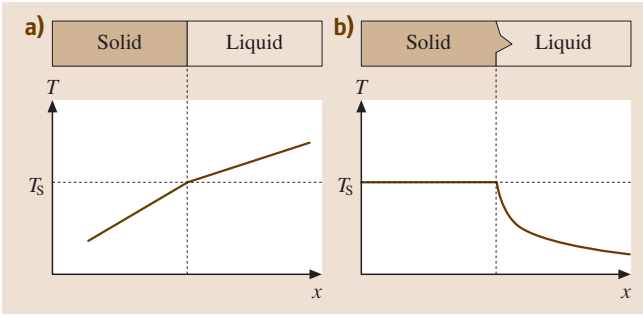

Fig. 3.25a,b Temperature distribution for solidification and the form of the solid–liquid interface when the heat is conducted through (a) the solid and (b) the liquid

Heat Flow and Interface Stability

Neglecting the effect of alloying, solidification is controlled by the rate at which the heat of crystallization is conducted away from the solid/liquid interface. Two options are conceivable:

1. If the solid grows with a planar interface into a superheated liquid (Fig. 3.25a), the heat flow away from the interface through the solid must balance that from the liquid plus the heat of crystallization generated at the interface. Then, a small branch of solid protruding into the liquid will arrive in a region of increased temperature. Consequently, more heat will be conducted into the protruding solid and less

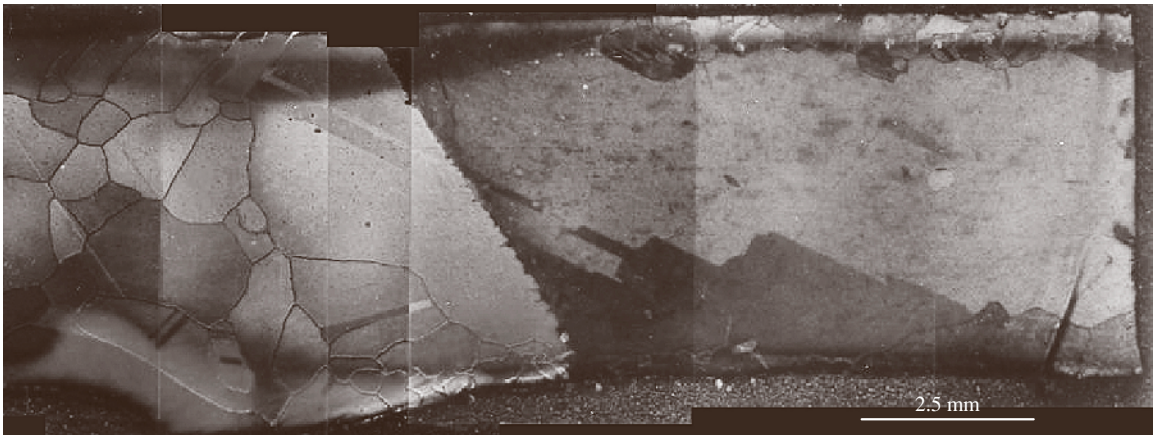

Fig. 3.26 Microstructure of a Ni−Cr20 alloy produced by zone melting

heat will be transported away such that the growth rate will slow down below that of the surrounding planar region and the protrusion will eventually disappear and the solid–liquid interface remains planar. Heat conduction through the solid, as depicted in Fig. 3.25a, can be promoted when solidification takes place from the cooler walls of the mould. This effect is applied technically by using a cold plate or a zone melter to apply a temperature gradient for producing microstructures consisting of coarse and elongated grains or even single crystals. An example for a Ni − Cr20 alloy is shown in Fig. 3.26: starting from the left side with coarse, but equiaxed grains the temperature gradient causes a single dominant grain to grow preferentially towards the right of the sample.

2. If the solid grows into a supercooled liquid (Fig. 3.25b), an eventual protrusion of the solid into the liquid is forced to grow more rapidly by the negative temperature gradient in the liquid because the heat is removed more efficiently from the tip of the protrusion than from the surrounding regions. Thus, a solid–liquid interface advancing into a supercooled liquid is inherently unstable.

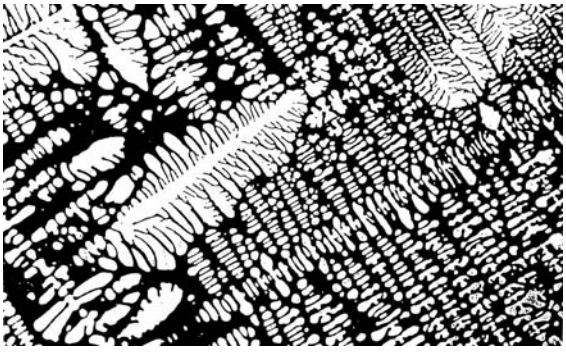

Fig. 3.27 Dendritic microstructure in a die-cast Al−Zn10−Si8−Mg alloy

In alloys the formation of dendrites is connected with compositional changes (or constitutional effects) between the solid and liquid phase, therefore dendrite formation is known to be caused by *constitutional supercooling*. An example for a dendritic microstructure in a cast Al alloy is shown in Fig. 3.27. For further details and a more quantitative treatment of these issues see [3.11].

3.1.5 Binary Phase Diagrams

In single-component systems all phases have the same composition, and equilibrium involves temperature T and pressure p as variables. Obviously, in alloys composition is also variable and understanding phase transformations requires an appreciation of how the Gibbs free energy of the respective phases involved depends on all these parameters. However, pressure p can be ruled out and treated as being constant in what follows since we consider only the liquid–solid transformation with both phases being essentially incompressible. Besides, to keep the physical model simple we restrict ourselves in the following to binary alloys, i. e., two-component systems.

Gibbs Free Energy of Binary Solutions

Assume that two components A and B can be mixed in any proportions (because they have the same crys-

tal structure; an example of this scenario would be the alloy system Cu – Ni). Then the Gibbs free energy of a homogeneous solid solution can be calculated in two steps: first, we bring together x_A mole of pure A and x_B mole of pure B, so the free energy of the system is simply the arithmetic mean

$$\bar{G}(x) = G_A x_A + G_B x_B , \tag{3.28}$$

with $x_A + x_B = 1$ for binary systems. For all alloy compositions $\bar{G}(x)$ lies on a straight line between G_A and G_B. The second step is now to let A and B mix in a random fashion. The free energy of the system will not remain constant during mixing and

$$G(x) = \bar{G} + \Delta G_M , \tag{3.29}$$

where $\Delta G_M = \Delta H_M - T\Delta S_M$ is the change in Gibbs free energy due to mixing. The simplest case of mixing is the *ideal solution*, in which one assumes that no preferences can be found for the different types of interatomic bonds between neighboring atoms. If preferred bondings are found, however, this situation is called a *regular solution* and describes more realistic scenarios of alloying; this case will not be treated here for simplicity. For ideal solutions $\Delta H_M = 0$ and $\Delta G_M = -T\Delta S_M$. From statistical thermodynamics [3.2,3] we know that entropy is quantitatively related to randomness by Boltzmann's equation and one obtains

$$\Delta G_M = -T\Delta S_M = RT(x_A \ln x_A + x_B \ln x_B) . \tag{3.30}$$

Since $\Delta S_M > 0$, i. e., there is an increase in entropy on mixing, ΔG_M is negative and the course of $G(x)$ according to (3.29) is shown schematically in Fig. 3.28. Note, that, as the temperature increases, G_A and G_B decrease and the free energy curve $G(x)$ assumes a greater curvature due to the increasing degree of randomness.

For any given mole fraction x_B the extrapolation of the tangent to G to both sides of the molar free energy diagram (Fig. 3.28) yields the chemical potentials μ_A and μ_B of the components A and B, respectively, which describe how the free energy changes when an infinitesimally small quantity of the atomic species i is added to the system (at constant T and p). Consequently

$$\mu_i = \left(\frac{\partial G}{\partial n_i}\right) . \tag{3.31}$$

Equilibrium in Heterogeneous Systems

Assume now that the components A and B do not have the same crystal structure. In this case, two free energy curves G_α and G_β have to be sketched, as shown in Fig. 3.29, and the stable forms of both structures are those with the lower free energy; thus, in thermodynamic equilibrium a homogeneous α solid solution is found for A-rich compositions and β is the stable phase for B-rich compositions. For alloy compositions near the crossover in the $G(x)$ curves (see, e.g., composition x_0 in Fig. 3.29), a minimal total free energy

can be achieved by separating the atoms into the two phases α and β with equilibrium compositions x^α and x^β. From Fig. 3.29 it can be concluded that heterogeneous equilibrium between the two phases requires that the tangents to each G curve at x^α and x^β lie on a common line (the *common tangent rule*). In other words each component must have the same chemical potential in the two phases and

$$\mu_A^\alpha = \mu_A^\beta\,, \quad \mu_B^\alpha = \mu_B^\beta\,. \tag{3.32}$$

Note that the same rule applies when $G(x)$ curves are compared for liquid and solid phases.

Binary Phase Diagram with Complete Miscibility

The simplest case conceivable is when the two components A and B are completely miscible in both the liquid and solid states and both are ideal solutions. Then, the free energy curves for the liquid and solid phases vary with temperature according to Fig. 3.30. At T_1 the liquid phase is thermodynamically stable over the whole composition range (Fig. 3.30a) thus $G_\alpha > G_L$. With decreasing temperature one approaches the melting points T_2 and T_4 of pure A and B (see Fig. 3.30b,d, respectively), where the $G(x)$ curves meet in a single point on either side of the diagram. These points are plotted on the temperature axes for pure A and B, respectively, in the *equilibrium phase diagram* (Fig. 3.30f). With a further decrease in temperature (T_5) the solid phase is stable for all compositions (Fig. 3.30e), and $G_\alpha < G_L$. In the temperature interval between T_2 and T_4, the common tangent rule indicates a two-phase region with coexisting solid and liquid phase (see the two

vertical dashed lines at T_3 in Fig. 3.30c). These points are transferred into the equilibrium phase diagram at T_3.

The Lever Arm Rule

Figure 3.31 shows an enlarged view of the binary phase diagram with complete miscibility derived in Fig. 3.30. The region where the two phases coexist is limited by the two curved lines, of which the upper one separates this region from the liquid phase. Consequently, this line is called the *liquidus line*. The lower line separates the two-phase region from the solid phase and is thus called the *solidus line*. For any given temperature T_3 and overall composition x_0 within the two phase region it may now be interesting to know the amount of liquid and solid phase, respectively, as well as their concentration (or, more precisely, their molar fractions). Drawing a horizontal straight line at T_3 the intersection with liquidus and solidus line yields the concentration x^{L} and x^{α} of the liquid and the solid phase, respectively, within the two-phase region. The amount of α-phase f^{α} can be graphically determined utilizing the lever arm rule

$$f^{\alpha} = \frac{x^{\mathrm{L}} - x^{0}}{x^{\mathrm{L}} - x^{\alpha}} \,. \tag{3.33}$$

Analogously, one obtains for the amount of liquid phase f^{L}

$$f^{\mathrm{L}} = \frac{x^{0} - x^{\alpha}}{x^{\mathrm{L}} - x^{\alpha}} \,, \tag{3.34}$$

and finally for the ratio between the solid and liquid phase

$$\frac{f^{\alpha}}{f^{\mathrm{L}}} = \frac{x^{\mathrm{L}} - x^{0}}{x^{0} - x^{\alpha}} \,. \tag{3.35}$$

Equations (3.33–3.35) hold in general for all two phase regions in binary phase diagrams, e.g., for the miscibility gaps (or the two-phase regions a1 and a2 in Figs. 3.32–3.34).

Eutectic Systems

Figure 3.32 exemplifies the situation where the liquid phase is approximately ideal but the solid phase α decomposes into two solid solutions α_1 and α_2, i. e., the atoms A and B *dislike* each other. Rather, preferred A–A and B–B-type bondings can be found and ΔH_{M} in (3.31) becomes positive (regular solution). Therefore, at low temperatures T_5 the (combined) free energy curves of α_1 and α_2 in Fig. 3.32 assume a negative curvature in the middle and the solid solution is most stable as a mixture of the two phases α_1 and α_2. This region is called the *miscibility gap* and the lever arm rules (3.35–3.37) apply. The second effect of $\Delta H_{\mathrm{M}} > 0$ becomes obvious at the *eutectic temperature* T_{E} where one common tangent line can be applied to the $G(x)$ curves of all three phases: as a consequence, the *eutectic* composition has the lowest melting point within the system.

For a *eutectic reaction*

$$L \rightarrow \alpha_1 + \alpha_2 \,. \tag{3.36}$$

Peritectic Systems

Figure 3.33 illustrates how a *peritectic* phase transformation is related to the free energy curves. Again, $\Delta H_M > 0$ but, in contrast to the eutectic system, the $G(x)$ curves for the two solid solutions α_1 and α_2 are shifted to one side of composition relative to the liquid phase L. As for the eutectic system one common tangent line can be applied to the $G(x)$ curves of all three phases at T_P and the *peritectic reaction* is

$$\alpha_1 \rightarrow L + \alpha_2 \,, \tag{3.37}$$

which quite naturally explains why peritectic systems likely emerge when two components with substantially different melting points are alloyed.

Systems with Intermetallic Phases

The opposite type of effect arises when $\Delta H_M < 0$ and the atoms *like* each other within a certain composition range. In such systems (Fig. 3.34) melting will be more difficult in the α_2 phase because of its very deep $G(x)$ curve and a maximum melting point may appear. If the attraction between the unlike atoms is very strong and the α_2 phase extends as far as the liquid, it may be called an *ordered intermetallic* phase.

3.2 Microstructure Characterization

3.2.1 Basics

The primary characteristic of a material is its integral and percentual chemical composition, that is, e.g., for metals, the chemical elements, for polymer materials the types of polymers and possible reinforcements, and for ceramics the oxides, nitrides or carbides. Starting with the chemical composition, a specific microstructure [3.18] will be generated during the solidification of a melt, the mixing of polymeric components, heat treatment, the manufacturing process (rolling, milling, deep drawing, welding), or during usage (aging, corrosion).

As pointed out in detail in Sect. 3.1.2 the (usually three-dimensional) microstructure of materials can consist of several constituents, for example, grains (or crystallites) with different crystallographic orientation (which are separated from each other by grain boundaries, Fig. 3.26) or precipitates, impurities (slags, oxides, sulfides), pores, reinforcement particles, fibres, and others.

The constituents of a microstructure are visualized by material-specific preparation and imaging methods. However, for complete characterization of a microstructure (materialography, or more specifically metallography, plastography, ceramography) more methods than microscopic imaging are often necessary. For the interpretation and understanding of a microstructure the knowledge of the presence and nature of crystallinity of the constituting phases is essential. This information is obtained by X-ray diffraction, which is a nonmicroscopic integral method. The information on the local chemical composition, the local crystal structure, and characteristic geometric parameters of the constituents is investigated by microscopic methods which differ in their generated signals, optical resolution, and contrast mechanism.

3.2.2 Crystal Structure by X-ray Diffraction

The first goal in microstructure characterization is to learn which crystalline phases are present in a material. This is achieved mainly by X-ray diffraction (XRD) [3.19, 20], which gives information on the crystal structure of constituents in a microstructure. This is possible by their crystallographic parameters: type of crystal lattice, crystal symmetry, and unit cell dimension (Sect. 3.1). Moreover, information on the perfection of the crystal lattice (number of dislocations), and from this on the degree of plastic deformation, and on the external and residual stresses acting on the lattice are also obtainable.

The theory of X-ray diffraction is based on Bragg's law, which describes how electromagnetic waves of a certain wavelength λ interfere with a regular lattice. At certain angles of incidence (θ) with regard to a set of parallel crystal planes, which are therefore called reflectors, constructive interaction takes place according to

$$n\lambda = 2d_{hkl} \sin\theta \,, \tag{3.38}$$

where n is a positive integer and d_{hkl} represents the interplanar spacing between the crystal planes that cause constructive interaction; λ is the known wavelength of the incident X-ray beam.

In XRD the specimen is irradiated by a monochromatic X-ray beam, Cu-KA_α or Cr-K$_\alpha$, which is

generated by an X-ray tube and a metallic film for monochromatization. The diffracted X-ray beam is detected by, e.g., a scintillation counter at an angle of 2θ with the incident beam and the signal is stored in a computer. Both, X-ray source and detector rotate on a circle around the sample in the center. The measuring spot typically has an area of several mm^2 – in special cases of some square micrometers. Measurements are possible on bulk specimens, powders, and on films. In materials science XRD applied to polycrystalline bulk materials is also called the *powder* diffraction method. Sample preparation is relatively easily accomplished by grinding or polishing, whereby destruction of the crystal structure by severe plastic deformation must be avoided. X-ray diffraction can be treated as an integral method for measuring the crystal structure, because usually the exposed area is composed of a number of crystallites. However, single-crystal measurements are also possible. The information depth of some ten micrometer depends on the angle of incidence, the atomic number of the sample, and the energy of the X-ray.

From the X-ray diffraction diagram, which is commonly plotted as intensity of X-ray versus 2θ (Fig. 3.35), the following information can be obtained [3.20, 21]. From the angles θ of the Bragg peaks the constants of the unit cell of the crystal can be calculated by application of (3.38). From the combination of those values the type of crystal and its symmetry can be deduced. Because a set of d values and the relative intensities of their corresponding X-ray peaks are characteristic of a certain crystalline material they are used for phase identification by comparing the measured diffraction pattern to those of phases contained in databases. The most commonly used database is the powder diffraction file (PDF) maintained and distributed by the International Center for Diffraction Data (ICDD).

In case of materials consisting of multiple phases the weight ratio of the crystalline phases of the material is calculated from the relative peak intensities. The quantification without a standard sample is based on the comparison of the peak intensities. A better way to get the ratios is to use a standard substance.

The width of the peaks gives information on the perfection of the arrangement of the atoms within the crystal lattice and on the number of dislocations resulting from plastic deformation. External and residual stresses applied to a crystal lead to dilatation or compression of the atomic distances and therefore to a shift of the diffraction peaks to greater or smaller angles. Practically the strain in a sample is measured by recording the angular shift of a given reflector as a function of angle of incidence. The measured strain is then used to calculate the stress with the help of the elastic modulus [3.22].

A preferred orientation of the crystallites in a polycrystalline material with respect to the sample coordinate system is called (crystallographic) texture. The orientation distribution can be determined by X-ray diffraction (XRD)-based texture analysis [3.23]. With this technique, pole figures are measured by recording the intensity distribution of a single reflection by tilting and rotating the sample while radiating it with an

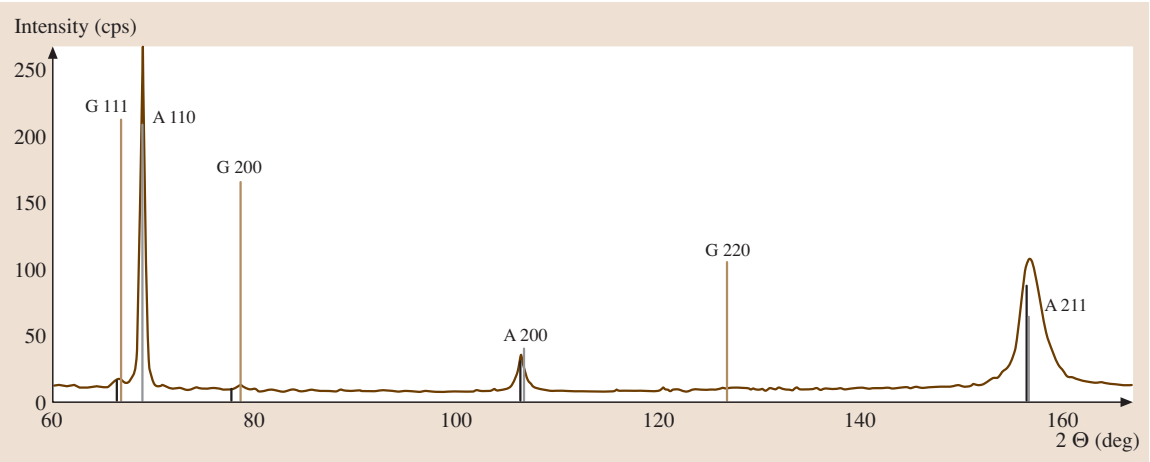

Fig. 3.35 X-ray diffraction pattern of a quenched and tempered hot-working steel 56NiCrMoV7, with metastable austenite (8%); the small peaks marked with a G represent the austenite phase whereas the large peaks marked with an A show the ferrite matrix. G and A are deduced from 8-Fe, and α-Fe, respectively

X-ray beam. In this way the orientation distribution of a single reflection, and thus for a single lattice plane, is determined [3.24].

3.2.3 Materialography

Materialography is the investigation of the microstructure of materials [3.25]. It includes specimen preparation and imaging of the microstructure, the quantification of the constituents (content, arrangement, size, shape, and orientation), as well as the local chemical and crystallographic characterization of the constituents, if necessary.

Specimen Preparation

The three-dimensional microstructure of a material is usually deduced from two-dimensional images, which are obtained by sectioning the sample. The resulting specimen is either in bulk form or thin and transparent, depending on the type of material and the goal of investigation. The whole process of specimen preparation, starting with cutting small parts from larger pieces, has to be performed without disturbing the microstructure by mechanical or thermal influences. Small specimens (wire, cross sections of sheet metal) are mounted in a resin using pans which can easily be handled and have the right size for grinding machines. Bulk samples are prepared by grinding and polishing using metallographic machines with rotating wheels. A large number of material-specific abrasives and lubricants are available [3.26]. The selection of the most suitable ones is based on the material's composition and on the mechanical properties of its constituents. Mechanical polishing is performed using a rotating wheel covered with cloth and small particle abrasives (for final polishing steps with grain size $< 1\,\mu m$), such as powders of diamond or aluminum oxide, or colloidal silicon dioxide. For further smoothing of the surface electrolytic polishing can be applied, especially for homogeneous, i. e., single phase, materials.

The prerequisite of microscopic imaging is a sufficient optical contrast, meaning that neighboring regions must show a certain difference of brightness or color. The contrast (C) is defined as the ratio of intensities I, which can be the intensity of white light (gray values) or the intensities of colors (red, green, and blue)

$$C = \frac{I_1 - I_2}{I_1}\,, \tag{3.39}$$

where $I_2 < I_1$. Contrast can already be present after polishing the samples, e.g., if black graphite is present in a bright matrix of grey cast iron, colored grains in copper alloys and mineralic materials, and contours due to different abrasion of constituents. In most cases, however, the contrast has to be developed by means of chemical or physical etching [3.27]. Chemical etchings

are water-based acidic or basic solutions or complex solutions of salts, sometimes containing organic substances. Grain boundary etching is usually applied to microstructures consisting only of one constituent (Fig. 3.36), where the etching agent reacts preferentially with the more reactive grain boundaries. Large differences in the etching rate of the constituents of a microstructure generate slopes at the grain boundaries between different constituents, which gives also a grain boundary contrast. For some etching agents the ablation depends on the crystallographic orientation of the grains and as a result topographies with different light-scattering capability are developed. If a grain consists of two phases, such as pearlite (consisting of ferrite and cementite), one of them can be selectively etched, leaving a light-scattering topography of pearlite grains, which are dark under the microscope, as compared with the brighter ferrite grains in a carbon steel (Fig. 3.37, compare also Fig. 3.39).

Physical etching methods are based on a selective ablation of constituents by a plasma generated in a glow discharge apparatus or by ion beam bombardment, for example in a focused ion beam (FIB) instrument (see later).

For light microscopy of polymer materials, transparent specimens are prepared by cutting lamellae, using a microtome with a glass or diamond knife, from the sample. The specimens are some micrometers thick and are positioned between a glass microscope slide and a cover glass by adding a drop of immersion oil to keep off air bubbles and to increase the refractive index of the interspace. Easily plastic deformable polymers, such as polyethylene, are cut at low temperatures (at −70 °C or lower) with a cryomicrotome. From polymer matrix composites thin transparent specimens are obtained by grinding and polishing small pieces which are glued to a glass strip.

Microscopy of the Microstructure

For some metallographic samples it is sufficient to image the specimen with no or only little magnification. This macrometallography is used, e.g., for the inspection of the microstructure of welds (Fig. 3.38).

In most cases, however, microscopy is necessary to visualize the microstructure. The most commonly used method is reflection light microscopy of bulk specimen. The contrast, as mentioned above, is based on the different reflection capability or color intensities of the constituents. If sufficient contrast cannot be obtained by specimen preparation, other imaging modes can be used, such as light microscopy with polarized light for aluminum and magnesium alloys, or differential interference contrast microscopy (DIC) for refractory metals (Mo, W, V).

Inverted microscopes are used for bulk metallographic samples, because they allow easy positioning of the specimen on the microscope stage with the viewed

surface exactly perpendicular to the optical axis. This is a basic requirement to have all parts of the viewed area in focus. Images are captured by a charge-coupled device (CCD) camera and a computer whereby easy-to-handle software is useful, and should allow calibration, setting scale markers (micron bar), and some interactive distance measurements. Patterns of microscope calibration standards are imaged for the calibration of the magnification of a selected microscope configuration. As a calibration value the pixel size, as micrometer per edge length of square pixels, is stored with the image. A micron bar can be placed permanently into the image if necessary, but one has to be careful if the micrograph is used for automatic image analysis afterwards.

In some cases dark-field microscopy, in which the diffuse reflected light is detected instead of the directly reflected light, gives better visibility of small objects. The lateral resolution of light microscopy is 0.25 μm at best (due to the wavelength of visible light). Best values are obtained when a substance with a large refractive index (immersion oil) is placed between the specimen and the objective.

For higher resolutions (and magnifications) than are possible with light optical methods *electron microscopy* is a method widely applied in metallography. In addition, it allows complementary information on the local chemical composition and the crystal structure to be obtained. *Scanning electron microscopy* (SEM) is used for imaging metallographically prepared surfaces of bulk samples, and *transmission electron microscopy* (TEM) is used for imaging thin foils which are transparent to electrons. In both instruments, the electrons are emitted from an electron gun, accelerated in an electric field (0.5–25 kV in SEM, and 80–400 kV – in some cases over 1 MV – in TEM) towards the anode and then formed to a small beam (with a diameter of a few nanometer) by means of an electron optical system. High vacuum is necessary all along the electron path to prevent collisions of the electrons with gas molecules.

In an SEM [3.28, 29] the specimen, mounted on a multi-axis stage in the specimen chamber, is scanned with the focused electron beam. The emitted secondary electrons (SE) and backscattered electrons (BSE) are registered by detectors which are mounted above the specimen and the signal intensities are stored as digital grey value images. The SE detector is a scintillator–photomultiplier system and for BSE a scintillator or a semiconductor detector can be used.

The best resolution is achievable with the SE signal, and can be as good as 1 nm for suitable instrument parameters and specimen constitution. The information depth is some tens of nanometers for the SE mode. For imaging of very small particles or thin layers, especially if they consist of low-atomic-number elements, the emission depth can be lowered by applying a lower accelerating voltage. With SE, a topography contrast is generated, which is based on the dependency of the SE intensity on the incident angle between the electron beam and the imaged surface area (Fig. 3.39).

With BSE a composition contrast image can be obtained, because the intensity of the BSE emission is related to the atomic number of the material. Regions containing higher-atomic-number elements are brighter than those composed of lower-atomic-number elements (Fig. 3.40). Even atomic number differences smaller then unity can result in a contrast, which is in many cases good enough for imaging the microstructure of polished, but unetched, specimens.

SEM samples have to be stable under high-vacuum conditions. This is not the case if they contain water or other liquids which can evaporate. Therefore, in some SEMs, fitted with special vacuum devices and detectors, imaging at a pressure of up to 25 mbar is possible by the injection of water into the specimen chamber; this is known as variable-pressure SEM (VPSEM) or environmental SEM (ESEM). The resulting water partial pressure prevents the evaporation of water from the specimen and an alteration of its structure. Cooling the specimen with the aid of a cooling stage to a temper-

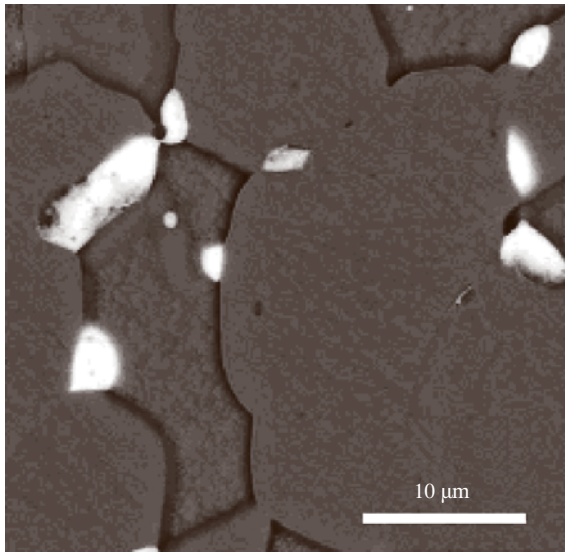

Fig. 3.40 Atomic number contrast in a SEM BSE image of brass; Pb particles are *bright* due to their higher atomic number as compared with Cu and Zn

ature just above the freezing point supports this effect. Imaging electrically nonconductive materials, such as polymers, ceramics, oxides, and mounting resins, is possible in different ways. Either they are coated with a conductive layer (Au, C, Pt, or Cr) by sputtering or evaporation, or a low accelerating voltage is applied (< 2 kV), or imaging is performed under low-vacuum conditions (at least 1 mbar), whereby ions that are generated by collision of electrons with gas atoms prevent the specimen surface from being charged.

Cross sections are commonly prepared for microstructural investigation of subsurface regions and of thin surface layers. The edge of the specimen has to be preserved to prevent its rounding and the ablation of thin layers during grinding and polishing. Often resins filled with hard particles are used, or a metal is plated on the sample surface before mounting; chemical deposition of Ni is preferred. A good alternative for the inspection of subsurface regions is cross sectioning with ion beams. Larger areas (up to some millimeters edge length) are cut with broad beams of Ar [3.30]. Target preparation of cross sections is performed using focused ion beam (FIB) instruments [3.31], in which a Ga^+ ion beam (0.5–30 kV accelerating voltage, 7 nm diameter) is scanned over the specimen. The ion bombardment results in a milling effect. Preparation is possible at any region of interest at the specimen surface by milling a stair-shaped trench, typically 20 µm wide and deep. The cross section is imaged after the specimen is tilted (Fig. 3.41). The edge of the trench is protected by a Pt strip, which is deposited before the milling by ion-induced decomposition of a metalorganic Pt compound fed into the specimen chamber through a small tube. Imaging is possible in a FIB by means of secondary ions (SI) and the ion-induced secondary electrons (iiSE), respectively. The latter give both topographical and compositional contrast. Some crystalline materials show good orientation contrast due to the channeling effect [3.32] and the microstructure is visible without etching (Fig. 3.42).

Modern instruments combine the functions of SEM and FIB. The SEM mode is used for conventional imaging with electrons, even during ion milling steps, and for charge neutralization. An energy dispersive X-ray spectrometer (EDX) and a camera for electron backscatter diffraction (EBSD) imaging (see later) can be additionally fitted to such an instrument. Thus, the real three-dimensional chemical composition, crystal structure, and microstructure of a sample can be obtained by slice-milling the wall of a cross section in small steps (50 nm to a few microns) and subsequent reconstruction of the microstructure from the resulting EDS and EBSD image series.

TEM [3.33] is used for the investigation of microstructural constituents smaller than about 50 nm in the conventional mode (CTEM) or the scanning mode (STEM), whereby a resolution of 0.1 nm can be achieved with dedicated instruments. The specimen has to be electron transparent with a thickness of 20–1000 nm, depending on the electron energy and

the specimen composition. Areal ion beam milling, electrolytic thinning and ultramicrotomy are common methods for specimen preparation. Usually, the specimen is mounted on a 3 mm-diameter Cu grit, which is fixed to the TEM specimen holder. Target preparation, starting with a bulk specimen, is possible by means of FIB milling. One approach is to mill a trench on either side of the region of interest, followed by cutting free the resulting lamellae and its transfer to a TEM grit with the help of a nanomanipulator.

The contrast in TEM imaging depends on different materials properties and imaging conditions. Mass–thickness contrast is based on differences in elemental composition and in thickness of the corresponding transmitted region. Diffraction contrast appears, if crystal planes are oriented in such a way that they give rise to Bragg diffraction (3.38) (Fig. 3.43). Analysis of the local chemistry of a sample in TEM is possible by means of EDX and *electron energy-loss spectroscopy* (EELS) [3.34] with a resolution of a few nanometers.

Local Chemical Analysis

Local chemical analysis is a mandatory tool to identify microstructural features such as grains, precipitates, particles, and corrosion products, or to register concentration profiles. For this purpose spectroscopy of X-rays, emitted as a result of the electron bombardment, is performed in a SEM or a TEM (*electron probe microanalysis*, EPMA) [3.35]. In most cases *energy-dispersive X-ray spectroscopy* (EDS, EDX) is used with a semiconductor detector (Si – Li or Ge) which

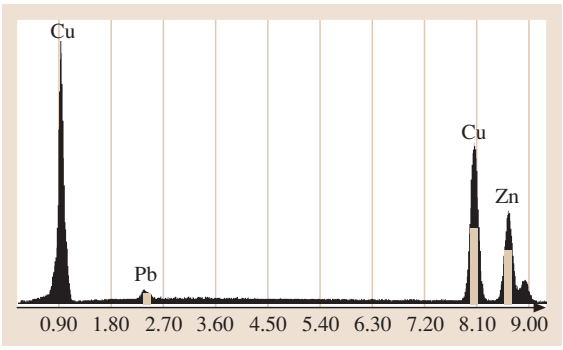

Fig. 3.44 Energy dispersive X-ray spectrum (EDX) of brass: element-specific peaks and energy windows for element mapping

is connected to a multichannel analyzer. The resulting X-ray spectrum (Fig. 3.44) gives information on the presence of chemical elements represented by the element-characteristic energy for X-ray emission. The quantitative composition is calculated from the intensities of the peaks, whereby some correcting parameters have to be taken into account [3.36]. The X-ray spectrum can represent the average elemental composition of a larger scanned area (up to 1 × 1 mm) or of a spot as small as about 0.5 µm diameter, which is the lateral resolution of EDX measurements. With a line scan the intensity of an element-specific peak (energy win-

dow) is registered and from that the concentration of this chemical element can be determined along a preselected line. Extending this method to an area of interest yields so-called element mapping (Fig. 3.45).

Typically, EDX measurements in a SEM have a lateral and a depth resolution of 0.5 μm for high-atomic-number elements, and up to 10 μm for low-atomic-number elements (graphite, polymers), respectively, and relative errors of 3–8%. Better resolution can be obtained if the analysis is performed on thin specimens (≈ 100 nm thick) in both a SEM or a TEM. Elements can be analyzed qualitatively starting with the atomic number of ^{5}B whereas quantitative results can be obtained for elements starting from ^{11}Na. *Wavelength-dispersive X-ray spectroscopy* (WDS, WDX), using one or more crystal spectrometers attached to a SEM, allows the quantification of low-atomic-number elements (B, C, N, and O) and the analysis of trace elements. Because WDX cannot be used in a TEM, EELS is the alternative method of interest here.

Chemical Analysis of Thin Layers

Methods suitable for the chemical analysis of thin layers (in the nanometer thickness range), for measuring the concentration profile within such layers, and for interface layers must possess a very small information depth. Layers of interest are, e.g., sputtered or plasma-assisted coatings, corrosion layers, tribological reaction layers, and grain boundaries. Methods most used for the analysis of engineering materials are *scanning Auger electron spectroscopy* (SAM), *X-ray-exited photoelectron spectroscopy* (XPS)/ electron spectroscopy for chemical analysis (ESCA), and *secondary-ion mass spectroscopy* (SIMS) [3.35]. The lateral resolution ranges from some nanometers (SAM, SIMS) to some microns (XPS). Concentration–depth profiles are available during spectroscopy with a resolution of a few nanometers by simultaneous sputtering of the specimen with accelerated ions (O^+, Ar^+, Ga^+, etc.).

Local Measurement of the Crystal Structure

Knowing the crystal structure locally in a microstructure, for example, of a single grain or a specific precipitate is of interest for the following reasons:

1. In cases when the EDX analysis is not able to discriminate between chemically similar phases, determining the crystal structure may support phase identification.
2. Crystallographic orientation of single grains with respect to the specimen coordinates, for example, with respect to the rolling direction of sheet metal, can influence many properties significantly, such as deformation behavior, corrosion, electrical conductivity, etc.

The local crystal structure is obtained by electron diffraction with different resolutions in a TEM (< 1 nm) or SEM (> 20 nm) by applying Bragg's law (3.38). In a TEM electron diffraction of a single grain gives rise to a point pattern (Fig. 3.46) from which the relevant crystal parameters (crystal structure, symmetry, unit cell dimensions) can be deduced. It is noteworthy here that TEM has the implication that only a few grains or particles can be investigated and that sample preparation may become a difficult and tedious task.

In an SEM *electron backscatter diffraction* (EBSD) [3.37, 38] patterns are registered by a combination of a phosphor screen and a CCD camera fitted to the specimen chamber. In the pattern (Fig. 3.47) each of the so-called Kikuchi bands represents a pair of lattice planes with their width corresponding to the lattice plane spacing. From the EBSD pattern the crystal structure, symmetry, and the crystallographic orientation of a single grain can be calculated using commercial software. This method is also known as orientation imaging microscopy (OIM) [3.38]. Note, that image quality (sharpness) is deteriorated with an increasing number of dislocations within a grain, in other words with the de-

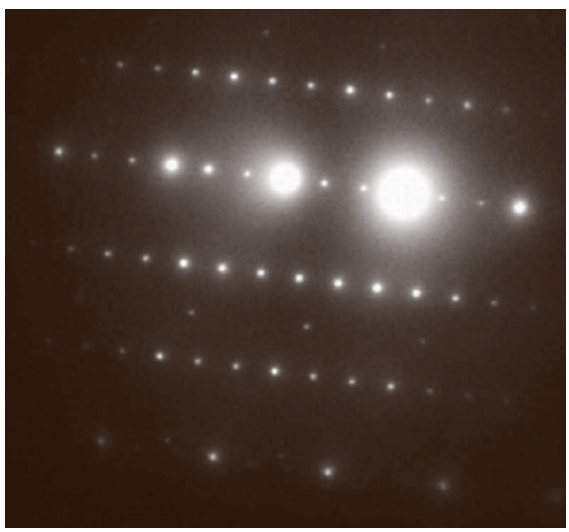

Fig. 3.46 Electron diffraction pattern of a Ni alloy obtained in a TEM at 200 kV; the small spots are superlattice peaks stemming from coherent and ordered precipitates embedded in a disordered fcc matrix

gree of plastic deformation. Since the information depth of EBSD is about 50 nm, the investigated surfaces have to be prepared very carefully by mechanical and occasionally electrochemical polishing, without disturbing the microstructure by generating dislocations due to plastic deformation [3.39, 40]. Milling the surface in a FIB or with a broad-beam ion miller is an elegant alternative preparation procedure.

For phase identification [3.41] the crystal structure obtained by EBSD and the chemical composition, which is simultaneously acquired by EDX analysis, are compared to the data of known phases contained in a database such as the ICDD database (Sect. 3.2.2).

The crystallographic orientation, defined as the orientation of the coordinate system of a crystallite with respect to the coordinate system of the sample, is calculated from the orientation of the diffraction pattern in the EBSD image. For engineering materials the coordinate system of the sample often is defined by the rolling direction (RD), the transversal direction (TD), and the normal direction (ND). To obtain an orientation map, selected areas of the specimen (up to several hundred microns edge length) are scanned with step sizes between 20 and 2000 nm, depending on grain size, and the orientation for each measuring point is calculated [3.42]. The results are usually presented as an inverse pole figure, in which the orientation is color coded (Fig. 3.48). Specifically, in Fig. 3.48, the red-colored grains have an orientation in which the crystallographic direction [001] is parallel to the normal direction of the sample, and the main axes of the cubic unit cell are parallel to RD, TD, and ND.

The different crystallographic orientation of neighboring grains can be used to generate an image of the microstructure. For this purpose the difference of the crystallographic orientation of adjacent measuring points is used; for example, a difference of less than 15° can be chosen as a criterion for discriminating between large-angle grain boundaries. The result is a colored grain map (Fig. 3.49), from which a quantitative determination of grain sizes is possible.

Quantification of Microstructure/Quantitative Stereology

In many cases, a quantitative analysis of the microstructure is desired, e.g., to detect small differences between microstructures for quality control purposes, or to obtain numbers for modeling of material behavior. One example is the correlation of the grain size with the strength of a material as described by the Hall–Petch equation (3.10).

Microstructure quantification can be performed by image comparison using standard charts, by manual measurement or counting, and with the help of digital image analysis software. Standards for microstructure quantification describe the specimen preparation as well as the measuring procedure, the necessary equipment, and the form of test report.

The study of the three-dimensional microstructure using images of two-dimensional sections through the structure is known as stereology [3.43, 44]. A basic stereological parameter [3.45,46] is the volume fraction $V_V(\alpha)$ of a constituent (α), expressed as the ratio of the constituent volume $V(\alpha)$ and the testing volume V_t

$$V_V(\alpha) = \frac{V(\alpha)}{V_t} \,. \tag{3.40}$$

The volume fraction equals that fraction which can be obtained from the corresponding equilibrium phase diagram, where the volume fraction has to be calculated from the weight fraction using the densities of the constituents. The volume fraction can be estimated using the fundamental stereological equation

$$V_V(\alpha) = A_A(\alpha) = L_L(\alpha) = P_P(\alpha) \tag{3.41}$$

from the areal fraction $A_A(\alpha)$ to be determined by digital image analysis, from the line fraction $L_L(\alpha)$ by digital image analysis or by measuring the sum of the length of all segments $L(\alpha)$ of test lines L_t which lie within the grains of constituent (α), or from the point fraction $P_P(\alpha)$. The latter is estimated by a manual point-counting procedure, in which a point grid is placed on the micrograph and the total number of points in the testing area P_t and the number of points hitting the constituent of interest $P(\alpha)$ are counted. This method has been standardized for steel [3.47] and duplex steel [3.48]. Rules for the use of automatic image analysis to determine the volume fraction of constituents are also described [3.49].

Another important stereological parameter is the surface density as an equivalent to the grain size. It is calculated as the sum of the surfaces (boundaries) of all grains $S(\alpha)$ of a constituent in a given test volume V_t

$$S_V(\alpha) = S(\alpha)/V_t \quad \left(\mathrm{m}^{-1}\right) . \tag{3.42}$$

$S_V(\alpha)$ is obtained by counting the number of intersections of test lines of total length L_t with grain boundaries P

$$S_V(\alpha) = \frac{2P}{L_t} = 2P_L \quad \left(\mathrm{m}^{-1}\right) . \tag{3.43}$$

Several parameters are known for the quantification of grains, for example, size, shape, orientation, and arrangement. A simple procedure for determining the average grain size is accomplished by comparing micrographs of the sample at a given magnification to a standard chart of grains, as standardized for graphite in grey cast iron [3.50] and for copper and its alloys [3.51], or by measuring the mean intercept length $\bar{L}_S$ (intercept method). The latter has been standardized for ferritic and austenitic steel [3.52, 53]. It is estimated by laying test lines of total length L_t over the micrograph and measuring the mean length of the segments $\bar{L}_S$ within the grains, or the number of intersections of test lines with grain boundaries P in order to calculate $\bar{L}_S$ as

$$\bar{L}_S = \frac{L_t}{P} \,. \tag{3.44}$$

The surface density is related to the mean intercept length by

$$S_V = \frac{2}{\bar{L}_S} = 2P_L \,. \tag{3.45}$$

A relatively simple and quick procedure to describe the grain size, particularly applied for ferritic and austenitic steel, is to use the grain size number G [3.53]. This is obtained by image comparison or by estimating the number of grains m for a unit area of 1 mm^2 of the specimen. In this procedure a circle is drawn into the micrograph and the number of grains within the circle n_1 and those touching the perimeter n_2 are counted. With the microscopic magnification g and the circle radius r the number of grains per mm^2 of the specimen surface is calculated as

$$m = \frac{\left(n_1 + \frac{n_2}{2}\right) g^2}{r^2 \pi} \,. \tag{3.46}$$

The grain size index G is calculated from [3.52]

$$m = 8 \times 2^G \,, \tag{3.47}$$

and is related to the mean intercept length $\bar{L}_S$ and the surface density S_V through

$$\begin{aligned} G &= 16.64 - 6.64 \log\left(\bar{L}_S\right) \\ &= 16.64 - 6.64 \log\left(\frac{2}{S_V}\right) \\ &= 16.64 - 6.64 \log\left(P_L\right) . \end{aligned} \tag{3.48}$$

The shape of single grains and particles is estimated by image comparison or by digital image analysis. With the latter method, geometric parameters for each particle such as area A, perimeter P, and greatest and smallest extent d_{max} and d_{min} are measured. Shape factors are calculated by expressing the deviation from circular shape (circular form factor $f_c = 4\pi A/P^2$) and the aspect ratio $f_a = d_{max}/d_{min}$. Those form factors are needed to verify the results of heat treatment, where grains are rounded, or rolling and deep drawing processes, where grains may be elongated.

3.3 Mechanical Properties

3.3.1 Framework

Concepts such as elastic properties, fracture toughness, fatigue, plastic flow, creep, etc. all belong to the framework of *mechanical properties*. Engineers and scientists working in fields related to engineering materials require a fundamental understanding of mechanical properties. Engineers are primarily concerned with the *strength* of the material, a measure of the external force required to overcome internal forces of attraction between the fundamental building blocks of the material.

W- Width
T- Thickness
R- Radius of filler
A- Length of reduced section
B- Length of grip section
D- Diameter of reduced section

Fig. 3.50 Schematics of flat and cylindrical tensile test samples with critical sample dimensions (after [3.49])

In most engineering applications, only very small deformation in a component under a given loading condition is tolerable, and strength often governs the choice of an acceptable material. For a production engineer, though, the ease of inducing permanent deformation at the expense of as little energy as possible (i. e., *malleability* and *ductility*) is the critical mechanical property for the material under consideration. Given the importance of mechanical properties, it is essential to have a range of tests to *quantify* these mechanical properties. Additionally, standardized and inexpensive tests are needed for *quality assurance*. Scientists and alloy designers routinely use mechanical tests to assess the *performance* of a new material as compared with available materials.

3.3.2 Quasistatic Mechanical Properties

Tensile Testing

In this section, we address the response of a material to the application of an external applied static (or quasistatic) force. In its simplest form, the basic description of a material is obtained by a *tension* (or pull) test. Standard procedures for sample preparation and conducting the test are described in ASTM standard E 8M-98. Accordingly, the test specimen may be plate, sheet, round, wires or pipes (Fig. 3.50) and must conform to certain guidelines in terms of sample dimensions. Different gripping mechanisms, such as wedge

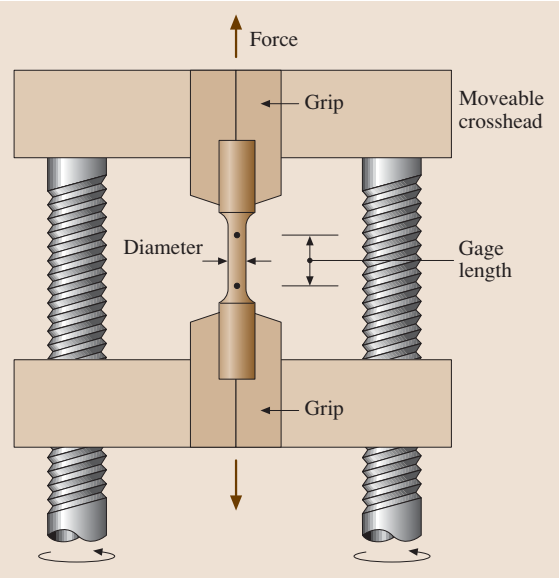

Fig. 3.51 Schematic representation of the components of a tensile testing machine (after [3.54])

grips, threads, pins or shoulders, may be considered during specimen design. It is important to emphasize that, during specimen preparation, special care must be directed towards ensuring that the reduced section of the sample is free of defects, both microstructural and machining defects, and that the specimen is representative of the bulk material.

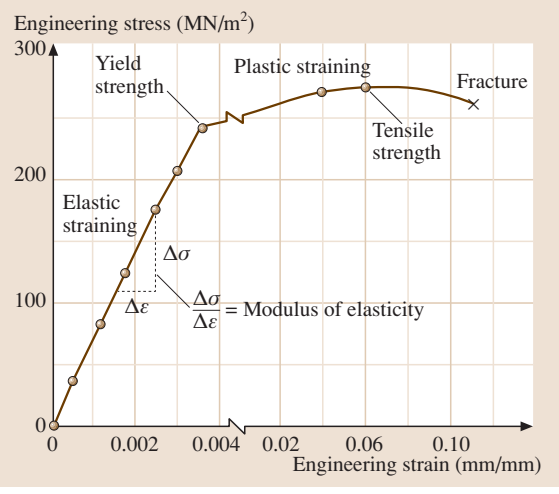

Fig. 3.52 A typical engineering stress–strain curve for a ductile material showing key mechanical properties (after [3.54])

A typical tensile testing machine (Fig. 3.51) comprises a stiff frame, a specimen gripping device, a force measuring device (or load cells), an elongation measuring device (extensometer), and a data-recording device (X–Y plotter or computer). After careful measurement of the relevant specimen dimensions, a tensile test may be run at a constant rate. The load required to produce a given elongation is recorded as the specimen is pulled and is plotted on a load–elongation chart. In order to obtain a more fundamental description of material properties, it is essential to normalize the load–elongation data for specimen geometry. To achieve this, load and elongation are converted into engineering stress and engineering strain, respectively.

Engineering stress (σ) is defined as

$$\sigma = \frac{P}{A_0}\,, \tag{3.49}$$

where P is the applied load in Newtons and A_0 is the original area of cross-section of the test specimen in square millimeters. Engineering strain (ε) is defined as

$$\varepsilon = \frac{l - l_0}{l_0} = \frac{\Delta l}{l_0}\,, \tag{3.50}$$

where l and l_0 are gage length (see Fig. 3.50 for definition) under load and original gage length, respectively.

Figure 3.52 shows a schematic engineering stress–strain diagram obtained from a tension test. The diagram is divided into two distinct regions:

1. Exclusively elastic deformation, i. e., linear and fully recoverable upon removal of load
2. (Elastic and) plastic deformation, where the latter is the nonlinear and nonrecoverable portion of total deformation

From this curve, certain key material properties can be evaluated as described below:

- *Young's modulus* E: The ratio of axial stress to corresponding strain in the elastic region. In some materials (typically polymers) the elastic region of the curve is not perfectly linear and a chord method is applied to estimate elastic modulus (Fig. 3.53).
- *Yield strength* σ_y: The stress at which it is considered that plastic elongation of the material has commenced. This stress may be specified according to one of the definitions:
  - A specified deviation from a linear stress-strain relationship, i. e., proof stress
  - A specified total extension attained or
  - Maximum and minimum engineering stresses measured during discontinuous yielding, i. e.,

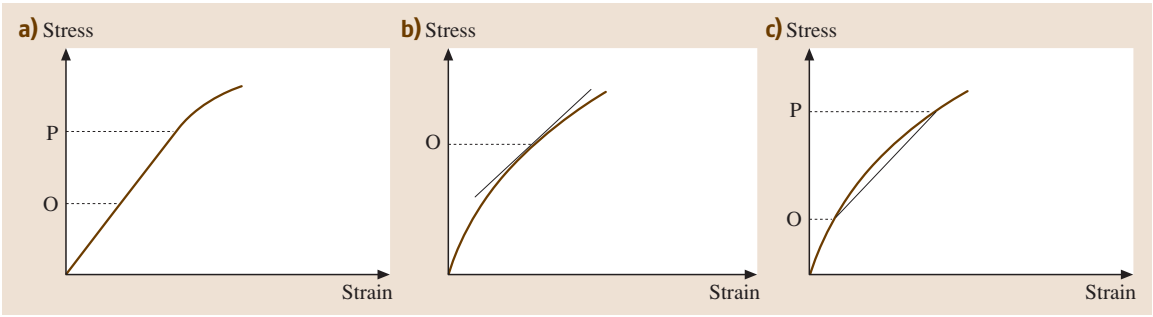

Fig. 3.53a–c Different methods to calculate Young's modulus: **(a)** from the slope of the curve between O and P below the proportional limit, **(b)** from the tangent at a given stress O, and **(c)** from the slope of the chord between stress O and P (after [3.53])

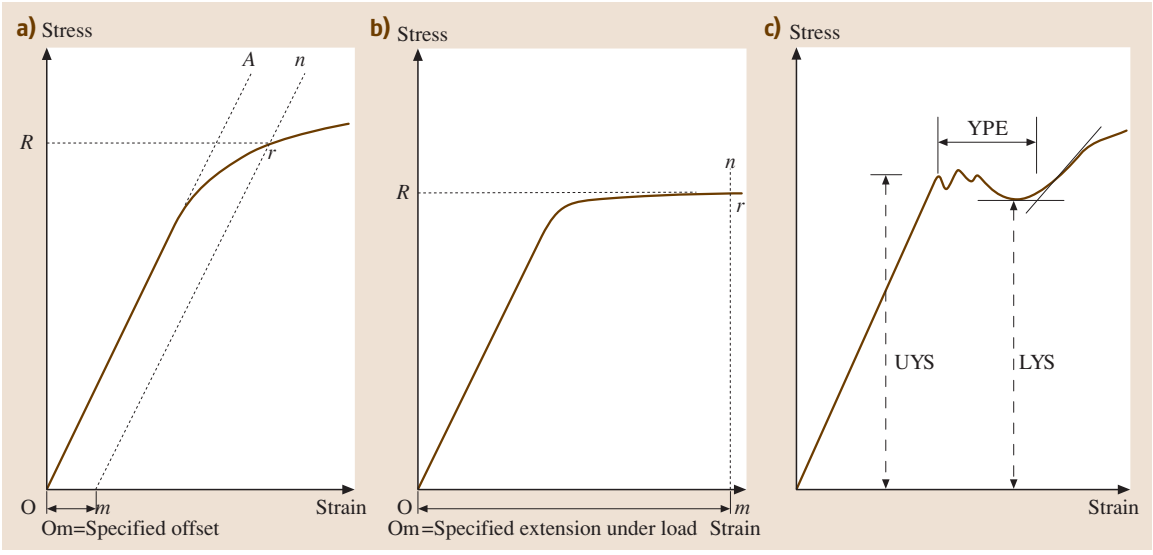

Fig. 3.54a–c Calculation of the yield stress according to **(a)** prespecified plastic offset **(b)** prespecified total strain, and **(c)** by upper and lower yield point (upper yield stress (UYS), lower yield stress (LYS), yield point elongation (YPE)) (after [3.53])

upper and lower yield point, respectively (Fig. 3.54)

The yield stress of a material may be engineered by altering grain size, and adding alloying elements and/or second phases.

- *Ultimate tensile strength (UTS)*: the maximum stress recorded during the tensile testing. After this stress level is reached, the specimen starts to show localized deformation called *necking*. Beyond this point, the engineering stress is seen to fall due to the fact that the engineering stress is defined according to original specimen dimensions. However, the true stress ($\sigma = P/A$, where A is the actual area of cross-section) continues to rise until fracture.
- *Ductility/elongation*: the ability of a material to deform before fracture under tensile load. Ductility, using this test method, is frequently quantified as percentage elongation at failure, i. e., $\varepsilon_{\text{fracture}}(\times 100)$, where $\varepsilon_{\text{fracture}}$ is the engineering strain at point of fracture.
- *Resilience and toughness*: The ability of a material to absorb energy when deformed elastically/plastically. It is defined as the area under the stress-strain curve in the elastic and plastic region, respectively.

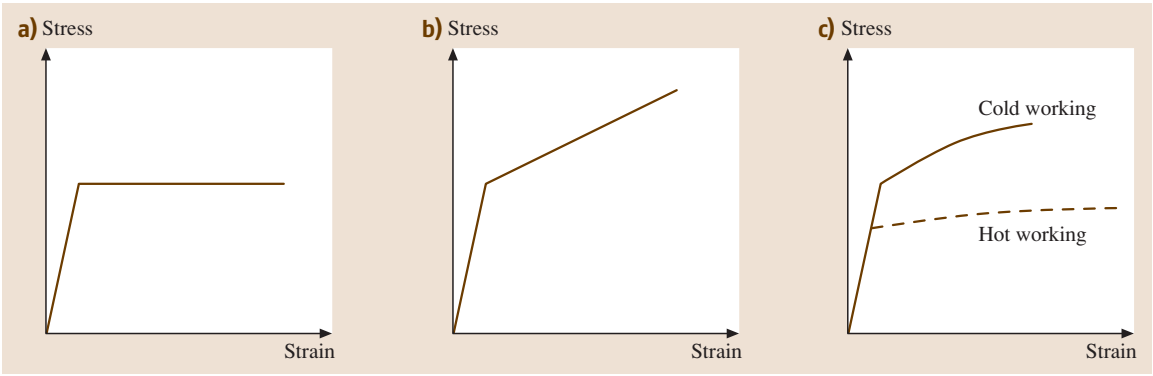

Fig. 3.55a–c Schematic representation of strain hardening in ductile metals. **(a)** elastic-ideal plastic, **(b)** elastic-plastic, and **(c)** flow curve during cold working showing strain hardening and hot-working without significant strain hardening (after [3.13])

To differentiate between elastic and plastic regions of the stress–strain curve, it is appropriate to look at the origin of strain. During elastic deformation, it is the stretching of interatomic bonds that leads to observed macroscopic strain and is linear due to the nature of interatomic forces. On the other hand, the fundamental mechanism of plastic deformation is distortion and reformation of atomic bonds. During this process the total volume of the material, however, is conserved. During plastic deformation, *dislocations* within the material become operative and *slip* due to shear stresses acting on them. For an ideal plastic, the stress required for dislocations to continue slipping is a material constant and does not depend on prior strain (Fig. 3.55a). However, in real materials, as deformation proceeds, more dislocations are generated within the material and additional driving force/stress is required for slip to proceed. This phenomenon is called *strain hardening* and is beneficially exploited during *cold working* to raise yield strength of the resultant material. Strain hardening may be overcome by *hot working* since dislocations start to become annihilated at higher temperatures ($T > 0.5T_m$, where the temperatures are calculated in Kelvin, Fig. 3.55). Furthermore, mechanical properties such as elastic modulus and tensile strength are strongly temperature dependent and decrease with increasing temperature. Ductility though is generally found to increase with increasing temperature.

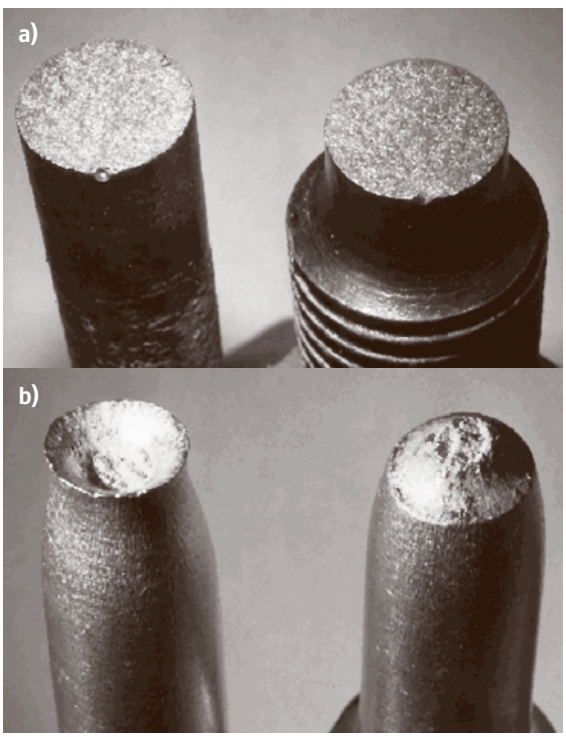

Fig. 3.56a,b Appearance of fracture surfaces after tensile testing. **(a)** Brittle fracture leads to a relatively flat surface whereas **(b)** ductile fracture shows considerable deformation prior to fracture, leading to a classical cup-and-cone arrangement

The plastic region of the true stress–true strain curve is also referred to as the *flow curve* as it is the locus of stress required to cause the metal to *flow* plastically to any given strain. The most common expression to describe the flow curve empirically takes the following form:

$$\sigma = K\varepsilon^n \,, \tag{3.51}$$

where K is the stress at $\varepsilon = 1$ and n, the strain hardening exponent, is the slope of a log–log plot of the flow curve. It can be shown mathematically that $n = \varepsilon_{\text{fracture}}$ and therefore a measure of the ductility of material.

The appearance of the surface of the specimen after fracture provides clues to the mode of fracture. A brittle fracture is accompanied by a flat (and *grainy*) surface as shown in Fig. 3.56a while ductile fracture after considerable plastic deformation has a *cup-and-cone* fracture surface (Fig. 3.56b).

Compression Testing

Mechanical properties such as yield strength, yield point, elastic modulus, and stress–strain curve may also be determined from compressive tests. This test procedure offers the possibility to test brittle and nonductile metals that fracture at low strains and avoids the complications arising out of necking. On the other hand, for certain metallic materials, *buckling* and *barreling* complicate testing (Fig. 3.57) and can be minimized by designing the samples as per specifications and using proper lubricants. Solid round/rectangular cylindrical samples (aspect ratio 0.8–10) may be used. Surface flatness and parallelism are important considerations during sample machining. After marking the gauge length and measuring the specimen dimensions, the specimen is placed in the test fixture and should be aligned carefully to ensure concentric loading. The specimen is then subjected to an increasing axial compressive load; both load and strain may be monitored either continuously or in finite increments. Relevant mechanical properties may be determined as described in Sect. 3.1.1. Compression testing is usually easier to conduct than tension test and is used more commonly at elevated temperature in plasticity or formability studies since it simulates compressive stress as is expected under rolling, forging or extrusion operation.

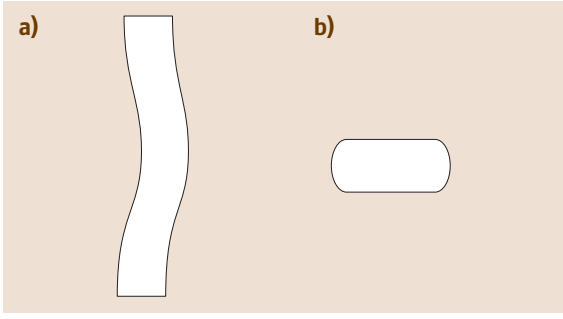

Fig. 3.57a,b Schematic representation of **(a)** buckling and **(b)** barreling during compressive testing (after [3.53])

Hardness

In general, the hardness of a material refers to its resistance to plastic deformation and is a loosely defined term. However, it is an easily measurable quantity and frequently employed in quality assurance and inspection. Standard hardness test procedure involves slowly applying an indentation to the surface of the material and measuring the relevant dimensions of the depression. Depending on the shape of the indenter and method of calculation, the following hardness tests are commonly employed.

Brinell hardness: An indenter of hardened steel or tungsten carbide *ball* with diameter D (1–10 mm) is forced into the surface of a test piece and the diameter of the indentation, d, left in the surface after removal of the test force F (100–3000 kgf) is measured. Brinell hardness (BHS or BHW) is then obtained by dividing the test force by the curved surface area of the indentation as

$$\text{BHS or HBW} = \frac{2F}{\pi D(D - \sqrt{D^2 - d^2})} . \qquad (3.52)$$

Later Meyer suggested a more rational definition of hardness based on projected area but it did not gain acceptance, despite its more fundamental nature. Meyer hardness is given as $4F/\pi d^2$ kgf/mm^2.

The *Vickers hardness* test uses a *square-based diamond pyramid* as the indenter with the included angle between the opposite faces being 136°. Due to the shape of the indenter, the Vickers hardness number (VHN or VPH) is also frequently referred to as the diamond-pyramid hardness number (DPH) and is defined as the load divided by the surface areas of indentation according to the following equation:

$$\text{DPH} = \frac{2F\sin(\theta/2)}{L^2} = \frac{1.854\,\text{F}}{L^2} , \qquad (3.53)$$

where L is average length of diameters in mm and θ is the angle between opposite faces of the diamond (= 136°). The advantage of the Vickers hardness is that it provides a continuous scale of hardness, from very soft metals to very hard materials. On the other hand, VHN is fairly sensitive to surface finish and human error.

Rockwell hardness is the most widely used hardness test in the industry due to its speed, freedom from personal error, and ability to distinguish small hardness differences in hardened steels. This test utilizes the depth of indentation, under constant load, as a measure of hardness. A minor load of 10 kg is first applied to seat the specimen, followed by the major load for the required dwell time. The depth of indentation is

automatically recorded electronically or by a dial indicator in terms of an arbitrary scale without units. THe Rockwell hardness indenter is either a 120° diamond *spheroconical* or steel *balls* 1/16–1/2 inch in diameter. Major loads of 60, 100, and 150 kg are used. Different combinations of load and indenter are used for material with different hardnesses and it is necessary to specify the combination employed when reporting Rockwell hardness. This is done by prefixing the hardness number with a letter indicating the particular combination. Hardened stress is tested on the C scale with the diamond indenter and a 150 kg major load.

Hardness testing is a very useful and reproducible method to measure and compare the mechanical strength of a material provided that sufficient precautions are taken during testing. Hardness tests are carried out on the surface of the specimen and therefore it is very important that the surface is flat, free of defects, and representative of the bulk material. Additionally there are empirical correlations available to estimate tensile strength from hardness value and to convert a result of one type of hardness test into those of a different type. However, it is important to verify these correlations for the specific class of material under consideration, though some standard conversion tables for commercial carbon and alloy steels and aluminum alloys are available. Micro- and nanohardness testing procedures are available for measuring hardness over smaller areas, while hot hardness testers are used to measure hardness at elevated temperatures.

Bend or Flexure Testing

Bend tests are used primarily for obtaining values of proof stress and modulus of elasticity in bending (E_b) as well as the ductility of relatively flexible materials such as polymers and their composites. Bend testing also provides a convenient method for characterizing the strength of the miniature components and specimens that are typical of those found in microelectronics applications.

There are two test types (Fig. 3.58): three-point flex and four-point flex. In a three-point test the area of uniform stress is quite small and concentrated under the center loading point. In a four-point test, the area of uniform stress exists between the inner span loading points (typically half the outer span length).

A flexure test produces tensile stress in the convex side of the specimen and compression stress in the concave side. This creates an area of shear stress along the midline. To ensure that the primary failure comes from tensile or compression stress the shear stress must

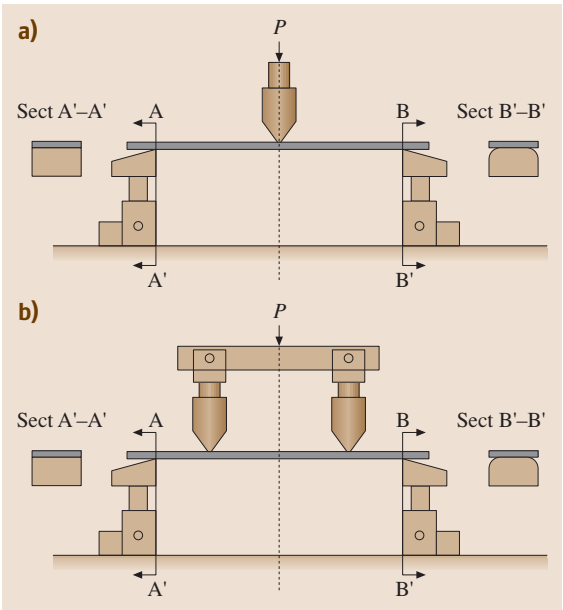

Fig. 3.58a,b Schematic representation of **(a)** three- and **(b)** four-point bend tests (after [3.53])

be minimized. This is done by controlling the span (S) to depth (d) ratio, the length of the outer span divided by the height (depth) of the specimen. For most materials $S/d = 16$ is acceptable. Some materials require $S/d = 32–64$ to keep the shear stress low enough. Usually, a rectangular cross-section of the specimen is used. E_b varies as the third power of beam thickness, and therefore uniformity in thickness is of paramount importance.

The test apparatus consists of two adjustable supports and means of measuring deflection and for applying load. The supports are generally knife-edge or convex. The load applicator is a rounded knife-edge with an included angle of 60°, applied either at mid span (for three-point testing) or symmetrically placed from the supports (for four-point testing). Elastic deflection δ is measured at the mid-span as shown in Fig. 3.58. Stress and E_b are related to applied load and deflection as follows:

$$\sigma_p = \frac{3PL}{2bh^2}\,; \quad E_b = \frac{PL^3}{4bh^3\delta}$$

for three-point bend testing (3.54)

and

$$\sigma_p = \frac{3Pa}{bh^2}\,; \quad E_b = \frac{Pa\left(3L^2 - 4a^2\right)}{4bh^3\delta}$$

for four-point bend testing (3.55)

Torsion Testing

Torsion tests have not met with the wide acceptance and use that have been given to tensile testing. However, in many engineering applications and theoretical studies, they are of considerable importance. Torsion tests are used to determine such properties as modulus of elasticity in shear (G), torsional yield strength, and modulus of rupture. During a torsion test, measurements are made of the twisting moment, M_T and the angle of twist θ. From linear elastic mechanics (Fig. 3.59), shear stress τ and shear strain γ can be calculated according to the following relation:

$$\tau_{max} = G\gamma = \frac{M_T r}{J}\,, \quad \gamma = \frac{r\theta}{L}\,, \tag{3.56}$$

where r and L are the radius and length of the test specimen, respectively, and J is the polar moment of inertia of the area with respect to the axis of specimen. For a solid cylindrical specimen, $J = \pi r^4/2$. Because of the stress gradient across the diameter of a solid bar, it is preferable to use a tubular specimen for the determination of the shearing yield strength and elastic modulus. However, care must to be taken to avoid buckling in this case.

Beyond the torsional yield strength, shear stress is no longer a linear function of distance from the axis and the analysis becomes slightly more complicated; in this case the maximum shear at the surface is given as

$$\tau_{max} = \frac{1}{2\pi r^3}\left(\theta\frac{dM_T}{d\theta} + 3M_T\right)\,. \tag{3.57}$$

It is possible to convert the shear stress–strain curve into a tensile stress–strain curve using the following relations:

$$\sigma = \sqrt{3}\tau_{max}\,, \quad \varepsilon = \frac{\gamma}{\sqrt{3}}\,. \tag{3.58}$$

A major advantage of torsion tests over tensile tests is that fracture is delayed and it is possible to extend the flow curve to larger strains. This is of significance in the study of the plastic flow behavior of ductile materials. Torsion tests are regarded as complicated due to the considerable labor involved in converting torque–twist data to stress–strain data. However, computational resources available today considerably ease this restraint. Torsion testing provides a more fundamental description of the plasticity of metals and avoids complications such as necking and barreling associated with tension and compression tests.

As mentioned earlier, specimen design and fabrication is rather important for obtaining reliable mechanical properties from torsion tests. Specimens in the form of solid cylinders should be straight and of uniform diameter with a length equal to the gauge length plus two to four diameters. In the case of tubes, the total specimen length should be the gauge length plus at least four outside diameters. The prescribed ratio of gauge length to diameter is at least four to ten. For tubular samples, the ratio of outside diameter to wall thickness should lie between eight and ten. During testing, the twist angle is generally applied by mechanical, optical or electrical means using rings fastened to the sample. A torsiometer, fastened to the sample and the base of the machine, is used to measure the angle of twist in radians in both elastic and plastic regions.

Creep Testing

A metal subjected to constant load at elevated temperature ($> 0.5T_m$, where T_m is the absolute melting temperature) undergoes time-dependent (anelastic) deformation called creep. At these temperatures the mobility of atoms increases significantly according to Fick's laws, (3.16) and (3.18), and according to (3.17) diffusion-controlled processes have a significant effect on mechanical properties. Rate of dislocation climb, concentration and mobility concentration of vacancies, new slip systems, and grain boundary sliding are all temperature and diffusion controlled and affect the mechanical behavior of materials at high temperatures. In addition, corrosion or oxidation mechanisms, which are diffusion-rate dependent, will have an effect on the lifetime of materials at high temperatures.

Conceptually a creep test is rather simple: a force is applied to a test specimen exposed to a relatively high temperature and the dimensional change over time is measured. If a creep test is carried to its conclusion (that is, fracture of the test specimen), often without precise measurement of its dimensional change, then it is called a stress rupture test. Although conceptually quite simple, creep tests in practice are more complicated. Temperature control is critical (fluctuation must be kept to $< 0.1–0.5\,°C$). Resolution and stability of the extensometer are important concerns (for low-creep materials, displacement resolution must be on the or-

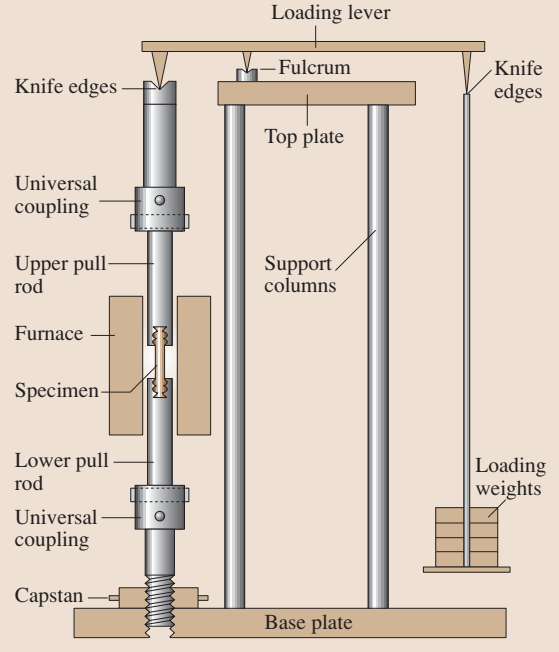

Fig. 3.60 Schematic of a constant-load creep-testing setup

der of 0.5 μm). Environmental effects can complicate creep tests by causing premature failures unrelated to elongation and thus must either mimic the actual service conditions or be controlled to isolate the failures to creep mechanisms. Uniformity of the applied stress is critical if the creep tests are to be interpreted properly. Figure 3.60 shows a typical creep testing setup.

The curve in Fig. 3.61 illustrates the idealized shape of a creep (strain–time) curve. The slope of this curve ($\mathrm{d}\varepsilon/\mathrm{d}t$ or $\dot{\varepsilon}$) is referred to as the creep rate. The initial strain $\varepsilon_\mathrm{i} = \sigma_\mathrm{i}/E$ is simply the elastic response to the applied load. The strain itself is usually calculated as the engineering strain, $\varepsilon = \Delta l/l_0$. The primary region (I) is characterized by transient creep with decreasing creep rate due to the creep resistance of the material increasing by virtue of material deformation. The secondary region (II) is characterized by steady-state creep (the creep strain rate $\dot{\varepsilon}_\mathrm{min} = \dot{\varepsilon}_\mathrm{ss}$ is constant) in which competing mechanisms of strain hardening and recovery may be present. The tertiary region (III) is characterized by increasing creep strain rate in which necking under constant load or consolidation of failure mechanism occur prior to failure of the test piece. The relative significance of the three creep stages depends on the temperature, creep stress, and material.

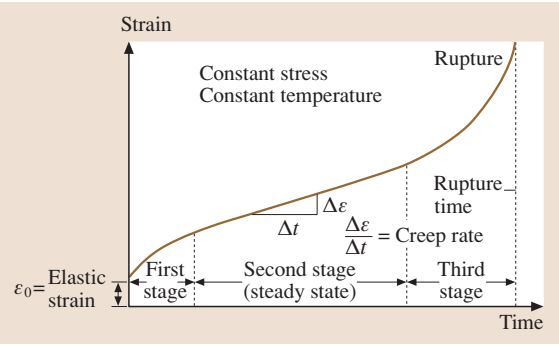

Fig. 3.61 An idealized creep curve showing the three stages during creep (after [3.54])

Traditionally, a creep curve is described by the following empirical relation, due to *Andrade* [3.54]:

$$\varepsilon = (1 + \beta t^{1/3}) \exp(\kappa t) \,, \tag{3.59}$$

where β and κ are empirically determined constants related to the primary and steady stages of the creep curve, respectively. However, for engineering applications, it is the steady-state creep rate that is of major concern; for example, what is the permissible stress needed to produce a minimum strain rate of 10^{-6}/h (i. e., strain of 0.01 in 10 000 h)? The *Mukherjee–Bird–Dorn* equation (3.60) is often used as a scaling relation

$$\frac{\dot{\varepsilon} k T}{D_0 G \boldsymbol{b}} = A_o \left(\frac{\sigma}{G}\right)^n \left(\frac{d}{\boldsymbol{b}}\right)^p \exp\left(-\frac{Q_c}{\mathrm{RT}}\right) \,, \tag{3.60}$$

where $\boldsymbol{b}$ is Burgers vector, d is grain size, D_o is the self-diffusion coefficient, G is the shear modulus, k is Boltzmann's constant, σ is the applied stress, Q_c is the activation energy for creep, R is the universal gas constant, T is the absolute temperature, and A, p, and n are dimensionless constants. Various creep mechanisms have been identified (both theoretically and experimentally) and are classified accordingly as:

1. Diffusion creep
2. Dislocation creep
3. Power-law breakdown

In diffusion creep processes atomic vacancies generated close to grain boundaries normal to the applied stress migrate to grain boundaries parallel to the applied stress, where they are absorbed. This process is leads to a shape change, but it does not involve dislocation flow (as the higher stress processes do). This diffusive transport of vacancies at higher temperatures occurs through the bulk of the grain (Nabarro–Herring creep) whilst at lower temperatures it occurs along the grain boundaries (Coble creep). Creep rates are reported

to be inversely proportional to the square of the grain size for Nabarro–Herring creep ($p = -2$ in (3.60)) and inversely proportional to the cube of the grain size for Coble creep ($p = -3$). When creep is controlled by diffusion alone, $n = 1$ in (3.60).

At higher stresses steady-state creep occurs by dislocation glide plus climb and values of n are typically 4–5; this is called the power-law regime. The upper boundary of the power-law creep regime is defined by the ratio of the applied shear stress to the elastic shear modulus that corresponds to the onset of general plasticity. For face-centered cubic (fcc) metals this ratio is given as 1.26×10^{-3} and deformation at stresses exceeding this value is said to be in the power-law breakdown regime. In the power-law breakdown regime, the Dorn equation is no longer valid. In the power-law and power-law breakdown regime, the steady-state creep rate is independent of grain size, i. e., $p = 0$. By solving the equations for diffusional flow, power-law creep, and general plasticity, it is possible to prepare deformation mechanism diagrams for a given material. The diagram for pure copper with a 100 μm grain size is reproduced in Fig. 3.62.

Two important phenomenon related to creep are *superplasticity* and *stress relaxation*. Superplasticity is the ability of a material to undergo large elongation without failure, see [3.56] for an overview. Stress jump tests are carried out to assess superplasticity of a material quickly at a given temperature by measuring the flow stress at different rates of loading, keeping the temperature constant. The strain-rate exponent, m ($= 1/n$, (3.59)), can then be evaluated and should be close to 0.5 for superplastic behavior to be observed. To determine the stress relaxation of a material, the specimen is deformed a given amount, and the decrease in stress is recorded over a prolonged period of exposure at a constant elevated temperature. The stress-relaxation rate is the slope of the curve at any point.

The goal in engineering design for creep is to predict performance over the long term. To this end, one of three approaches is applied:

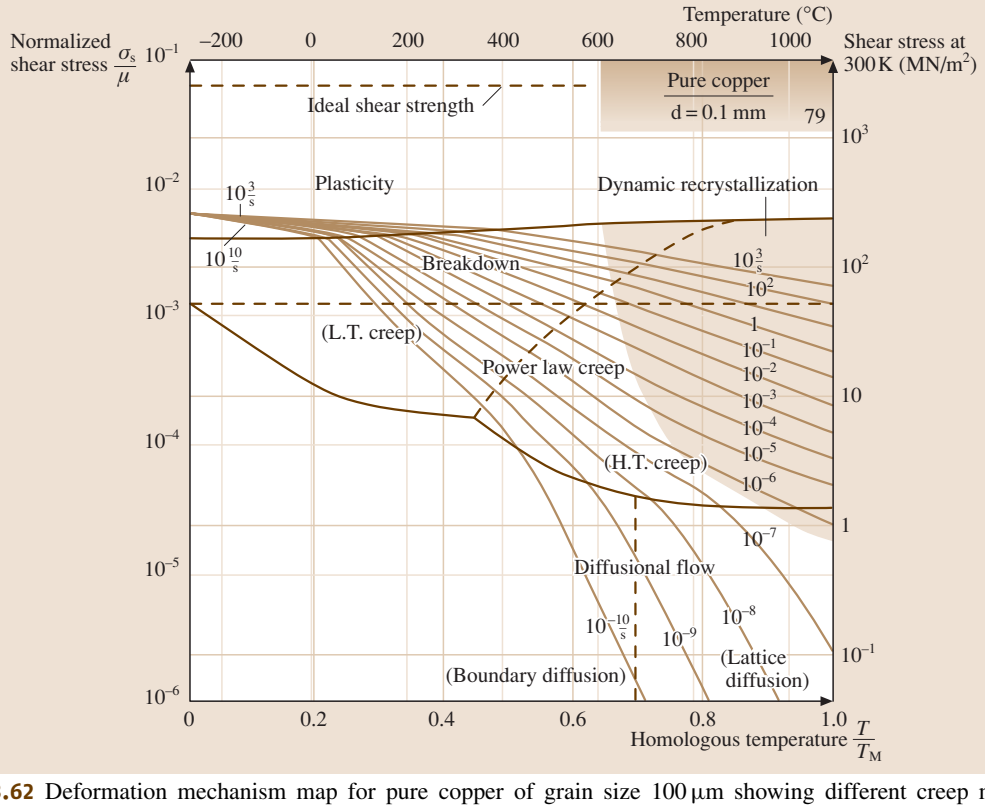

Fig. 3.62 Deformation mechanism map for pure copper of grain size 100 μm showing different creep mechanisms operating under a given temperature–stress region (after [3.55])

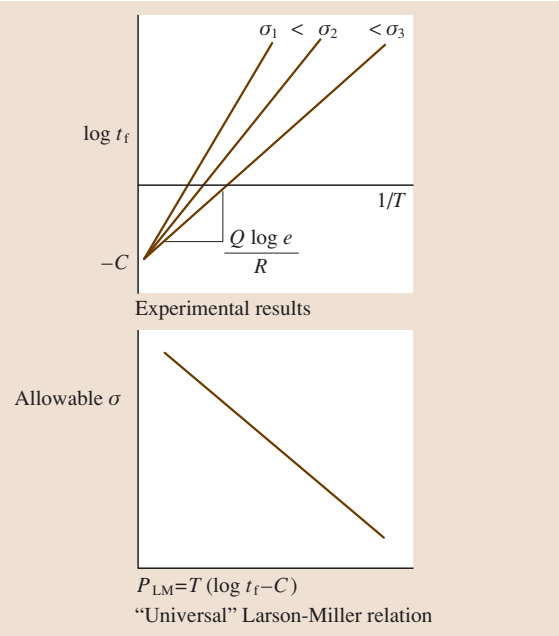

Fig. 3.63 Summary of the Larsen–Miller method for creep life prediction

- Stress-rupture tests. A large number of tests are run at various stresses and temperatures to develop plots of applied stress versus time to failure. While it is relatively easy to use these plots to provide estimates of stress rupture life, it is a very expensive and time consuming to develop these plots. Additionally, extrapolation of the data can be problematic.
- Minimum strain rate versus time to failure. This type of relation is based on the observation that strain is the macroscopic manifestation of the cumulative creep damage. A critical level of damage, independent of stress and/or temperature, is then defined as the failure criterion as follows:

$$\dot{\varepsilon}_{\min} t_f = C \propto \varepsilon_f \,. \qquad (3.61)$$

A log–log plot of $\dot{\varepsilon}_{\min}$ versus t_f or Monkman–Grant chart can then be constructed from a relatively few creep tests to determine the value of the empirical constant C and be used to predict creep life.

- Temperature-compensated time. In these methods, a higher temperature is used at the same stress so as to cause a shorter time to failure such that temperature is traded for time. In this form of accelerated testing it is assumed that the failure mechanism does not change and hence is not a function of temperature or time. In the most commonly used method, the Larson–Miller parameter P_{LM} at a given stress is expressed as

$$P_{LM} = 2.303 \frac{Q_c}{R} = T(C_1 + \log t_f) \,, \qquad (3.62)$$

where C_1 is the Larson–Miller constant, typically ranging between 25 and 60. Experimental data in terms of log t_f and $1/T$ at a given stress is plotted to estimate Q_c and C_1 as in Fig. 3.63.

3.3.3 Dynamic Mechanical Properties

In structural applications, members are often subjected to varying load/stress over time either in the form of vibrations or high-energy impacts. It is important to have an understanding of the effect of such forces on structural integrity to avoid catastrophic failure by fracture.

Impact Testing

Toughness is a qualitative measure of a material's ability to absorb impact energy by undergoing plas-

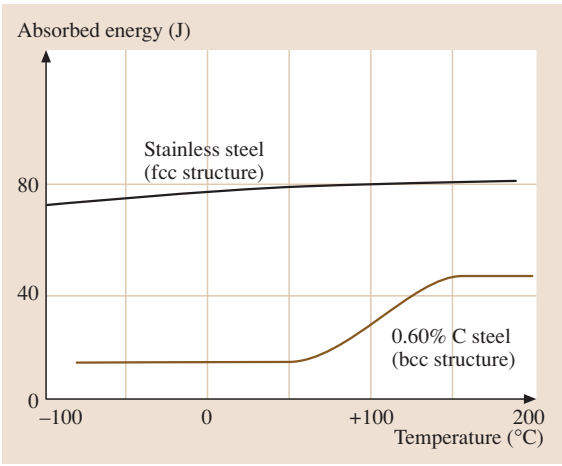

Fig. 3.65 Variation of absorbed energy as a function of temperature showing ductile to brittle transition (DBTT) in a plain carbon steel (after [3.13])

tic deformation. Notched-bar impact tests are generally used to detect the tendency of a material to fail in a brittle manner. Two classes of notched specimens are commonly used for these class of tests, namely the *Charpy* notched bar and the *Izod* specimen (Fig. 3.64). The specimen may have a square or circular cross-section and a V notch is machined either at the center (Charpy) or towards one end (Izod) of the specimen. The impact load is then applied by a heavy swinging hammer as indicated in Fig. 3.64. The presence of the notch creates a triaxial state of stress on the fracture plane. The response of the sample is usually measured by the energy absorbed in fracturing the specimen and can be estimated from the loss in kinetic energy before and after the impact.

The notched-bar impact test is most meaningful when conducted over a range of temperatures. Most metallic materials undergo a transition from a ductile to brittle mode of fracture with decreasing temperature. This transition temperature is called the ductile to brittle transition temperature (DBTT) and is an important design parameter. Figure 3.65 shows the typical variation of absorbed impact energy as a function of temperature for two steels, a ferritic (bcc structure) and an austenitic (fcc structure) one. The material with lowest DBTT should be preferred in structural applications at low temperatures to avoid catastrophic failure, hence, austenitic stainless steels are recommended.

Cyclic Testing

It is well known that a component subjected to a load well below its yield stress fails by fatigue, i. e., fluctuating load over a period of time (Fig. 3.66). Fatigue failure usually occurs without any obvious warning and is usually accompanied by fracture. A periodic stress cycle of the kind shown in Fig. 3.67a and b comprises a mean stress, $\sigma_m (= (\sigma_{max} + \sigma_{min})/2)$, and an alternating stress amplitude $\sigma_a (= (\sigma_{max} - \sigma_{min})/2)$. The stress ratio R is then defined as

$$R = \frac{\sigma_{min}}{\sigma_{max}} , \qquad (3.63)$$

where σ_{max} and σ_{min} are the maximum and minimum stress, respectively. The basic method of presenting engineering fatigue data is by means of the S–N curve, which represents the dependence of cycles to failure N on the maximum applied stress σ_{max}. Most investigations of fatigue properties are made by means of a rotating beam machine, where $\sigma_m = 0$ and $R = -1$. Figure 3.67 shows a schematic of the test apparatus and a typical S–N curve for this type of test. For most ferrous alloys, the S–N curve becomes horizontal at a certain limiting stress called the endurance or fatigue limit. Most nonferrous metals have S–N curves that do not show a true endurance limit and in such cases it is customary to define the endurance limit as the maximum stress that does not cause failure after 5×10^8

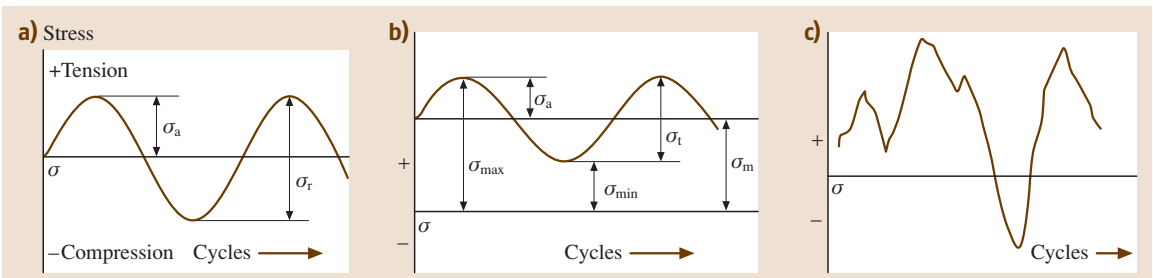

Fig. 3.66 **(a)** and **(b)** definition of different stress parameters during cyclic stress testing of materials. **(c)** A typical stress variation curve for an aeroplane foil in service (after [3.13])

cycles. It must be noted that considerable scatter is observed during fatigue testing and it is standard to test three or four samples at a given stress level.

Application of a cyclic load, i. e., σ_a, leads to a cyclical strain response $\Delta\varepsilon_a$, which comprises elastic $\Delta\varepsilon_e$ and plastic $\Delta\varepsilon_p$ components. Figure 3.68 shows the variation of the elastic, plastic, and total strain amplitude as a function of number of cycles to failure. Based on this figure, it is easy to visualize that, below a particular *transition life* ($N_{f,t}$), plastic deformation controls the cycles to failure, while above the transition life elastic strain is the major source of fatigue damage. The two regions are termed low- or high-cycle fatigue, respectively, and the transition life is usually close to 10^4 cycles.

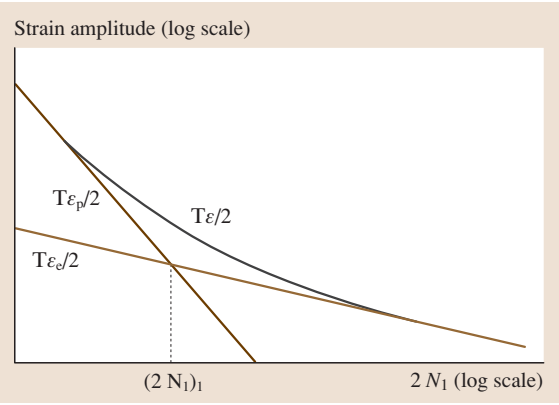

Fig. 3.68 Definition of a transition life between low- and high-cycle fatigue (after [3.57])

The fatigue process of a material can be divided into the following stages:

- *Crack initiation*, which including the early development of fatigue damage due to localization of slip at persistent slip bands (PSB) or embryonic cracks.
- *Slip-band crack growth*, which involves the deepening of the initial crack on planes of high shear stress. This is frequently called stage I crack growth.
- *Crack growth on planes of high tensile stress*, which involves the growth of well-defined cracks in a direction normal to the maximum tensile stress. This is usually called stage II crack growth.
- *Ultimate ductile failure*, which occurs when the crack reaches sufficient length that the remaining cross section cannot support the applied load.

In general, larger proportions of the total cycles to failure are involved with the propagation of stage II cracks in low-cycle fatigue than in high-cycle fatigue, while stage I crack growth comprises the largest segment for low-stress high-cycle fatigue. If the tensile stress is high, as in the fatigue of specimens with preexisting surface flaws or notches, stage I crack growth may not be observed at all. Specialized crack growth-rate tests using specimens which have been precracked in fatigue (see below) are employed to establish material selection criterion and to establish the effect of the following factors that are known to have a significant influence on fatigue life:

1. Stress or strain range
2. Mean stress
3. Surface finish and quality
4. Surface treatments
5. Load sequence and overload

A typical test results from these crack growth studies is shown in Fig. 3.69. Additional factors such as environmental conditions, elevated temperatures, and corrosive media drastically affect fatigue life and accelerate failure.

Fracture Mechanics

New nondestructive testing techniques allow designers to adopt a more *damage-tolerant* approach to structural

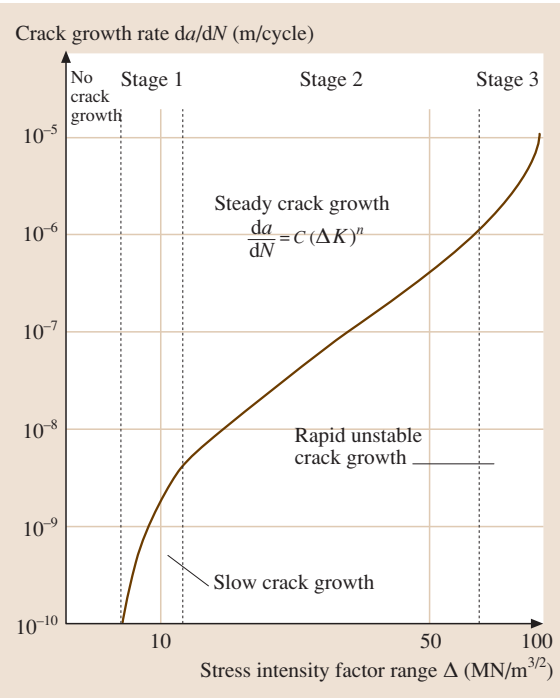

Fig. 3.69 A schematic fatigue crack-growth curve showing the three regimes of crack growth (after [3.54])

design. Accordingly, material with defects is no longer considered as failed but can be further used in service provided it is safe against *fast fracture*. The criterion for continued safe operation is that the strain energy release rate (called G for brittle materials and J for ductile materials) should be less than a critical value. The strain energy release rate is the amount of energy per unit length along the crack edge that is supplied by the elastic and plastic energy in the body and by the applied force in creating the new fracture surface area.

From linear elastic theory, the stress field around a crack (Fig. 3.70) can be expressed as

$$\lim_{r\to 0} \sigma_{ij}^M = \frac{K_M}{\sqrt{2\pi r}} f_{ij}^M(\theta) \,, \tag{3.64}$$

where the superscript and subscript "M" denotes the mode of load application (Fig. 3.71), f_{ij} is a function of location, and K is the stress intensity factor expressed as

$$K = Y\sigma\sqrt{\pi a} \,, \tag{3.65}$$

where Y is a dimensionless factor dependent on the sample geometry and a is the crack half-length. K can be related to G according to the following relations:

$$G = \begin{cases} \frac{K^2}{E} & \text{(plane stress)} \\ \frac{K^2}{E}(1-\nu^2) & \text{(plane strain)} \end{cases} \tag{3.66}$$

For ductile materials, the equivalent of energy release rate G is the J-integral, which is defined as

$$J = \int_\Gamma \left(W\,\mathrm{d}y - \overline{T}\frac{\partial \overline{u}}{\partial x}\,\mathrm{d}s \right) , \tag{3.67}$$

where W is the load per unit volume, Γ is the path of the line integral that encloses the crack tip, $\mathrm{d}s$ is the increment of the contour path, and $\overline{\boldsymbol{T}}$ and $\overline{\boldsymbol{u}}$ are the outward traction and normal vectors, respectively, on $\mathrm{d}s$. The first term corresponds to the elastic component while the second term corresponds to the plastic energy due to the crack.

As mentioned earlier, the stress intensity factor K should be less than a critical value (K_c) as a design

criterion. The critical stress intensity factor in tension mode, K_{Ic}, is a material property and can be interpreted as the inherent resistance of a material to failure. Hence, it is frequently called the *fracture toughness* of a material. Like other mechanical properties, it is determined experimentally as described below. The same test procedure applies to the determination of the J-integral, though the test data is treated differently. The test specimen may be a single-edge notched beam, com-

pact tension or cylindrical disc (Fig. 3.72). Load line displacement is recorded as a function of applied load. A fatigue precracked test specimen is loaded in tension or bending to induce either:

1. Unstable crack extension (or *fracture instability*) or
2. Stable crack extension (or *stable tearing*)

The first method is used to determine the value of fracture toughness at the point of instability, while the second method results in a continuous relationship for fracture toughness versus crack extension (called the *R*-curve, Fig. 3.73). For *R*-curve determination, crack extension is also recorded simultaneously by optical or electrical means. The recorded data is then used to evaluate K_{Ic}, J_{Ic} or the J–R curve using standard relations. K_{Ic} is independent of the specimen geometry only under plain-strain conditions and this criterion should be assessed carefully. Similar crack growth tests may also be used to evaluate the performance of a material under creep and/or fatigue.

Table 3.3 summarizes standards for mechanical testing of materials according to ASTM [3.58].

3.4 Physical Properties

While the prime design criterion in most applications in mechanical engineering is mechanical properties (Sect. 3.3), physical properties are instead decisive for most applications as functional materials. As some of these materials are of paramount importance in fields related to mechanical engineering such as microelectronics, mechatronics, and the production, conversion, and distribution of electric power, we will briefly discuss in this section selected properties such as electrical and thermal conductivity with respect to materials in mechanical engineering, i. e., metals, ceramics, glasses, and polymers, as described in more detail in Sect. 3.6. Particularly, a discussion of the broad and still emerging fields of *magnetism and superconductivity* and *semiconducting materials* must be omitted here. For in-depth information, the interested reader is referred to the recent version of the *Encyclopedia of Magnetic and Superconducting Materials* [3.59] and to the *Springer Handbook of Condensed Matter and Materials Data* [3.1].

3.4.1 Electrical Properties

Ohm's Law and Electrical Conductivity

The relation between the voltage U (in Volts, V) and the current I (in Ampères, A) in an electric conductor (often in the form of a wire) is given by (the macroscopic) form of *Ohm's law* as

$$R = \frac{U}{I} , \tag{3.68}$$

where R is the resistance (in Ohms, Ω) of the material to the current flow and depends critically on the geometry and (intrinsic) properties of the material, therefore

$$R = \rho \frac{l}{A} = \frac{l}{\sigma A} , \tag{3.69}$$

where l is the length and A is the cross-section of the conductor; ρ (Ω m) and σ ($\Omega^{-1}\,\mathrm{m}^{-1}$) are the *electrical resistivity* and *electrical conductivity*, respectively, being specific for the material under consideration. Combining (3.68) and (3.69) yields

$$j = \frac{I}{A} = \sigma \frac{V}{l} = \sigma E , \tag{3.70}$$

with the current density j ($\mathrm{A/m^2}$) and the electric field strength E (V/m). Alternatively, j is given by the product of the number of charge carriers n, the charge of each carrier q, and the average *drift velocity* v of the carriers, thus

$$j = nqv . \tag{3.71}$$

Setting (3.70) and (3.71) equal yields the microscopic form of Ohm's law, which is more relevant for materials engineers

$$\sigma = nq \frac{v}{E} = nq\mu . \tag{3.72}$$

The term v/E is called the *mobility* μ ($\mathrm{m^2\,V^{-1}\,s^{-1}}$) of the charge carriers. While the charge q of the carriers of the electric current is a constant, one may readily recall from (3.72) that the electrical conductivity of materials can be controlled essentially by two factors, namely:

1. The number of charge carriers n
2. Their mobility μ

While electrons are the charge carriers in conductors (metals), semiconductors, and many insulators, ions carry the charge in ionic compounds. Therefore, in pure materials the mobility μ depends critically on the bonding strength and – in addition in ionic compounds – on

diffusion rates, which in turn gives rise to the tremendous variation of electrical conductivity over more than 20 decades, see Table 3.4.

Effect of Temperature on the Electrical Conductivity of Metallic Materials

When heat is applied to metallic materials the atoms gain thermal energy and vibrate at a particular amplitude and frequency. Thus, increasing the temperature increases the probability of scattering electrons within the crystal, which ultimately leads to a reduction of the mobility of electrons; the resistivity ρ_T (of a pure material) at a particular temperature changes according to

$$\rho_T = \rho_{RT}[1 + a(T - RT)] , \tag{3.73}$$

where a is the *temperature resistivity coefficient* and "RT" indicates room temperature. The relationship between resistivity and temperature is linear over a wide temperature range; values of a for metals are positive and are tabulated in [3.1].

Effect of Lattice Defects on the Electrical Conductivity of Metallic Materials

An additional contribution to electron scattering stems from all kinds of lattice imperfections, as listed in Sect. 3.1.2. As a representative, the increase in resistivity due to atoms in solid solution can be described as

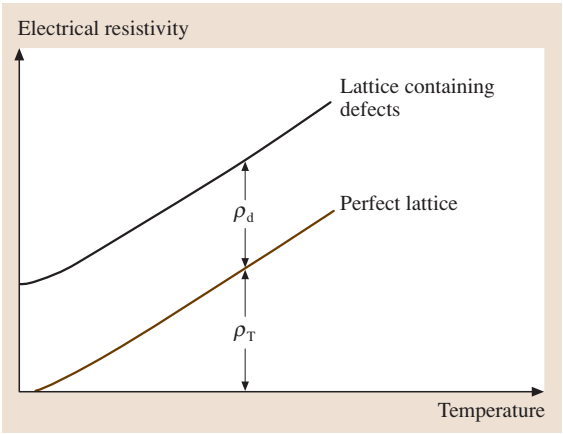

Fig. 3.74 Dependence of electrical resistivity of metallic materials on temperature; for further explanations see text

$$\rho_d = C(1 - x)x , \tag{3.74}$$

where ρ_d is the increase in resistivity due to the lattice defects present in the material and x is defined as the molar fraction of these defects (Sect. 3.1.2); C is the defect resistivity coefficient. Thus, the overall resistivity is

$$\rho = \rho_T + \rho_d . \tag{3.75}$$

Note that the effect of defects is virtually independent of temperature (Fig. 3.74).

3.4.2 Thermal Properties

As outlined in Sect. 3.1.2 the atoms in a material have a minimum free energy at absolute zero. However, as mentioned in the previous subsection supply of thermal energy causes the atoms to vibrate at a particular amplitude and frequency. This gives rise to a number of physical effects and related quantities such as the *heat capacity* or *specific heat*, *thermal expansion*, and *thermal conductivity*, which will be discussed briefly in the following subsections.

Heat Capacity and Specific Heat

Since vibrations of atoms are transferred through the whole crystal as elastic waves, heating up or cooling down of a material is realized by accepting or loosing *phonons* of energy

$$E = \frac{hc}{\lambda} = h\nu . \tag{3.76}$$

Table 3.5 Specific heat c of selected materials at RT [3.1, 54]

Then, the *heat capacity* is the energy required to raise the temperature of *one mole* of a given material by one *Kelvin* (K). It can be determined by various methods either at constant pressure C_p or at constant volume C_V. As depicted in Fig. 3.60 the heat capacity approaches a nearly constant value of $C_p = 3R \approx 25\,J\,mol^{-1}\,K^{-1}$ at sufficiently high temperatures for most metallic (above $\approx$ RT) and ceramic (> 800 K) materials. An exception to this rule is the (toxic) element Be which has a mere $C_p \approx 16\,J\,mol^{-1}K^{-1}$ [3.1].

By contrast, the *specific heat* c is the energy required to raise the temperature of a particular weight or mass of a material by 1 K. The relationship between heat capacity and specific heat is simply given by $c = C_p/M$, where M is the atomic mass (see periodic table). For engineering applications, specific heat is more appropriate to use than heat capacity. A compilation of the specific heat of typical materials is given in Table 3.5. Data on water (liquid) and nitrogen (gas) are given also for comparison, with H_2O having the highest value of specific heat. Note that neither specific heat nor heat capacity depend significantly on microstructure.

Thermal Expansion

As pointed out in Sect. 3.1.1 the lattice constant of a material is a measure of the strength of atomic bonding, which is in turn the result of force equilibrium between an attractive and a repulsive potential. If a material gains thermal energy, however, this equilibrium separation increases since the material is lifted from its energy minimum into a higher-energy state. The change in the dimensions of the material is usually measured by *dilatometry* as

$$\alpha = \frac{l_f - l_0}{l_0(T_f - T_0)} = \frac{\Delta l}{l_0 \Delta T}\,, \qquad (3.77)$$

where the indices "f" and "0" denote the final and initial values of length l and temperature T. Linear coefficients of thermal expansion α at RT for selected materials are listed in Table 3.6.

Two conclusions can be drawn from the compilation in Table 3.6, namely that materials possessing strong atomic bonds, in particular covalently bonded materials such as many ceramics, have:

1. Low α values and
2. High melting points T_m

The latter relationship is shown for metals in Fig. 3.76.

A particular behavior must be noted for the Invar alloy Fe–36%Ni, which reveals that interaction with magnetic domains may suppress thermal expansion nearly completely until the Curie temperature is reached. This makes Invar attractive for bimetallic applications.

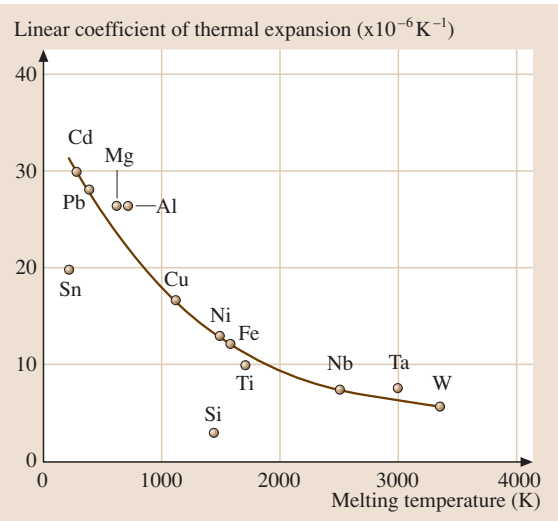

Fig. 3.76 Relationship between the linear coefficient of thermal expansion (at RT) and the melting point in metals

Thermal Conductivity

In essence, *thermal energy* is transferred in solid materials by two mechanisms:

1. Transfer of free (valence) electrons
2. Lattice vibrations (phonons)

of which the latter is closely related to the phenomenon of storing thermal energy, i. e., the *heat capacity* (see above).

Hence, the *thermal conductivity* k is a measure of the rate at which heat is transferred through the material and follows the relationship

$$\frac{Q}{A} = k\frac{\Delta T}{\Delta x}\,, \tag{3.78}$$

where Q is the heat transferred through a cross-section A induced by a temperature gradient $\Delta T/\Delta x$. Note the

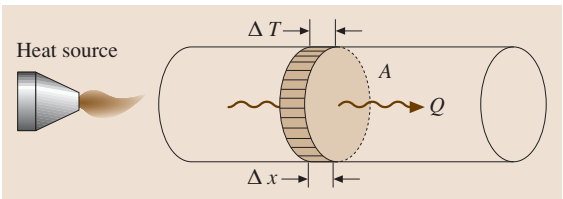

Fig. 3.77 Schematic of the method for measuring the thermal conductivity k according to (3.75, 78)

striking similarity between k and the diffusion coefficient D in mass transfer (3.14), where the *heat flux* Q/A is analogous to the flux of atoms j_D. A schematic experimental setup for measuring k is shown in Fig. 3.77, where heat is introduced on one side of a bar- or disc-shaped sample through a heat source and the change of temperature on the other side is measured as a function of time. The commonly employed technique is called the *laser flash method*.

Values for the thermal conductivity k of selected materials are listed in Table 3.7. A comparison yields that the k values of metals and alloys are usually much larger than those of ceramics, glasses, and polymers. This is due to the fact that in metals and alloys thermal energy is transferred through the movement of (loosely bonded) valence electrons which can be excited with little thermal energy into the conduction band. This leads to a relationship between thermal and electrical conductivity in many metals of the form

$$\frac{k}{\sigma T} = L = 2.3 \times 10^{-8}\,\mathrm{W\,\Omega\,K^{-2}}\,, \tag{3.79}$$

where L is the Lorentz constant.

In contrast, the prime energy transfer mechanism in ceramics, glasses, and polymers is vibration of lattices and (silicate or molecular polymeric) chains, respectively. Since the electronic contribution is absent, the thermal conductivity in these material classes is usually much lower than that in metals and alloys. An exception to the rule is *carbon* in its covalently bonded form as *diamond*, which has the highest k value and therefore commonly serves as a *heat sink* material.

The situation is reversed when the temperature of the materials is increased: the greater lattice and chain vibrations usually lead to an increase of the thermal conductivity in ceramics, glasses, and polymers. In metals and alloys the same mechanism applies in principle, however, the electronic contribution will be lowered, even though the number of carriers is increased, as their mobility is more strongly reduced due to increasing scattering effects. Therefore, thermal conductivity in metals and alloys usually decreases with increasing temperature. Like the electrical conductivity, thermal conductivity in metals and alloys also decreases with increasing number of lattice defects of various dimensionality (Sect. 3.7.2), introduced into the microstructure due to the increased electron scattering.

3.5 Nondestructive Inspection (NDI)

Nondestructive inspection (NDI) includes all methods to characterize a material without indenting, extracting samples, reducing its service capabilities or even destroying it. NDI includes defect detection and quantification, called nondestructive testing (NDT), and the assessment of material properties, called nondestructive evaluation (NDE). NDI is an integral part of component design, manufacturing, maintenance, and recycling of components.

More and more components are designed following the rule of fitness-for-service. This concept assumes the presence of a maximum undetectable-by-NDI defect. The design has to make sure that this defect does not become critical during a well-defined service period. To keep the safety coefficient at a predefined level the component will be larger or heavier than it should be without the defect. With increasing capabilities of NDI this maximum undetectable defect decreases, allowing the designer to reduce the component weight while keeping the safety coefficient at the same level.

In manufacturing, NDI enables the inspection of the whole output while destructive methods rely on a more or less satisfying quantity of samples being more or less representative for the current party. Besides suitability, the inspection speed is the deciding criterion for NDI application.

In maintenance there is no alternative to NDI. According to considerations of fracture mechanics the concept of damage tolerance requires the detection and characterization of all defects starting from an individually defined level. Depending on the findings of NDI the next service period may be shorter or longer. The typical requirement for inspection is a high probability of defect detection accompanied by a tolerable rate of false indications. Modern maintenance concepts include online monitoring of the structural health of a component or the whole construction.

All industrial branches use NDI, the best known being flying structures. However, pipelines, heat exchangers, vessels, bridges, and car components are also inspected nondestructively. We will focus on the most important and widely used methods in mechanical engineering but also touch on the promising field of structural health monitoring (SHM).

3.5.1 Principle of Nondestructive Inspection

The basic principle of NDI is shown in Fig. 3.78. The goal is either to detect relevant defects or to estimate quality parameters such as hardness, heat treatment or coating layers. This goal cannot directly be reached nondestructively. The only possible way is to measure physical properties such as conductivity, sound propagation or magnetic behavior. Both the quality parameters and the physical properties are defined by the material's structure. The challenge is to find a correlation between them. It is a matter of current research to complete the knowledge about the relations between the quality parameters to be inspected and the physical properties recordable nondestructively.

A wide variety of NDI sensors and transducers are known to record the physical properties locally or integrally. These signals are processed in an instrument and displayed in different forms. Some physical properties may be recorded by matrix sensors, immediately providing an image, while other properties have to be measured by point-like sensors that are hand-guided by an operator or mechanically guided by a scanner.

The indication is either an image, a vector or a scalar value. In most applications a threshold is used to separate appropriate from inappropriate quality (go/no go). For this purpose, differential measurements are most suitable. The current measurement is compared with the measurement of a master piece or the measurement of a neighboring area of the same object. If the difference is below the threshold, the object passes, otherwise it is failed. If quantitative assessment is required, calibration curves have to be taken basing on well-known samples with gradual variation of the parameter to be evaluated. Here, the increasing performance of numerical modeling is providing valuable help. In some cases NDI is expected to provide absolute values of a physical property, which is provided by dedicated instruments.

How reliable is NDI? To date no method is known to detect defects with a probability of 100%. Vice versa, all methods may produce false indications, e.g., indicate a defect in sound material. All NDI applications have to be optimized regarding both probabilities.

The following sections present a selection of approved methods and show the direction of future development. The references [3.60–64] are the most appropriate introductions to NDI. Further references on individual methods in each section provide more detailed information but cannot exempt the user from contacting experienced specialists. International standards and rules of application exist for all methods.

3.5.2 Acoustic Methods

Acoustic methods rely on the propagation of sound waves though the material. These waves may be excited by external or internal sources. In solids, longitudinal (compressional) and transverse (shear) waves may spread and are partially reflected and mode converted at boundaries. Additional wave modes may exist at the material's surface and in thin plates (Rayleigh and Lamb waves). While propagating through the material the waves are attenuated depending on the material's properties and the wave's frequency.

Ultrasonic Methods

Principle. The basic idea is to transmit a short elastomechanical wave packet into the material. If its wavelength is short enough it will interact with defects starting from approximately 0.5 mm in diameter. Therefore exiting frequencies from 0.5 to 15 MHz are required (ultrasonic frequencies). Depending on the material's attenuation the wave packet travels long distances through the material. In the transmission technique the pulse is received at the opposite side of the object whereas in the pulse-echo technique the reflected waves are recorded

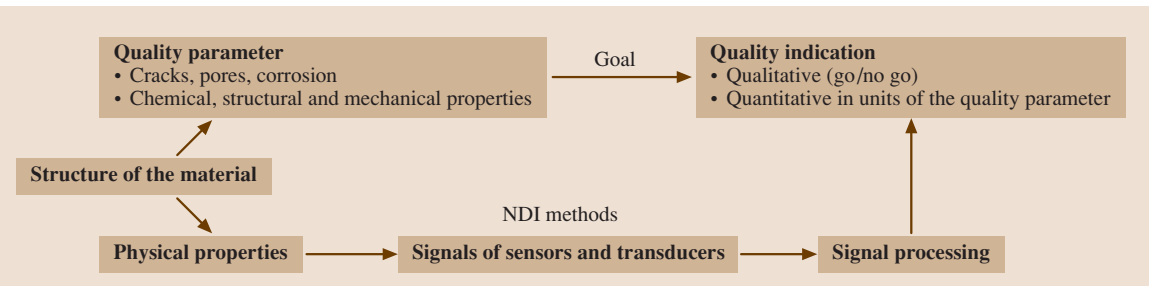

Fig. 3.78 The principle of nondestructive inspection

at the same side where they are fed. Nearly all metals, ceramics, concrete, and low-damping plastics and composites may be inspected [3.65, 66].

Probes (Transducers). For perpendicular wave propagation, perpendicular-incidence probes are attached to the surface. For nonperpendicular wave propagation angle-beam probes are required, commonly generating longitudinal waves that are diffracted into a longitudinal and a transverse wave at different angles at the material's surface. The acoustic waves must be coupled to the material using a couplant such as water or grease. Figure 3.79 presents a perpendicular-incidence probe consisting of a piezoelectric ceramic disc emitting and receiving the ultrasonic waves. A resin damping block absorbs the waves emitted in the reverse direction. The ultrasonic waves are passed through a protecting layer and the couplant into the material. After entering the material the sound field is characterized by local maxima and minima due to the interference of waves emitted from different parts of the piezoelectric disc. This initial area of the sound field is called the near field, where no inspection is possible. The near field becomes taller and ends in a final maximum of the sound pressure. From this point onwards the sound field diverges and the sound pressure gradually decreases. This area is best suited for NDI.

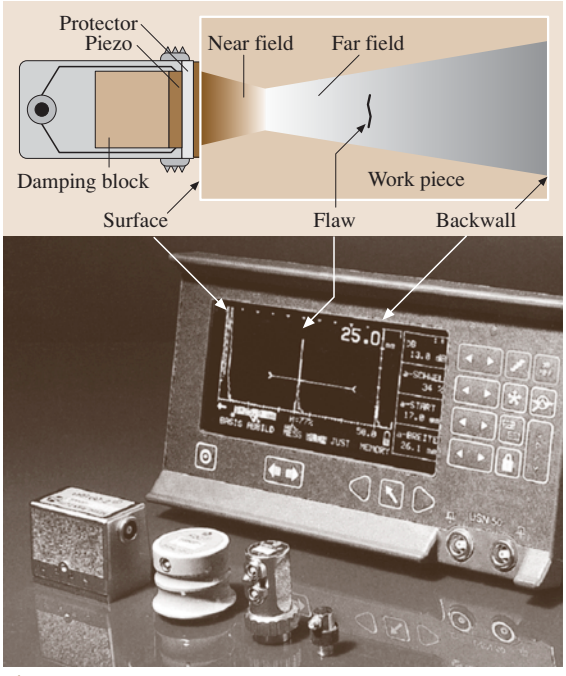

Fig. 3.79 Principle of ultrasonic inspection, instrument, transducers, and signal representation

NDT. Defects may be detected if they interact with the ultrasonic waves. The best detection performance is available for defects oriented perpendicularly to the sound field axis. Both transmission and pulse-echo techniques are suitable. With decreasing wavelength (increasing frequency) smaller defects may be detected but reflections from grain boundaries are also superimposed the signal. In Fig. 3.79 the screen of an ultrasonic instrument displays the A-scan formed by the rectified and amplified echo sequence. At the entrance a significant part of the sound energy is directly reflected back to the probe, producing the large entrance echo. At the back wall nearly all the sound energy is reflected. A properly oriented planar or volumetric defect produces an intermediate echo between the entrance and back wall echo. This echo may be analyzed to evaluate the defect's position and dimension. In weld inspection angle beam probes must mostly be used due to the nonsmooth surface of the weld and the orientation of possible defects.

NDE. The sound velocity and attenuation carry information about the structural and geometrical parameters of the material. The time-of-flight method is used for measuring the dynamic Young's modulus and for evaluating the structure of cast iron with spherical graphite, stress and strain assessment in steel, and the thickness of metal or nonmetal walls. Grain boundary reflections are welcome to estimate grain size or surface hardening depth. Sound attenuation measurement is also applied for structural characterization such as grain sizing and deformation-induced alterations.

Tendency. Instead of single transducers, one- or two-dimensional arrays are used two incline and shape the ultrasonic beam. Electronic movement enables fast imaging techniques. To avoid liquid couplants current research is focused on air-coupled techniques and thermally induced sound waves and interferometric read out.

Resonance Methods

Principle. The object is excited by a mechanical pulse or a continuous wave in a defined audible or ultrasonic range. It starts vibrating on its eigenmodes and the eigenfrequencies are recorded. The signal is analyzed in the time and frequency range, comparing the signals to those of one or more master pieces with well-known properties. Nearly all metals, ceramics, plastics,

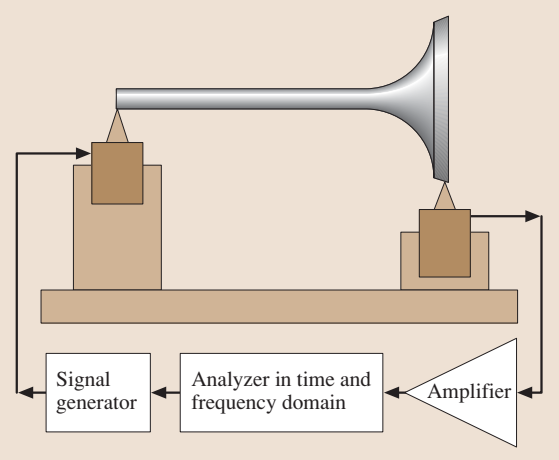

Fig. 3.80 Schematic view of valve inspection using resonance method (after [3.67])

and composites, and often the adhesive bonding between them, may be inspected according to the go/no go principle.

Setup and Probes. The object is positioned on a low-damping fixture and is excited by defined mechanical pulses using impact hammers, piezoactuators or electromechanical shakers. In the low-frequency range the acoustic response can be heard or is picked up by microphones via air coupling. At higher frequencies and lower amplitudes piezoelectric sensors are attached to the object or optical interferometers record the oscillation at one or more positions. Figure 3.80 shows the setup for valve inspection. Figure 3.81 presents the signals in the time and frequency domains.

NDT. Complex-shaped objects such as gears and cast housings are inspected for missing components, imperfect shape, cracks, and cavities. Mostly the frequency content of the response signal is analyzed. In a first step a representative amount of sound and flawed objects is analyzed in a broad frequency band. Comparing the response spectra, the most sensitive narrow bands are selected for defect detection.

NDE. The resonance method allows the estimation of structural damping, the comparison of elastic properties between identically shaped samples, and even the measurement of the dynamic Young's modulus with simply shaped specimens.

Tendency. With increasing sensitivity smaller defects become detectable. Extensive signal processing allows

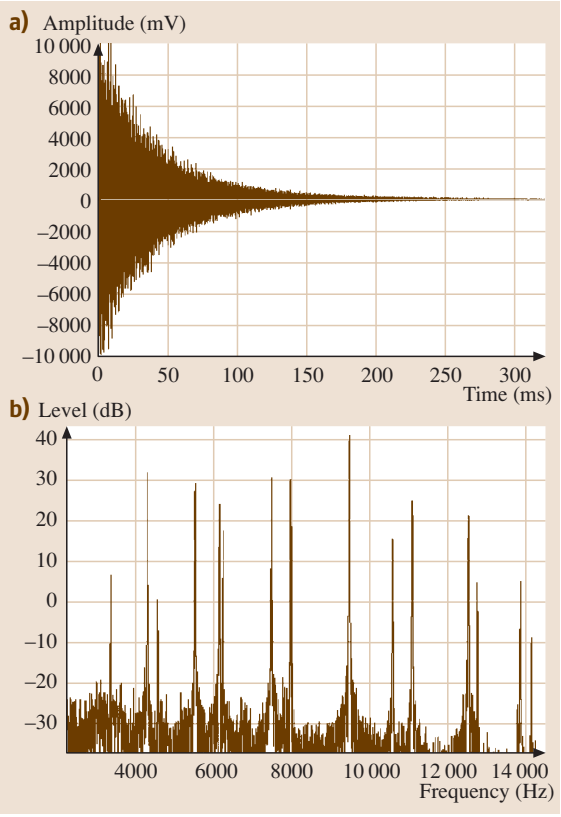

Fig. 3.81a,b Resonance analysis of valve: **(a)** signal in the time domain, **(b)** signal in the frequency domain (after [3.68])

the suppression of disturbing signals from the environment.

Acoustic Emission Analysis

Principle. When an object is loaded, defects grow and discontinuously radiate elastic wave bursts (Figs. 3.82, 3.83). These bursts are picked up and analyzed according to their spectral content, signal energy, and other specific parameters. Defect location becomes possible using time-of-flight differences to different sensors [3.69]. For leakage detection the continuous acoustic radiation arising at the leak point is recorded. For leakage location, signals from two or more separated sensors are correlated to define the time-of-flight difference.

Setup and Probes. For loading the object may be heated or stressed by different means. Piezoelectric probes with internal or closely attached external preamplifiers pick

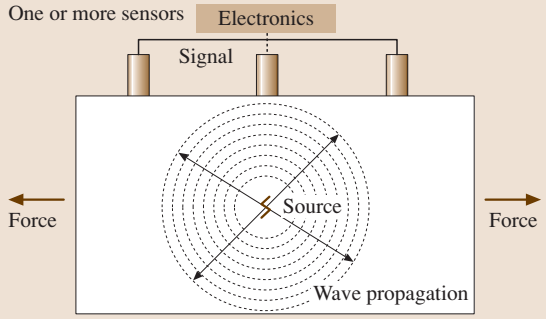

Fig. 3.82 Acoustic emission generated by a discontinuously growing crack

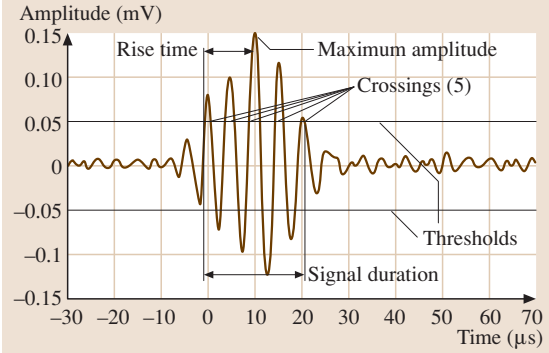

Fig. 3.83 Burst signal recorded by attached sensors

up the emission. Mostly, more than one sensor is required to cover the whole object or to locate the defects.

NDT. Growing cracks, hydrogen embrittlement, stress corrosion, and creep can generate acoustic emissions. The advantage of their analysis is that they enable information about the whole object to be attained at once. Inspection is commonly performed before running the object and during inspection breaks. Generally, acoustic emission may be recorded online, thus enabling structural health monitoring (Sect. 3.5.9). No information about defect dimensions is available.

Tendency. With increasing knowledge about signal generation, signal conversion, and nonresonant sensors more detailed information can be obtained by characterizing the source of radiation, thus making acoustic emission analysis more reliable.

3.5.3 Potential Drop Method

Principle

Once found, a surface crack's depth should often be estimated. For this, an electric current is passed perpendicularly across the crack. The current will be deflected by the crack, depending on its depth and length [3.70]. Two electrodes are contacted on both sides of the crack to measure the potential drop. Assuming that the crack is much longer than it is deep, the voltage primarily depends on the crack depth. Figure 3.84 shows the reason for increasing potential drop with increasing crack depth.

Probes

Modern probes combine the current supply and potential drop electrodes into one probe. Figure 3.85 presents

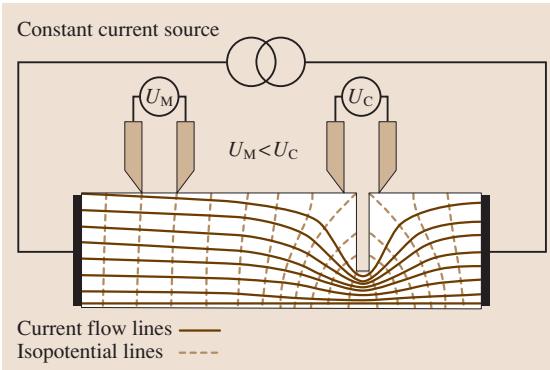

Fig. 3.84 Potential drop measurement of crack depth

Fig. 3.85 Potential probes are able to measure crack depth and inclination

such a four-point probe. The outer electrodes feed the current and the inner ones measure the voltage. For online observation of crack growth, electrodes may be permanently fixed to the object.

NDT

For crack depth assessment in ferrous steels alternating current is advantageous due to the skin effect. This effect causes a current concentration at near-surface regions while direct current spreads out much deeper. That is why the crack's influence on lengthening the current path is more pronounced with alternating than it is with direct current. After careful calibration the crack depth can be estimated with an accuracy of some tenths of a millimeter, taking into account that the first electric bridge between the crack faces defines the measured crack depth. To estimate crack inclination an additional electrode fixed a greater distance from the crack is necessary.

NDE

Potential drop measurement can be used for measuring the conductivity of metals. The advantage over the eddy-current method (Sect. 3.5.5) is its suitability also for ferrous steels, while eddy-current conductivity measurement may only be applied for nonferromagnetic materials. The disadvantage is the unavoidable direct contact to the metal, requiring at least local stripping of paint and corrosion products.

Tendency

Calibration curves of most common materials are stored in the instrument. Combined inductive feed and contact gauging is the subject of current investigations.

3.5.4 Magnetic Methods

Magnetic methods use the ferromagnetism of ferritic steels. A magnetic flux passed through the material orients the magnetic domains of the material, thus increasing the flux density. This orientation process is nonlinear and follows a hysteresis loop. When all domains are oriented according to the exciting field, the material is magnetically saturated. For NDI a number of physical properties may be used such as saturation induction, remanence, coercive force, and magnetic permeability [3.71].

Stray Flux and Magnetic Particle Inspection

Principle. If the magnetic flux passed through the ferromagnetic material faces a boundary to a less permeable area (e.g., air in a crack) it is refracted into this area nearly perpendicularly to the boundary. Figure 3.86 details this situation where a part of the flux spreads over the boundaries of the workpiece. This stray or leakage flux is much wider than the crack. The remaining flux

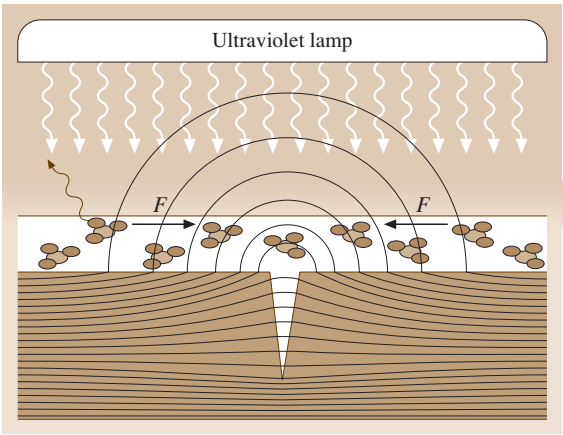

Fig. 3.86 Magnetic stray flux generates the force F attracting the magnetic particles

lines pass below the crack or cross it. They are not accessible for NDI. The estimation of crack depth is not possible.

Setup and Probes. The magnetic flux must be oriented perpendicularly to the crack. This flux may be excited, whether by permanent magnets, electric current or coils (electromagnets). For stationary equipment combined electric and electromagnetic excitation is preferred to produce a circular magnetic field. The objects are placed in the gap of a yoke that carries the magnetic flux as well as the electric current. Mobile excitation is possible by electromagnetic hand yokes and current electrodes. The stray flux can be detected by magnetic sensors such as flux gates, magnetoresistors, Hall sensors or moving coils, or even visualized by magnetic particles (magnetic particle inspection, MPI). After inspection the object has to be demagnetized.

NDT by Flux Sensors. In automatic inspection lines objects such as pipes, rods or sheets are moved through a magnetizing yoke. Between the poles sensors or sensor arrays are guided over the surface to detect and quantify the stray flux.

NDT by MPI. A suspension of high-permeability fluorescent powder in a low-viscosity carrier liquid is flushed over the surface. The magnetic particles are attracted by the stray flux, dragging the fluorescent particles with them. In a darkroom under ultraviolet illumination these particles become visible, indicating the crack (Fig. 3.87) [3.72]. For documentation photographs can be taken. In difficult conditions such as underwater in-

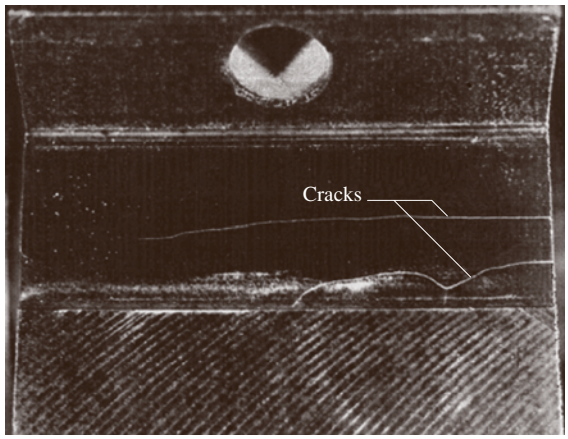

Fig. 3.87 Magnetic particle indication of cracks in a switch shaft

spection the suspension is contained in a double-wall package. After exposing the package to the stray flux the suspension can be cured by a second component to fix the particles at their positions and to analyze the image later.

Tendency. To increase the reliability of MPI attempts are being made to record the MPI image using video cameras and process the image automatically. Instead of magnetic particles magneto-optical flux sensors are being investigated in order to enable direct visualization of stray flux.

Flux Method

Principle. The object becomes a part of a magnetic circuit. The flux in this circuit is generated by a permanent magnet or an electromagnet. The measured flux magnitude depends on the object's cross section and its magnetic permeability.

Probes. The flux in the circuit is measured directly by flux gates, magnetoresistors, Hall sensors or mechanical forces caused by the flux.

NDT. To detect and quantify corrosion damage that reduces the cross section of ferritic steel components magnetic yokes are guided over the surface. Assuming that the permeability of the material is constant the flux only depends on the cross section of the object. To locate the corrosion the flux magnitude can be mapped.

NDE. Under the assumption of constant permeability, the wall thickness or cross section of ferritic steel components such as sheets, pipes or cables may be assessed. Measurement of magnetic permeability becomes possible with components of sufficient thickness and lateral dimensions starting from a few square centimeters. The sensors pick up the degree of flux deflection caused by the ferromagnetic object. The same principle may be used for thickness measurements of nonferromagnetic walls. An additional ferromagnetic body (mostly a steel ball) placed on the backside deflects the magnetic field [3.73].

Tendency. For the assessment of more distant ferromagnetic objects high-sensitivity superconducting quantum interference devices (SQUIDs) are being used.

Residual-Field Method

Principle. In a first step the ferromagnetic object or a part of it is magnetized by a strong direct field as close as possible to its saturation. In a second step the residual field (Fig. 3.88, remanent induction, remanence) is measured, carrying information about the presence of the object, its microstructure, dimensions, and orientation.

Setup and Probes. The object can be magnetized by a yoke, a permanent magnet or an electromagnet. The magnetization can include the whole object or can be limited to a small area of a few square millimeters. The

residual field is measured by flux gates, magnetoresistors, Hall sensors, or SQUIDs.

NDT. This method is suitable for the detection and characterization of ferromagnetic particles in nonferromagnetic surroundings such as splinters of cutting tools in nonferromagnetic pieces [3.75].

NDE. The residual induction strongly depends on the microstructure of the ferromagnetic steels or cast iron due to its correlation with the mobility of magnetic domain walls. Evaluating the residual induction allows one to assess heat treatment, toughness, hardness, surface hardening (Fig. 3.89, [3.74]) or even carbon content. Calibration is the most important feature for the success of this method and should be accomplished according to appropriate guidelines. The method allows fast automatic inspection using conveyer movement of the objects through a magnetization tunnel and along a sensor station. Usually the object must be demagnetized afterwards.

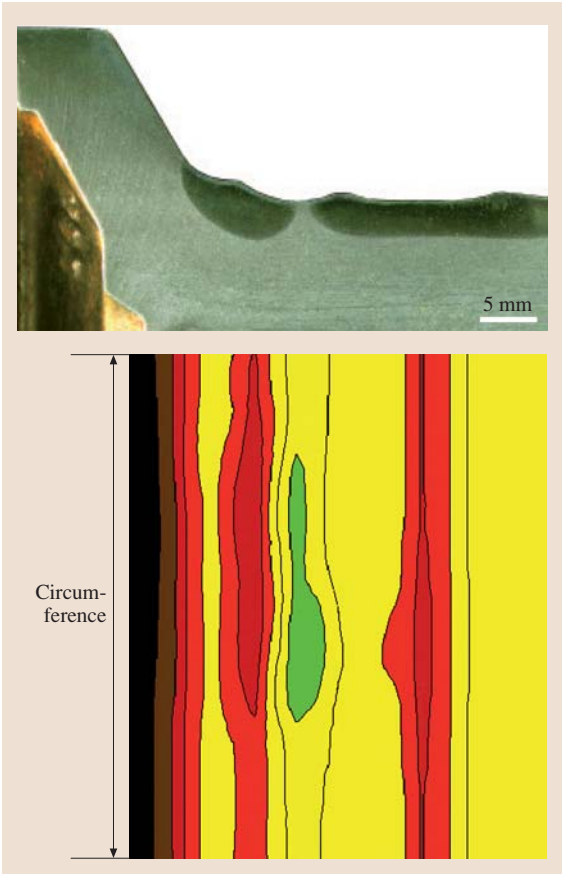

Fig. 3.89 Imperfectly hardened surface layer and the residual field distribution along the circumference (after [3.74])

Tendency. For reduction of the dimension's influence on the NDE results the coercive force may be evaluated. For this, after magnetization, the object is demagnetized by a contrary field and the strength of the demagnetizing field when the residual field vanishes is recorded.

Barkhausen Noise Analysis

Principle. The excitation of ferromagnetic material by a magnetic field that varies with time changes the spatial dimensions of the magnetic domains. The Bloch walls separating the domains from each other move discontinuously through the grain, emitting electromagnetic pulses. The superposition of these pulses produces a noise-like signal called magnetic Barkhausen noise [3.76]. The amplitude and rate of these pulses are discontinuously distributed over a complete magnetization cycle. Close to the coercivity they reach their maximum.

Setup and Probes. Excitation is accomplished by a magnetic yoke placed on the object. The driving coil is fed by an alternating current of a frequency ranging from a few tenths of a Hertz to a few hundred Hertz. Figure 3.90 displays a yoke and a sensing coil between the yoke limbs to receive the emitted pulses.

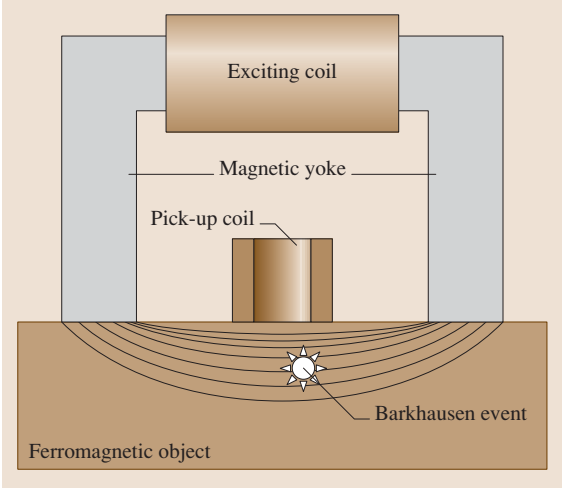

Fig. 3.90 Barkhausen noise excitation and measurement

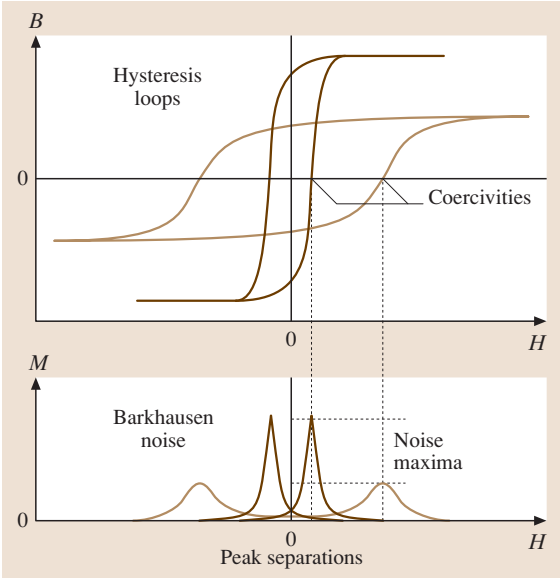

Fig. 3.91 Assessment of surface hardening depth of ferromagnetic steel (after [3.77])

NDE. The amplitude and pulse rate of Barkhausen noise depend on the Bloch wall mobility at different field strengths. This mobility is influenced by load and residual stress, grain and phase boundaries, grain orientation, and microstructural defects such as vacancies, dislocations, precipitates, segregations, and inclusions. The method is used to estimate hardness obtained by lattice defects, laser- and case-hardening depth, and stress state.

Figure 3.91 shows the principle of thickness assessment of surface-hardened layers in ferromagnetic steel.

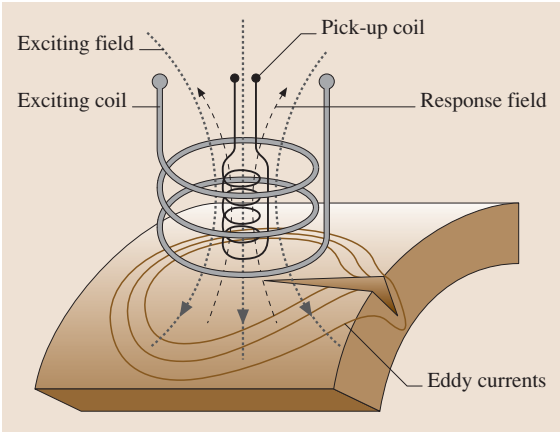

Fig. 3.92 An eddy-current surface probe detects cracks due to the deflection of eddy-current lines

The wide hysteresis loop describes the magnetic properties of the surface layer while the narrow loop results from the bulk material. During cyclic magnetization, different maxima of the Barkhausen noise amplitude may be observed [3.77]. At lower field strength the bulk material provides the first maximum followed by the maximum of the surface layer. The ratio between these maxima correlates with the hardened layer depth [3.78].

Tendency. Frequency analysis of the noise signal yields the source depth of the pulses. In combination with other micromagnetic parameters such as incremental permeability, local remanence or tangential field strength the method will find a wide field of applications.

3.5.5 Electromagnetic Methods

Electromagnetic methods not only rely on magnetic properties but also on the behavior of the material in an alternating electric field. For conductive materials such as metals even low-frequency electromagnetic fields induce an electric current. For nonconductive materials such as most ceramics and plastics, higher frequencies ($> 10\,\text{MHz}$) are necessary to generate a so-called dislocation current caused by various polarization mechanisms in the atoms or molecules.

Eddy-Current Method

Principle. An alternating magnetic field between 10 Hz and 10 MHz is applied to a conductive material. This field induces a circular voltage that drives a circular current with alternating direction almost parallel to the surface. As Fig. 3.92 shows, this so-called eddy current builds up its own magnetic field that counteracts the source. The sensor evaluates the resulting field, which contains information about the magnetic permeability, conductivity, and geometry parameters [3.73].

Probes. The probe consists of a transmitter generating the alternating magnetic field and a receiver to pick up the resultant magnetic field. The transmitter is commonly a coil; the receiver may be a coil or another magnetic field sensor such as a magnetoresistor, a flux gate, or even a SQUID for very low frequencies. Most simple sensors combine the transmitter and receiver in a single coil. For direct visualization of eddy currents in flat surfaces their magnetic field can be picked up by magneto-optic sensors such as garnet films.

NDT. Surface crack detection in all metals even below nonconducting coatings is the most common field of

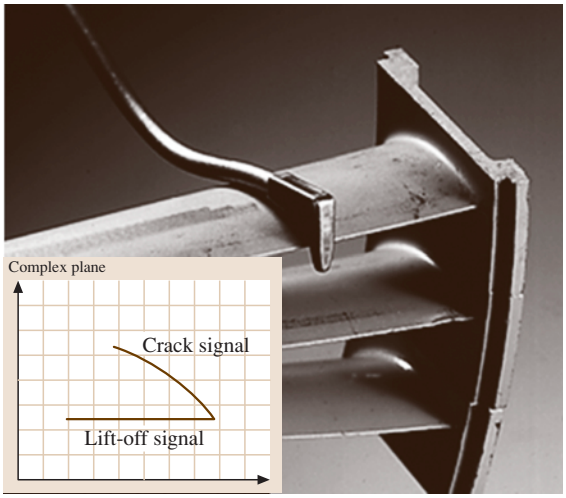

Fig. 3.93 Eddy-current inspection of the trailing edge of a turbine blade

application [3.79]. The detection and quantification of hidden defects such as pores, corrosion, and cracks is also possible in nonferromagnetic materials up to a few millimeters below the surface. Figure 3.93 shows the example of eddy-current turbine blade inspection.

NDE. The eddy-current method is best suited for conductivity measurement in nonferromagnetic materials and heat treatment characterization of pure metals and alloys. Material sorting can be accomplished as well as thickness assessment of nonconducting layers on conducting bulk or wall thickness assessment of nonferromagnetic sheets or pipes. In conducting composites such as carbon fiber reinforced plastic (CFRP) fiber orientation can be evaluated using the anisotropy of conductivity.

Tendency. Array sensors provide a fast and convenient opportunity to visualize eddy-current behavior. Highly sensitive and resolving sensors make smaller defects visible at greater material depth.

Microwave Method

Principle. Electromagnetic fields excited at frequencies from a few gigahertz to a few hundred gigahertz provide wavelengths in the centimeter and subcentimeter range, so called microwaves. These waves are reflected at the surface of metals but can penetrate many nonmetals, such as plastics, ceramics, and composites. various polarization mechanisms of the material components change the amplitude, phase, and polarization of the microwaves.

Setup and Probes. Mostly horn aerials are used to transmit and receive microwaves. Single- or double-sided aerials allow reflection and transmission measurements. For near-field applications an aperture may shape the field transmitted from the antenna. Directional couplers, phase shifters, and modulators complete the equipment [3.80].

NDT. Flaws in metals may be detected and characterized if they break through the surface. At very high frequencies wave propagation in open cracks may be used for crack depth estimation. In dielectric material internal flaws such as pores and delaminations may be detected due to the scattered energy.

NDE. Nonconductive materials can be inspected for material composition, structure, density, porosity, homogeneity, orientation of reinforcing fibers, state of cure, and moisture content. The reinforcing components in concrete of buildings may be visualized. For metals only thickness measurement of plates becomes possible using a double-sided reflection technique [3.81].

Tendency. Smaller electronic devices enable the integration of increasing numbers of components into one instrument, so that handling problems are decreasing. With increasing frequencies smaller defects will become detectable.

3.5.6 Thermography

Principle

Heat storage and transport capabilities depend on the heat capacity and thermal conductivity of the material as well as the local geometry of the object. Stimulated heat transport is used to evaluate the material for homogeneity, isotropy, and defects. For noncontact assessment the temperature distribution on the object is recorded using the thermally induced electromagnetic radiation of the object, which starts from wavelengths of about 10 μm at room temperature and can be visualized by using infrared sensors.

Setup and Probes

Figure 3.94 shows that a dynamic heat flow can be generated by periodically activated external (or internal) sources. External sources such as lamps, electric heaters, fans, and liquids heat the object from the front or back side. Internal sources may be stimulated by vibration or electric current. The temperature of the surface is recorded by infrared cameras based on scanning point, line or matrix sensors [3.82, 83].

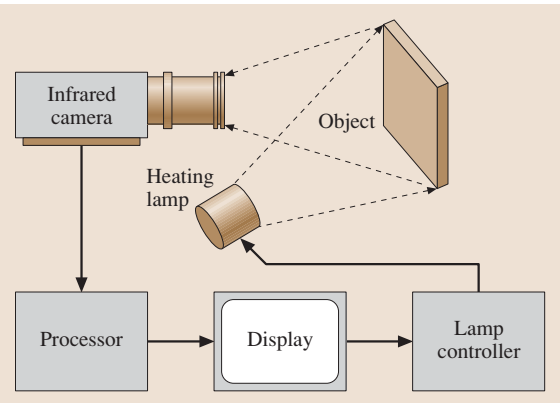

Fig. 3.94 An infrared camera picks up the temperature profile of the surface. The object can be heated by lamps (after [3.82])

NDT

Lock-in thermography is based on harmonic excitation of the heat source. The surface temperature of the object is analyzed according to its amplitude and phase. The phase signal is free of disturbances resulting from the emissivity of the surface. Another approach is the pulsed heating of the object and the time-dependent analysis of the surface temperature. Both methods are able to detect and characterize inner flaws like delaminations in composites, impact damage and debonding of joints. Figure 3.95 presents an application for turbine blades.

Defect selection may be achieved by activating cracks as heat sources. To do this, powerful acoustic waves are fed into the object. A local temperature increase due to face friction indicates the presence of a crack.

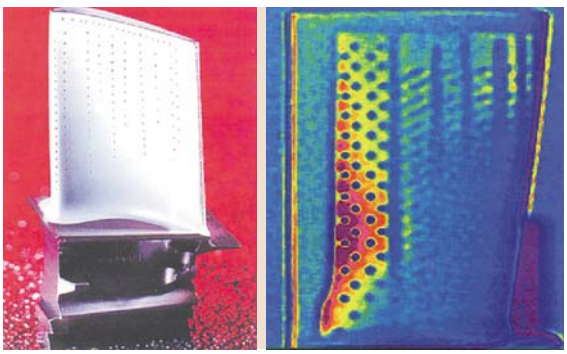

Fig. 3.95 Turbine blades with heat protection layer and cooling channels. Thermography highlights clogged channels

NDE

The thickness of surface layers on conducting and nonconducting bulk material may be addressed as well as the orientation of carbon fibers in CFRP.

Tendency

Current investigations are focused on defect-selective thermography, the assessment of the quality of adhesive joints, and composite materials. The increasing efficiency of infrared sensors is making infrared cameras increasingly affordable and convenient.

3.5.7 Optical Methods

This subsection summarizes methods based on visible light that is reflected from the object surface. Most attention has to be paid to the illumination and the visual abilities of the operators. Clear instructions and master pieces of what to look for are required.

Visual Methods

Principle. The object surface is cleaned and systematically searched for defined patterns corresponding to cracks, corrosion, microstructure or other features.

Probes. Many tasks are solved by the naked human eye. If necessary, lenses, microscopes, endoscopes, and appropriate recording instruments are used. The incident, intensity, and color of the illumination have to be optimized for the inspection task.

NDT. Without optical enlargement only large surface-breaking defects may be detected. For maintenance of engines, gear boxes, and other nearly closed hollow objects, endoscopes combining illumination, sensors, and sensor controllers are used [3.84]. Despite the distorted aspect ratio of the recorded picture it is possible to measure the dimensions of the visual pattern.

NDE. For the analysis of structural features the object has to be carefully prepared, including mechanical surface treatment such as grinding, polishing, and if necessary etching. The pattern can be interpreted under defined illumination and requires long experience.

Tendency. Tube-based endoscopes are being substituted by fiber and video endoscopes. Additionally, endoscopes may carry sensors for other NDI methods such as eddy-current probes. Some endoscopes allow the use of mechanical tools to treat any defects found.

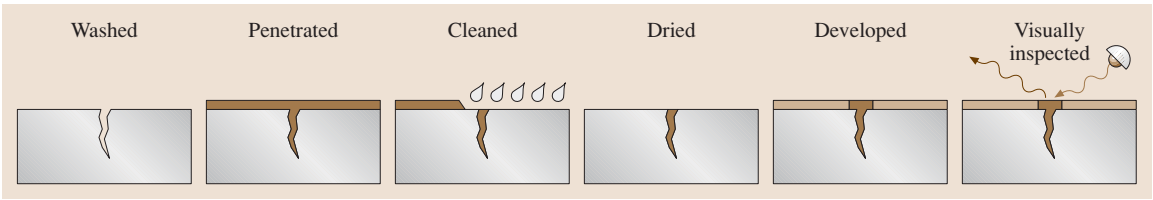

Fig. 3.96 For penetration inspection the object is first washed, then penetrated, cleaned, dried, developed, and visually inspected

Penetration Methods

Principle. Figure 3.96 illustrates the operation of this method. The cleaned surface of the object is coated with a penetrant in which a visible or fluorescent dye is dissolved or suspended. The penetrant is pulled into surface cracks by capillary action. After cleaning the surface of excess penetrant a developer is sprayed or dusted over the object, partially lifting the penetrant out of the crack. Under defined illumination the penetrant provides an enlarged crack pattern with high contrast [3.85]. A roller with surface cracks is shown in Fig. 3.97.

Equipment and Inspection Agents. For manual inspection spray cans with the penetrant and the developer are used. In modern inspection lines all the objects are washed, penetrated, cleaned, and developed automatically at defined agent temperatures and action times in immersion tanks. Visual inspection for defect indications is performed by human operators under either visible or ultraviolet illumination.

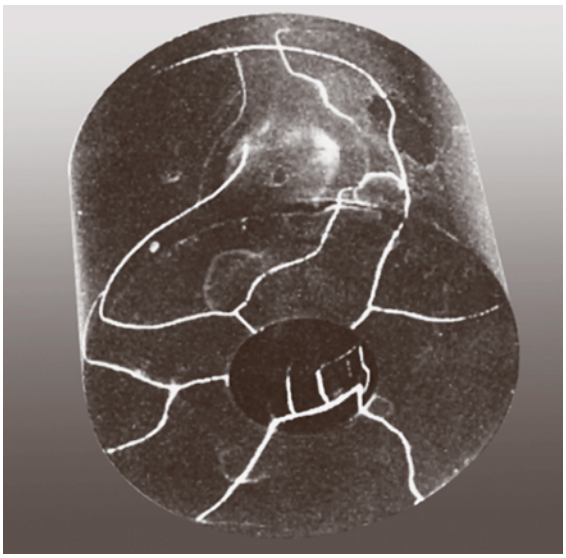

Fig. 3.97 Result of penetrant inspection for cracks in a roller

NDT. The crack indication varies with developing time. Reference master pieces with known defects and exact instructions enhance the reliability of this method. No information about defect depth can be obtained. Post-emulsifiable penetrants keep the viscosity at a low level over time.

Tendency. To date the interaction of the operator is needed to distinguish between real defects and pseudo-indications. Much effort is focused on substituting the inspector with an automatic vision system.

Speckle Interferometry

Principle. Speckle interferometry uses the interference phenomena of laser light. Figure 3.98 shows that the object is entirely illuminated with laser light, producing a speckle pattern on the object surface. This pattern is superimposed by reference light and the resultant image is recorded by a video camera. For NDI this method is used to detect and quantify surface dislocation at loading.

Setup and Probes. Laser illumination is performed by a defocused laser so that the entire surface is illuminated at once. No scanning is necessary. To smooth the illumination the laser light may reach the surface via several

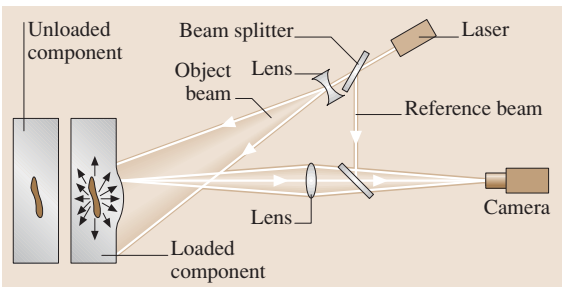

Fig. 3.98 Electronic speckle interferometer (after [3.82])

Fig. 3.99 Speckle fringes caused by discontinuities of off-plane surface displacements

paths. A beam splitter directs a small portion of the light as a reference to the camera for interference with the reflected light from the object. The camera records the images and passes them to data storage.

NDT. The speckle pattern of the object is recorded twice. The correlation of the images of the unloaded and loaded object highlights discontinuities of displacements penetrating the surface and allows local debonding, delaminations, and cavities to be recognized as fringes. An example is shown in Fig. 3.99.

Tendency. The differential speckle interferometry method known as shearography highlights differences in surface dislocation of points at a certain distance from each other. The method is less sensitive to disturbances and best suited for in-field inspection [3.86].

3.5.8 Radiation Methods

High-energy radiation is able to penetrate solid bodies and to interact with their atoms. The transmitted intensity depends on the atomic number, the density of the material, and its thickness. The object is illuminated entirely and imaging can be performed by films or electronic matrix imagers [3.87, 88].

X-Ray Method

Principle. An X-ray tube generates radiation with energy up to a few hundred keV. The radiation is directed to the object positioned a certain distance from the tube. A radiographic film or conversion screen close behind the object records the transmitted radiation intensity as a grey scale image.

Equipment. An X-ray source is shown in Fig. 3.100. It consists of an evacuated tube in which a cathode

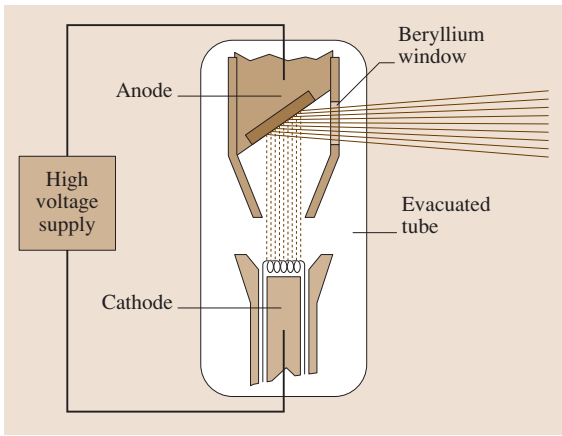

Fig. 3.100 Scheme of an X-ray tube (for explanation see text)

emits electrons that are accelerated towards the anode. The electrons strike the anode and emit bremsstrahlung, i. e., X-rays with a continuous range of energies. This energy can by controlled by the voltage between the cathode and anode. The radiation leaves the tube via a beryllium window and radiates the object. Increasingly, conversion screens and storage foils are uses for imaging.

NDT. Defect detection is based on alteration of the X-ray attenuation by the defect. Depending on the defect material, this attenuation may be smaller or greater than in its absence, so that either increased or decreased X-ray intensity can be detected. While the detection of volume defects such as pores starting from a defined extension is very reliable crack detection requires their correct ori-

entation in the X-ray beam. Figure 3.101 presents the equipment and an X-ray image of a weld. For defect detection in steel X-ray energy of up to 500 keV is required to penetrate walls of 100 mm thickness.

NDE. X-rays are used to gauge the wall thickness of pipes and sheets. With a multi-energy technique it is possible to detect the atomic order of the material, which is used for material identification.

Tendency. To reduce the blur of X-ray images microfocus tubes are used. For cross-sectional imaging computer tomographs are used, turning the object in the X-ray beam. Tubes with turning anodes are needed to increase the X-ray intensity by increased electron current in the tube.

Gamma-Ray Method

Principle. The radioactive decay of some elements produces high-energy gamma rays that are able to penetrate metals to a thickness of a few centimeters. Small pellets measuring a few millimeters are activated in a nuclear reactor and then stored in highly damping containers. These continuously radiating pieces are called sources. The decrease of their activity with time is described by their half-life constant and depends strongly on the source material.

Equipment. For exploitation the source is loaded into a mobile source holder made from a dense material such as tungsten, uranium or lead. Via remote control this holder is opened and the source is moved out to radiate the object through a beam collimator. The transmitted radiation is recorded by using a radiographic film.

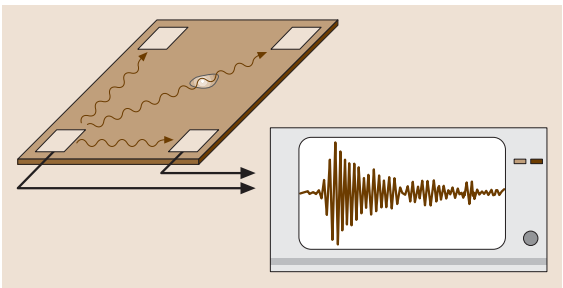

Fig. 3.103 Acousto-ultrasonic measurements (*left*) reveal defects between transmitter and receiver

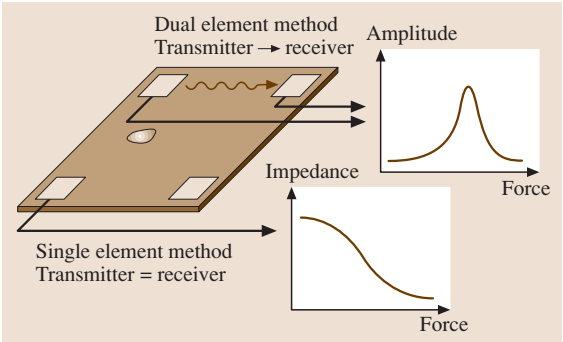

Fig. 3.104 Impedance spectroscopy allows the detection of defects on or close to the piezoelectric element (after [3.90])

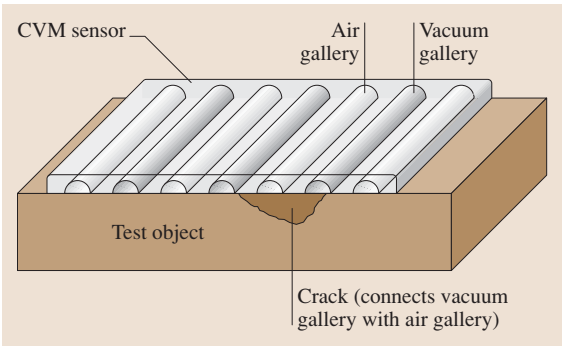

Fig. 3.105 Comparative vacuum monitoring (CVM) detects defects due to varying differential pressure (after [3.91])

NDT. For very thick steel components cobalt-60, which radiates with an energy of more than 1 MeV, is used. For steel thickness of less than 50 mm softer sources such as iridium-192 are sufficient. The safety requirements for X- and gamma-ray exploitation are very restrictive due to their harmful interaction with biologic tissues.

Tendency. Selenium-75 is best suited for steel walls up to 30 mm and has a significantly longer half-life. This source is able to replace X-ray equipment.

3.5.9 Health Monitoring

(SHM) *Structural health monitoring* refers to nondestructive inspection methods that rely on integrated sensors in the inspected structure itself. The sensor signals may be monitored online at the loaded structure or recorded for offline analysis. Various such NDI techniques are being investigated for applications in aircrafts [3.92, 93], buildings [3.94], and power stations. Active sensors can transmit and receive signals while passive sensors receive signals generated by the damage process or damage growth.

Acoustic emission (Sect. 3.4.2) can be recorded by embedded or attached piezoelectric sensors. As shown in Fig. 3.102 the source of an emission can be an impact, the growth of cracks, fiber or matrix breakage, delamination, and other damaging processes. To localize these sources signals from different sensors are correlated, yielding differences in time of flight for use in triangulation algorithms.

Acousto-ultrasonic interrogation is a single-sided nondestructive inspection technique employing separated sending and receiving transducers (Fig. 3.103). The method is used for assessing the microstructural condition and distributed damage state of the material between the transducers [3.70].

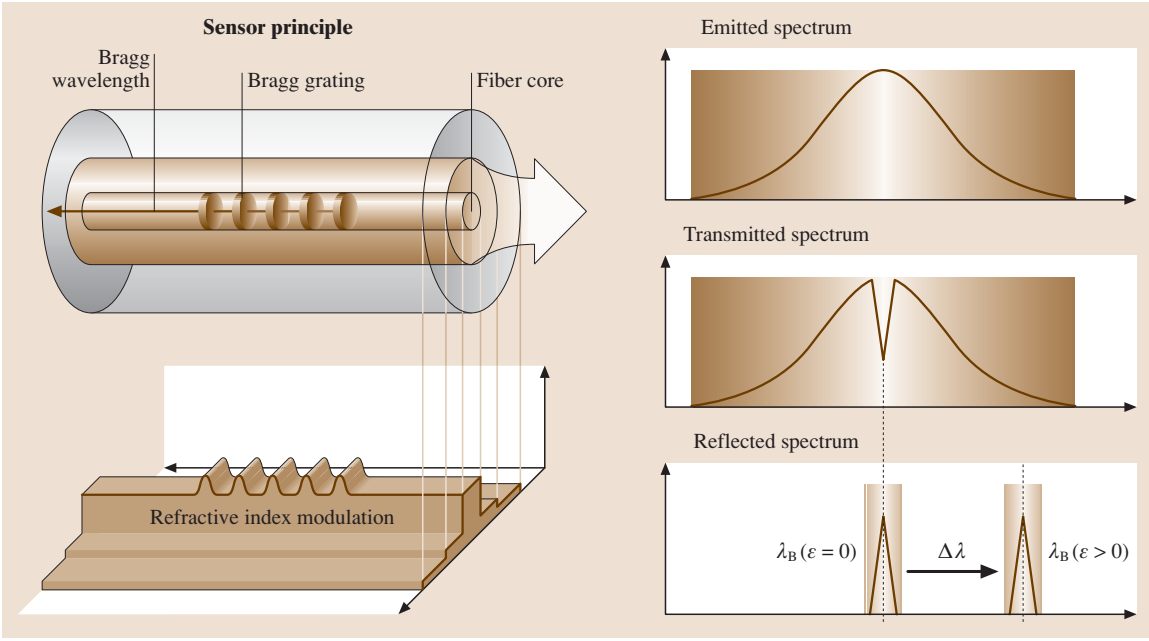

Fig. 3.106 Fiber Bragg grating (after [3.91])

Impedance spectroscopy uses either a single piezoelectric element or a transmitter–receiver combination (Fig. 3.104). The excitation oscillates in a predefined frequency band and the measurement is either the impedance or the complex voltage at the receiver. The frequency-dependent behavior of the measurement indicates defects on or close to the piezoelectric element [3.90]. Both, acousto-ultrasonic and impedance spectroscopy can be used to inspect polymer matrix composites, metal matrix composites, ceramic matrix composites, and even monolithic metallic materials.

Eddy-current foil sensors are an alternative technology to the classical eddy-current technique (Sect. 3.5.5) for the detection of surface or hidden cracks. In this method, a copper winding is printed onto a plastic substrate, just like an electronic track. Due to their thin geometry, they can be mounted onto interfaces between structural parts, around bolts, in corners, and hardly accessible regions. Periodic reading of these coils can provide information on structural health.

Comparative vacuum monitoring offers an effective method for in situ real-time monitoring of crack initiation and/or propagation. This method measures the differential pressure between fine galleries containing a low vacuum alternating with galleries at atmosphere in a simple manifold (Fig. 3.105). Comparative vacuum monitoring enables the monitoring of the external surfaces of materials for crack initiation, propagation, and corrosion. The galleries can also be embedded between components or within material compounds such as composite fiber.

Fiber Bragg gratings measure either the tensile or compressive strain applied along the grating length of an optical fiber (Fig. 3.106). The grating consists of a periodic variation of the index of refraction and provides a linear relationship between the change in wavelength of the reflected light and the strain in the fiber caused by externally applied loads or thermal expansion. To operate multiple sensors along a single optical fiber, the various Bragg gratings should have different Bragg wavelengths in order to differentiate between them.

3.6 Corrosion

3.6.1 Background

In general, corrosion is understood to refer to material degradation through reaction with its environment. This has led to a common tendency to assess it in terms of the corrosion products which are formed, i. e., concentrating on the phenomenon rather than its cause. Recent developments in observing and measuring corrosion are increasingly changing this picture. As a result, it is necessary to give up commonly held assumptions in order to understand the nature of corrosion. Among other things, the order of standard potentials of the elements has been overemphasized for some time in terms of its relevance.

In contrast to the other topics described in this Chapter, it is hardly possible to describe the corrosion behavior of technical equipment and structural components by means of formulae, tables or guidelines. The reason for this is that their corrosion resistance, and thus corrosion itself, is not just a property of the material, but rather of the system as a whole. The actual corrosion behavior is dependent in equal measure on the metal (as a technical material, taking into account all its properties), the environment (i. e., the concentration, temperature, flow rate, etc. of the corrosive medium), and the equipment design. In this context, design has to be understood in a broader sense to encompass everything from microscopically small surface roughness, methods of joining parts together, combinations of materials (including crevices resulting from the design) right through to the equipment construction as a whole. As a result, a large number of influencing factors are involved and the possible variations become difficult to comprehend. Thus corrosion behavior always has to be assessed in terms of the character of the complete system, and a so-called *corrosion atlas* is of little help. Even if the appearance of material damage is similar in more than one case, this does not mean that the causes are the same.

In practice, the cumulative experience gained from failures, one's own technical knowledge, and the corrosion data to be found in the literature always possess validity only over a narrow range of situations. Small deviations in particular parameters (locally reduced concentration of oxygen with stainless steels, shifts in the pH value with aluminum, attainment of a critical temperature level, etc.) can have dramatic consequences. A number of physical factors, such as

Table 3.8 Energy required to produce metals from the compound state and the standard potential E_0 at 25 °C within the order of potentials of individual elements (SHE = standard hydrogen electrode), see also [3.95]

Metal	Metal oxide	Energy required for production (kJ/kg)	(kJ/mol)	Standard potential (mV) (SHE, 25 °C)

Cr	Cr_2O_3	10 260	534	−740
Fe	Fe_2O_3	6600	367	−440

mechanical stresses or the uptake of solvents leading to swelling of plastics, also have a strong influence on corrosion behavior. This virtually unlimited spectrum of influencing factors and conditions cannot be accommodated within rigid guidelines. Instead, it is important to become acquainted with the nature of corrosion itself (and with its apparent contradictions) in order to be in a position to assess the risk in a concrete situation, or to clarify specific aspects in cooperation with experts, sometimes by carrying out appropriate experiments.

Corrosion can be divided into two main types:

1. Electrochemical corrosion (the atmospheric corrosion of steels, often equated with rusting, is an important example here)
2. Chemical corrosion (high-temperature corrosion, leading to scale formation on steels, is a key area here, but the corrosion of glass, ceramics, and concrete is also primarily chemical in nature)

3.6.2 Electrochemical Corrosion

Fundamentals

In order to understand corrosion, it is vital first to consider its ultimate cause, i. e., the driving force. Most common metals are produced under the expenditure of large amounts of energy from their compounds, mostly oxides; for example, 6600 kJ/kg are required to produce iron from Fe_2O_3 and as much as 29 200 kJ/kg to produce aluminum from Al_2O_3. Further examples are given in Table 3.8. The durability of metals is thus limited by nature, since the material always attempts to attain a condition of lower energy. In general, the conversion back to this state occurs more quickly, and the tendency for this to happen is higher, the further away the metal is from the energetically stable condition. Human efforts to prevent this are limited to influencing the kinetics of the reconversion and delaying the attainment of the thermodynamically stable, nonmetallic state. This can be achieved over an appropriate period of time by means of various measures, the use of coatings being one such example.

If a metallic surface comes into contact with water, the process of metal dissolution begins spontaneously. During this process, the metal goes into solution as an ion (Me^{z+}) and, depending upon its valence (z), one or more electrons (ze) are set free and remain within the metal. The release of electrons is also known as oxidation. Note, however, that oxidation is not necessarily associated with oxide formation. The originally neutral metal becomes negatively charged via the electrons left behind during this process and thus the dissolution can be described electrically by means of Faraday's law

$$\Delta m = \frac{MIt}{zF}(g)\,. \tag{3.80}$$

In (3.80), Δm is the loss of mass, M is the molarity, I is the flow of electrons (current amplitude) as a result of metal dissolution, t is time, and F is Faraday's constant. If the electrons are not consumed, charge separation rapidly leads to an increase in electrostatic forces, which then prevents further metal dissolution. Thus a so-called dynamic equilibrium is attained, in which the same number of metal ions undergo dissolution as are returned to the metallic state

$$\mathrm{Me} \leftrightarrow \mathrm{Me}^{z+} + z\mathrm{e}^{-}\,. \tag{3.81}$$

In analogy to a plate condenser, the charge in the metal (free electrons) is opposed by an equivalent level of positive charge within the electrolyte (Fig. 3.107). This electrolytic double layer is the location of the potential difference between the metal and the electrolyte, i. e., the electrode potential E. This potential can

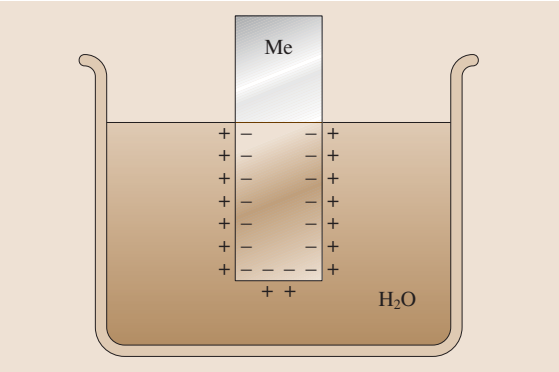

Fig. 3.107 Formation of an electrolytic double layer at the phase boundary metal/water; the more metal ions enter solution, the more negative the metal becomes

only be determined indirectly with the aid of a reference electrode (e.g., the standard hydrogen electrode or a calomel electrode). The size of the electrode potential (the charge separation) depends upon the metal, the valence, the temperature, and the natural logarithm of the concentration of metal ions already present in solution.

This behavior was summarized in an important equation, named after its discoverer, the German physicist and physical chemist Nernst (1864–1941)

$$E = E_0 + \frac{RT}{zF} \ln c_{Me^{z+}}(V) \,. \qquad (3.82)$$

In this equation, E_0 is the so-called standard potential, and c_{Me}^{z+} is the concentration of ions of the relevant metal in solution. If a metal is inserted into an aqueous solution where the concentration of its own ions amounts to 1 mole per liter, the right-hand term in the equation becomes zero (since $\ln 1 = 0$) and $E = E_0$. The standard potentials E_0 can be found in the table of standard electrode potentials of the elements (Table 3.8). These demonstrate very clearly the correlation between the energy expended and the tendency to return to the energetically lower state. The table of standard electrode potentials is *unsuitable*, however, as a basis for assessing practical corrosion behavior, since entirely different parameters (medium, alloying elements, film formation, area ratios, etc.) play the dominant role here. Up to this point, only a homogeneous electrode has been considered. In practice, however, metals represent technical materials which are anything but homogeneous. The presence of impurities and/or alloying elements (either in solution or as precipitates), the existence of different heat treatment states, levels of deformation, different protective or adsorbed layers, crystallographic anisotropy, and various lattice defects all lead to the creation of locations with different (usually higher) energy. The tendency of the metal to return to an energetically lower state is thus particularly high at such locations.

As discussed above, electrostatic forces between the free electrons and the metal ions in solution prevent further dissolution of the metal. This only becomes possible through a process which consumes electrons, whereby only four reactions need to be considered. Unfortunately these are generally present and lead to various different types of corrosion:

- Discharge of hydrogen ions (corrosion in acids)

$$2H^+ + 2e^- \rightarrow H_2$$
$$\text{(more exactly:} \quad 2H_3O^+ + 2e^- \rightarrow 2H_2O + H_2) \qquad (3.83)$$

- Reduction of oxygen dissolved in the water (atmospheric corrosion leading to the formation of rust via subsequent reactions)

$$O_2 + 2H_2O + 4e^- \rightarrow 4OH^- \qquad (3.84)$$

- Deposition of more noble metallic ions (corrosion through use of mixed metals)

$$\text{e.g.,} \quad Cu^{2+} + 2e^- \rightarrow Cu \qquad (3.85)$$

- Applied current (e.g., corrosion through stray currents in the Earth near tram lines)

The process which consumes electrons does not have to occur at the location of metal dissolution, but can also occur in an entirely separate place which is more favorable for electron transfer. Thus, the popular description *consumed by acid* is very misleading, since

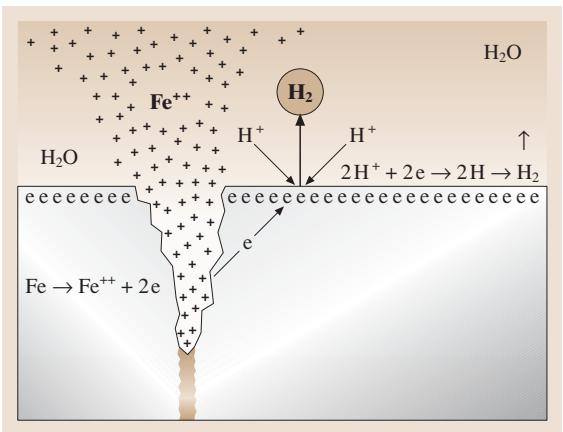

Fig. 3.108 Corrosion at a grain boundary (schematic)

the metal atoms can continue to leave their lattice as ions *only through the take-up of electrons* and this will take place at locations of higher energy, such as grain boundaries, hardened regions, etc.. The concept of acid *eating into metal* is, in any case, false since the positive hydrogen ions would have to flow into the regions of positively charged metal ions, a process that would be made impossible by the forces of electrostatic repulsion. Figure 3.108 shows schematically the dissolution of metal at a grain boundary. It is intended to make clear where metal dissolution occurs and demonstrate that the effect of acids (via an electron-consuming process) actually takes place elsewhere, namely at the grain surfaces.

The misfit in the grain-boundary region is larger, the higher the orientation differences between adjacent grains. This is why metal ions can easily leave such locations, provided that electron consumption is possible. It also explains the fact that grain boundaries appear to be of different width following metallographic etching. The spatial separation between the location for dissolution (anode) and for electron consumption (cathode) can become relatively large if multiphase materials are involved, or particularly if components made of different metals are connected together so that electron conduction is possible (see bimetallic corrosion). This effect is used to great advantage in batteries. Inhomogeneities can also exist in the medium (the environment surrounding the metal) in an analogous way to the inhomogeneities on the metal surface (which transform uniform into selective dissolution). Such differences can occur, e.g., through processes leading to a reduction (consumption of hydrogen ions) or increase (alkalization through the formation of OH^-ions) in the concentration of species, diffusion processes (transport to and from the surface, as well as in the bulk), blockage of charge transfer via adsorbed layers, and secondary corrosion products (rust).

Figure 3.109 shows the influence of the thickness of a moisture film on atmospheric corrosion. If no water is present (moisture approaches zero), no electron-consuming process can take place in accordance with (3.84). As the amount of water increases, the electron consumption becomes more rapid and the metal can undergo dissolution more easily. After a certain film thickness (100 µm) is reached, however, the rate of corrosion again decreases, since the oxygen from the atmosphere now has a longer diffusion path and consequently cannot consume so many electrons. In practice, this means that condensation can be more effective in causing corrosion than rain, or that a motorcycle which is stored during the winter under a so-called *protective*

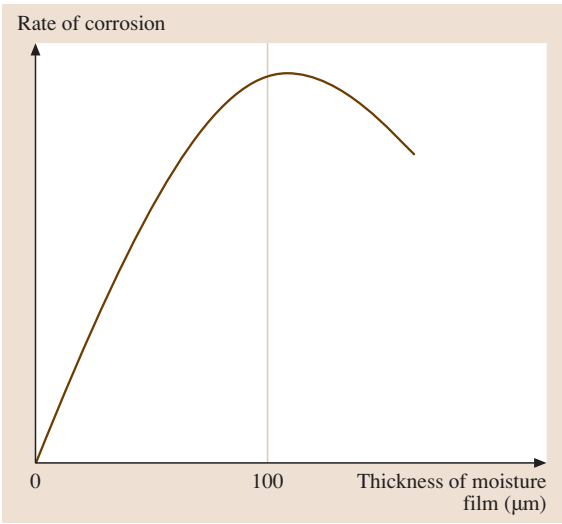

Fig. 3.109 Influence of the thickness of a moisture film on the rate of atmospheric corrosion (after [3.96])

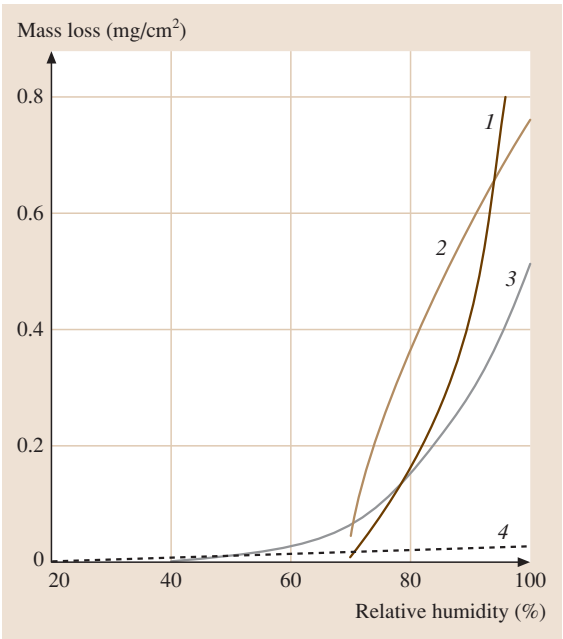

Fig. 3.110 Influence of air humidity on the corrosion of iron at constant temperature: 1 – air with 0.01 vol. % sulfur dioxide, and solid particles; 2 – air with 0.01 vol. % sulfur dioxide; 3 – air with solid particles; 4 – pure air (after [3.97])

cover can be exposed to ideal conditions for corrosion as a result of poor air circulation.

Atmospheric Corrosion, Rusting

Equation (3.84) indicates that atmospheric corrosion requires oxygen and water for the oxidation (electron consumption) of iron to occur. Oxygen is available in sufficient quantities from the atmosphere. With increasing temperature, the air can take up more water. This leads to a decrease in humidity for constant overall wetness (g/m^3). Conversely, the relative humidity increases (for the same wetness level) with decreasing humidity. The temperature at which the relative humidity is 100%, i. e., when the air is saturated with water, is called the dew point. Below this temperature, condensation occurs and leads to the formation of liquid water. Water can also form, however, at considerably lower relative humidity on air pollutants (dust particles) or on surfaces, since these both function as sites for the initiation of condensation.

Figure 3.110 shows the influence of air humidity on the corrosion of iron at constant temperature. It can be seen that the mass loss through corrosion increases dramatically at humidities above 70%. This relative humidity level is therefore referred to as the critical air humidity. If the humidity is lower, no significant corrosion occurs in practice. In very pure air, no real corrosion takes place even at a relative humidity of 100%. However, other factors such as air impurities (particularly sulfur dioxide) can lead to increased corrosion. Sulfur dioxide arises in large amounts from the combustion of organic fuels. Hygroscopic dust particles, such as corrosion products or airborne impurities (e.g., soot particles, salts), also favor condensation and lead to the formation of electrolyte films that permit corrosion to occur.

The formation of rust involves a secondary reaction following corrosion under atmospheric conditions according to (3.84). After iron ions have gone into solution, i. e., after corrosion has already occurred, these can react with hydroxyl ions (OH^-) and form $Fe(OH)_2$

$$Fe^{2+} + 2OH^- \rightarrow Fe(OH)_2 \,. \qquad (3.86)$$

Figure 3.111 shows the corrosion of iron under a water droplet. The diffusion path for oxygen is shortest at the edge of the droplet and this is where the electron-consuming processes take place with the formation of OH^- ions. The corrosion itself occurs at the center of the droplet, where iron atoms leave the metallic lattice and go into solution as ions. The electrons which are thereby set free

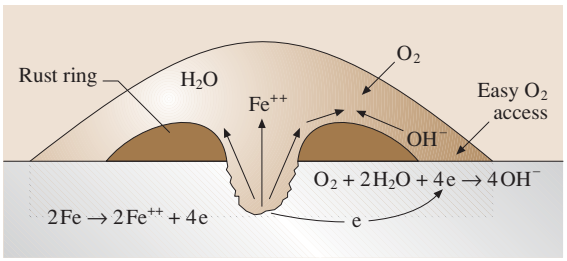

Fig. 3.111 Corrosion under a water droplet (after [3.98])

are consumed by reduction of oxygen. The iron and hydroxyl ions diffuse towards each other and initially form iron(II) hydroxide (3.86) which – in the presence of oxygen – is subsequently oxidized to γ-FeOOH (lepidocrocite) as the first crystalline product, according to

$$2Fe(OH)_2 + \frac{1}{2}O_2 \rightarrow 2FeOOH + H_2O \,. \qquad (3.87)$$

As the process continues over time, a number of further chemical reactions also occur and transform the initial rust into a mixture of different rust minerals. Depending upon its exact chemical composition, the volume of the rust is six to eight times larger than the missing (corroded) amount of iron. Lepidocrocite, also known as esmeraldite, is an unstable modification of the hydrohaematite FeOOH, which is contained primarily in the rust on low-alloy steels. It exhibits a red to brown color. The complex influence of climatic factors transforms the metastable form of lepidocrocite (γ-FeOOH) in part into the much more common rust mineral goethite (α-FeOOH). The name originates with Johann Wolfgang von Goethe, who first described this naturally occurring mineral. It is a further species of the metastable hydroxide FeOOH and is the primary reaction product on carbon steels. It exhibits a light yellow to blackish brown color. Direct transformation is hard to conceive, since lepidocrocite possesses the most dense packing of oxygen atoms in a cubic structure, while goethite has the most dense packing of oxygen atoms in a hexagonal structure. Instead, it has to be assumed that the transformation proceeds via the dissolution of lepidocrocite, followed by precipitation from a solution containing Fe(III). This assumption is supported by the 30 000 times better solubility of γ-FeOOH in comparison to α-FeOOH. An amorphous Fe(III) hydroxide forms as an intermediate product and is transformed into α-FeOOH by ageing. Higher temperatures accelerate this process. The composition of the corrosion products is also dependent upon the access of oxygen.

Table 3.9 Relative amounts of the crystalline phases as a function of the climatic conditions (selection) [3.99]

Climate	Rust composition		
	Lepidocrocite	Goethite	Magnetite
Industrial atmosphere	5	3	1
Marine atmosphere	0	2	3
Forest atmosphere	3	7	1

Magnetite (Fe_3O_4) is formed at those locations where component design limits the access of oxygen (corners and crevices). This so-called *dense rust* can cause plastic deformation or failure of component fasteners as a result of the increase in volume. It has a blackish brown to black color. The access of oxygen is also limited under thick layers of water.

A system of reversible reactions is formed [3.100]

$$Fe^{2+} + 2FeOOH \underset{O_2\ \text{deficiency}}{\overset{O_2\ \text{entry}}{\rightleftarrows}} FeO_4 + 2H^+ . \tag{3.88}$$

Depending upon the amount of water and the access of oxygen, the following phases can also be formed directly, provided prior oxidation of Fe^{2+} to Fe^{3+} has taken place

$$Fe^{3+} + 3OH^- \rightarrow FeOOH + H_2O , \tag{3.89}$$

$$2Fe^{3+} + 6OH^- \rightarrow Fe_2O_3 + 3H_2O . \tag{3.90}$$

Haematite (Fe_2O_3) forms under limited oxygen supply, either via reoxidation of Fe_3O_4 to Fe_2O_3, or by prior oxidation of Fe^{2+} to Fe^{3+} and subsequent reaction with hydroxyl ions. It exhibits a light brown color and has a cubic structure.

The relative amounts of the crystalline phases arising in the course of weathering can be determined by X-ray analysis, as shown in Table 3.9. These results are strongly dependent upon climatic conditions.

The factors already discussed demonstrate that the corrosion products on unalloyed steel are highly heterogeneous as a result of the variety of compounds which are formed, their ability to undergo transformation, and their different crystal structures. As a result they do not form adherent, protective layers on the steel.

Passivity

After very rapid, initial corrosion (e.g., as a consequence of plentiful oxygen supply in the water and the strong reactivity of the metal itself), a metallic surface can become spontaneously covered with an oxidic layer, a so-called passive film. Among others, the metals aluminum, titanium, zirconium, zinc, chromium, tantalum, cobalt, and nickel all fall into this category. Figure 3.112 illustrates what happens when these metals are exposed to the atmosphere, rather than under the special conditions of standard potential, absence of oxygen, and a one-molar solution of their own ions. Although thermodynamic properties are still valid, they disappear into the background and kinetics dominate the corrosion behavior as a result of the formation of passive films (which are electronically semiconducting or isolating). The only thing that then matters is what can still dissolve through the film and how the electron-consuming processes can occur. This characteristic transforms these nonnoble metals into the most important technical alloys.

For iron under atmospheric conditions, the reaction does not occur quickly enough: as a result, the dissolution process, rather than film formation, dominates and leads to the formation of undesired rust via secondary reactions. However, in alkaline media (e.g., in concrete where the pH value is > 12) or in strongly oxidizing acids (e.g., nitric acid), passivity can also occur spontaneously with unalloyed and low-alloy steels. In order to protect iron-based materials outside these special cases, they are alloyed with chromium to attain the desired state of passivity. This effect was discovered at the beginning of the 20th century by Maurer and Strauß while studying an experimental heat of steel (V2A) and was patented by the Krupp company in 1912.

Chromium is lower in the list of standard potentials than iron. Thus its addition as an alloying element actually makes the metal less not more *noble* in a thermodynamic sense. However, the passivity of the resulting alloy leads to it being referred to as

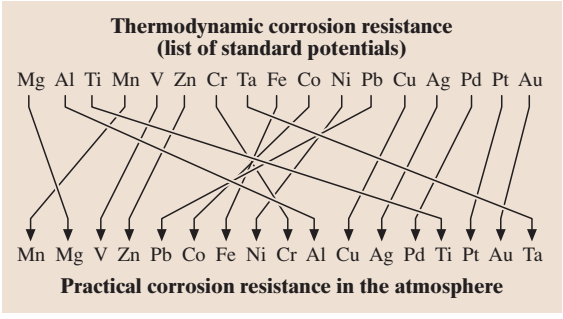

Fig. 3.112 The *nobility* of metals, thermodynamics versus kinetics (schematic)

a stainless steel. In German, such alloys are sometimes called *noble steels*, which is confusing with regard to corrosion and originates, in fact, from the way in which their phosphorus and sulfur contents were strongly reduced and low levels of nonmetallic inclusions were attained in the steel. Chromium's tendency to react very rapidly with the environment and form a subsequently protective film of corrosion product is transferred to iron–chromium or iron–chromium–nickel alloys once a concentration of approximately 12% chromium is attained in the material.

Passive films form naturally and their nature is thus very different from the properties of coatings or plated layers on steel. With stainless steels, the passive layer is remarkably thin: of the order of 10 nm (some 50 atom layers) and even less (five atom layers) with pure chromium. Such layers cannot be detected by conventional means, since their thickness is much smaller than the wavelength of visible light. The film is subject to very strong mechanical stresses and exhibits an extremely high potential gradient of 1 MV/cm. It is nonuniform in nature, both in terms of chemical composition and structure: adjacent to the metal, the film is amorphous, but it becomes increasingly crystalline towards the interface with the medium. Passive films are capable of repairing themselves after being damaged mechanically, which is of great practical importance and distinguishes them significantly from organic coatings, since the latter no longer provide an effective barrier once damaged.

In recent decades, research into the phenomenon of passive films has made astonishing progress. It is now known that the film does not correspond to an unchanging layer, but is part of a dynamic system. The relevant specialist literature now talks about the passive film *living*, whereby both birth and death events take place [3.102]. At any moment in time, activation and repassivation processes occur on a submicroscopic scale and statistically distributed over the surface. Under certain circumstances, these can be measured as small impulses of potential and current. For some years now, it has been recognized that these impulses, which are known as electrochemical noise, are dependent upon the nature of the metal and its actual state, the temperature, the pH value, and the type and concentration of ions dissolved in the medium. They provide an important source of information on corrosion behavior and electrochemical noise exists even when it is not being measured. In the meantime, there are numerous practical examples for the application of electrochemical noise measurements, e.g., in corrosion monitoring or in the quality control of incoming products.

Figure 3.113 shows a transient (localized dissolution of metal) as typically generated continuously during exposure of a stainless steel to a medium of approximately neutral pH which is free from chlorides. The amount of charge involved here corresponds to 1.5×10^{-12} C and is equivalent to approximately 5000 billion iron ions going into solution. This corresponds to a cubic defect with an edge length of ca. 40 nm for a face-centered cubic structure with a lattice constant of 0.364 nm. During the early stages, dissolution is crystallographically oriented and more hemispherical dissolution is only observed for much larger defects.

This tiny, active location very rapidly becomes covered again with a passive film, i. e., repassivation occurs. If one observes a freshly prepared surface on which the passive film is still being formed (Fig. 3.114a), it is possible initially to measure much larger transients. In the example shown, some 100 events greater than 25 pA were observed during the first 300 s. As time proceeds, the events become rarer and their amplitude decreases. The electrochemical noise behavior observed is significantly different, however, if the investigation is begun in a solution which already contains chloride ions (Fig. 3.114b). Firstly, many more events larger than 25 pA can be counted (ca. 300 here during the first 300 s). Secondly, the noise impulses decay only to a small extent, even after longer times. The effect of chlorides here can be understood not in terms of initiating local defects, but as delaying their repassivation.

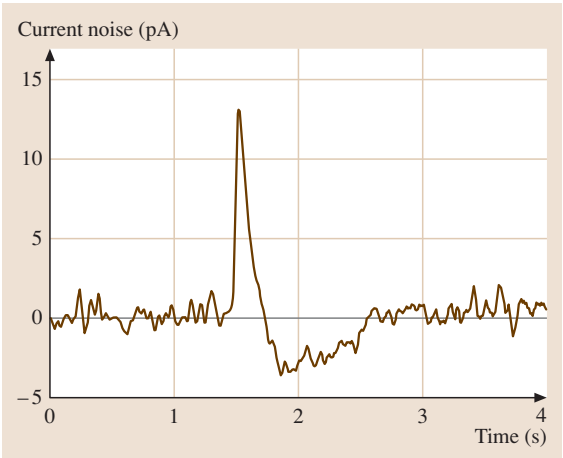

Fig. 3.113 Individual transient (maximum 13 pA) on a passive 18/10 Cr/Ni stainless steel in an oxygen-saturated aqueous solution free from chlorides (after [3.101])

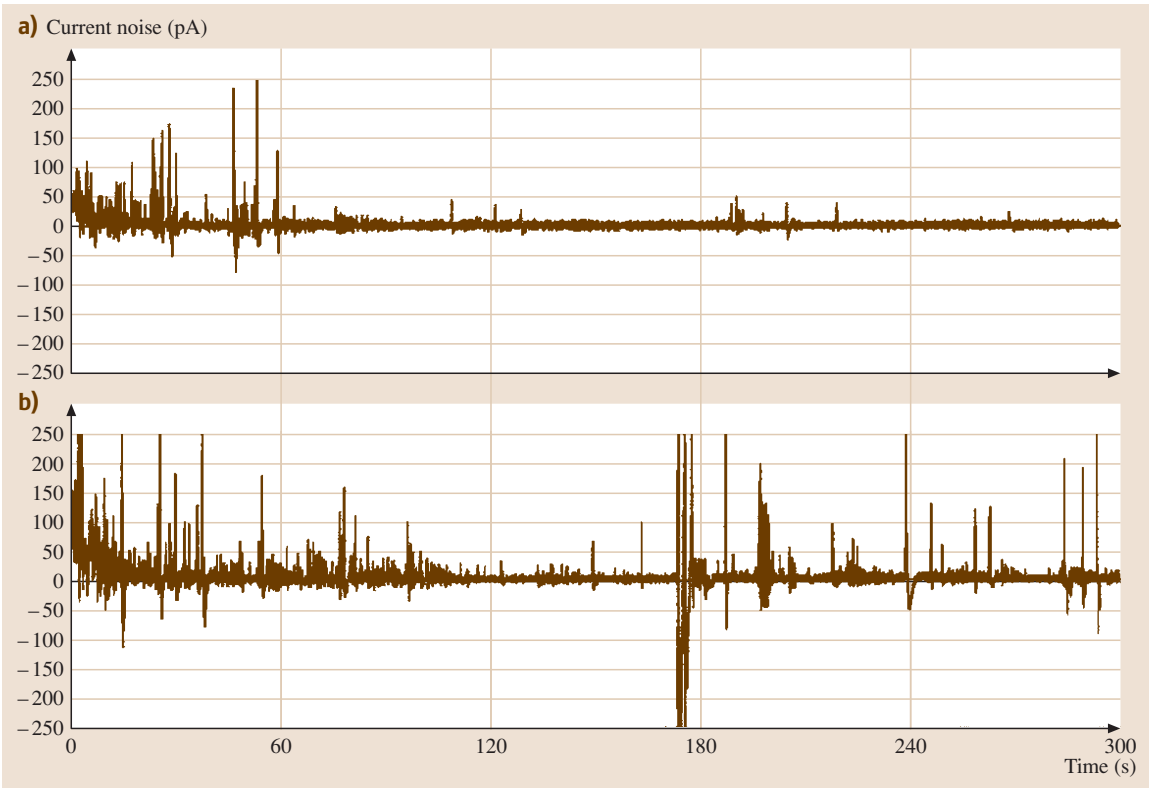

Fig. 3.114a,b Electrochemical current noise on a freshly prepared 18Cr/10Ni stainless steel surface in air-saturated aqueous solutions: **(a)** without Cl^-, **(b)**with 10^{-4} M NaCl (after [3.101])

It is thus incorrect to speak of chloride-induced corrosion, even though the behavior has this appearance. With larger amounts of chloride, and supported by impurities in the material, repassivation can be delayed to such an extent that the active locations become sufficiently large and stable to form the point of origin of corrosion pits (see later). In practice, this means that it is advisable to wait until the natural activity of passive film formation has virtually ceased before adding chloride ions when stainless-steel containers are filled. Depending upon the exact conditions, this may take hours or even days.

It is important for the fabricator or user of highly alloyed, stainless steels to be aware that he is not dealing with a robust material that is *inert* with regard to corrosion, but rather that the apparently *noble* properties of the steel arise from a very delicate film which needs to be treated with great respect. In essence, he needs to understand that something is involved which is invisible, but very effective, and that this can only function satisfactorily if the conditions remain conducive to film repair. If insufficient oxygen is present, as can occur, e.g., in crevices resulting from poor design, the rate at which the film reforms can be lower than the rate of dissolution, leading to rapid corrosion of the steel. Furthermore, the pervasive presence of chloride ions can delay local repassivation at spots where the film has *died*, or even prevent this completely. The latter case can lead to strongly localized dissolution of metal, i. e., pitting corrosion. Deposits of any kind that are present on the surface, whether visible or not, also make the formation of an intact passive film more difficult, or even impossible. For example, sweat from hand contact, dust, residues from tool abrasion, and fine rust particles can form the initiation points for corrosion which later becomes visible to the naked eye. Alterations to the metal itself, such as strong heat input, localized deformation, tensile stresses, etc., also influence the formation of the passive film and thus the corrosion behaviur.

In summary, even highly alloyed steels that are said to be resistant to rusting and to withstand exposure to acids are not in any sense *noble* and can corrode if they

are wrongly selected, stored, loaded, worked, welded, joined, combined, cleaned, pickled, ground, abraded, polished, or – more generally – insufficiently cared for. Furthermore, there is no point in trying to compensate for bad fabrication practices by choosing a more expensive steel, since such steels require special attention in the way they are treated and used in order for advantage to be taken of their inherently valuable properties. What has been stated here for highly alloyed, stainless steels is also valid for other metals and alloys which rely on passivation for their corrosion resistance. In every case, attention has to be paid (also during the design phase) to ensuring that repassivation can occur in an appropriate way.

Types of Corrosion

The different types of corrosion, and the associated damage they produce, are very varied. In addition to uniform surface attack, which is relatively straightforward, a number of nonuniform modes of attack often appear. These result from concentration elements (e.g., differential aeration cells), bimetallic couples, selective dissolution (e.g., intergranular corrosion), static and cyclic loads (stress corrosion cracking and corrosion fatigue), stray electrical currents, anions which hinder repassivation (pitting corrosion), rapid flow of the corrosion medium, etc.

Uniform Surface Attack. The progression of uniform surface corrosion can be predicted reasonably well. Thus, the loss of structural integrity as a result of corrosion reducing the wall thickness of a component can easily be compensated for by including extra margin during design. Note, however, that this only makes sense if the contamination of the medium from corrosion products can be tolerated. Even small amounts of heavy-metal ions can easily render a product unusable, or endanger the environment. Locations where dissolution occurs preferentially can result if protective layers are not formed uniformly, or if inhibitors are used at too low a concentration (dangerous attempts to protect against corrosion), and this leads to attack in the form of broad to sharp pitting.

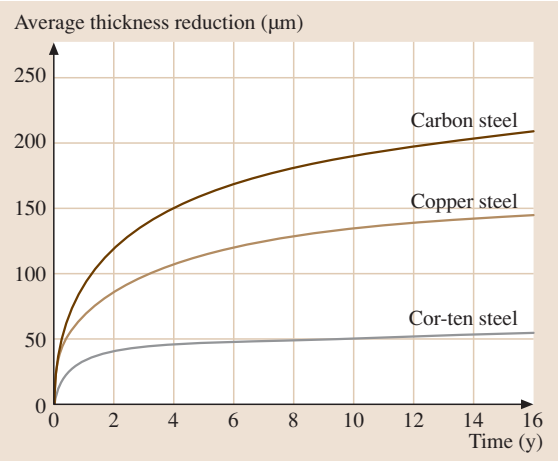

Fig. 3.115 Corrosion versus time curves for three steels in an industrial atmosphere (after [3.95])

The rate of corrosion is quoted in millimeters per year (mm/year) or in grams per square meter per year (g/m^2/year). If conditions for uniform surface dissolution occur, metals can be divided according to the velocity of lateral penetration (V_L) and the practical requirements into three main groups [3.103]:

1. $V_L \leq 0.15$ mm/year. The metals in this group have rather good corrosion resistance and are used for parts which would otherwise be especially endangered. These include, e.g., valve seatings, pump shafts and impellers, and springs.
2. $V_L = 0.15–1.5$ mm/year. The metals belonging to this group are adequate for service requirements where a higher rate of corrosion can be tolerated. Examples here include the fabrication of boilers, piping, valve bodies, bolt heads, etc.
3. $V_L > 1.5$ mm/year. Metals which corrode at such high rates are basically unsuitable for use in practice.

Steel corrodes in seawater, e.g., at a relatively uniform rate of around 2.5 g/m^2/year or 0.13 mm/year (not valid in tidal regions). Since the initial rate of corrosion is higher than the final value, such values are always averaged over a certain period of time. The measurement duration should always be quoted when making such statements.

Figure 3.115 shows the corrosion behavior versus time of three different steels exposed to an industrial atmosphere. The high initial rates are immediately apparent, as is the later improvement, particularly with Cor-ten steel, as a result of the formation of partially protective rust layers.

Flow-Induced Corrosion. All important technical metals are produced under the expenditure of a lot of energy and thus have a strong tendency to return to the lower-energy state by means of corrosion. They are prevented from doing so within reasonable limits by the existence of protective surface layers, which are themselves

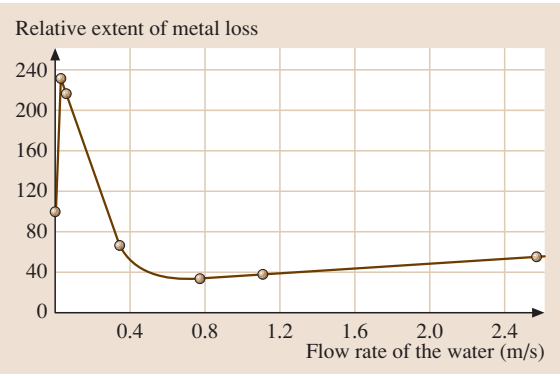

Fig. 3.116 Influence of the rate of flow of drinking water on the corrosion of an unalloyed steel (after [3.104])

produced via secondary reactions (usually involving oxidation). The flow rate of the medium is important in this context, as will be illustrated using the example of drinking water in a pipe made of unalloyed steel (Fig. 3.116). As the flow rate increases from zero, the corrosion rate initially rises, since more oxygen can be transported to the steel surface and thus more electrons can be consumed. At slightly higher flow rates, however, the corrosion products form a protective layer at the steel surface and the metal loss is significantly reduced. If the flow rate continues to increase, shear stresses eventually develop at the surface which lead to a reduction in thickness (and thus effectiveness) of the protective layer. The permissible flow rates are thus limited to a certain region. Table 3.10 gives guideline values for the water flow rate for various materials.

There is an additional consideration regarding the necessary oxygen concentration for formation of the protective layer and the velocity of water flow: at rates of around 0.5 m/s, 6 mg/l of dissolved oxygen is required, whereas only 2 mg/l are sufficient at rates above 1 m/s. The corrosion of highly alloyed, Cr/Ni stainless steels is not affected so much by flow rate. However, pitting corrosion occurs more readily in stagnant or weakly flowing water than when the medium is flowing rapidly. Each medium is associated with a particular type of protective layer. Thus if the medium changes, the layer also changes, or is dissolved and replaced by a different one. Frequent changes in the composition of the layer, however, may lead to complete loss of its protective nature, which can also happen as a result of temperature variations.

Pitting Corrosion. Pitting corrosion is much feared with highly alloyed, Cr/Ni stainless steels, but also with titanium-, aluminum-, and nickel-base alloys. Under certain conditions, the repassivation rate (see *passivity*) is lowered to such an extent by factors such as high levels of halide ions, concentration of sulfides in the metal, lack of oxygen, etc. that the active locations become sufficiently large to be stabilized. They are then effectively decoupled from the bulk medium. Such pits often exhibit only a limited opening at the metal surface (thus reducing the diffusion of oxygen) and the internal electrolyte within the pit can become highly acidic (pH < 2) as the result of electrolytic processes. These conditions lead to extremely rapid local corrosion rates, since the fundamental reactivity of chromium is no longer restricted.

Pitting is affected not only by the nature of the metal surface, but also by the alloying elements. Apart from

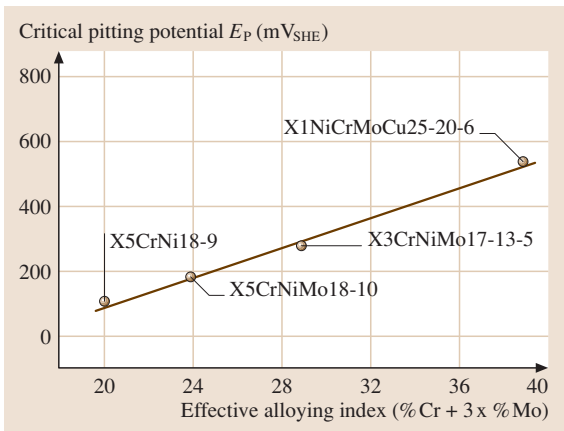

Fig. 3.117 Critical pitting potentials of various stainless steels as a function of their content of the alloying elements chromium and molybdenum (after [3.105])

chromium, molybdenum is especially important here. A so-called *effective index*, formed by multiplying the concentrations of individual alloying elements by appropriate factors, is used to describe this effect. This permits the creation of pitting resistance diagrams (plots of critical electrochemical pitting potential versus effective alloying index), as is shown in Fig. 3.117 for various common steels.

The critical pitting temperature (CPT) is also often used to describe pitting behavior, since temperature is a key factor affecting this type of corrosion. The advantage here is that the determination of this value can be made without the need for external instrumentation (such as an electrochemical potentiostat). The temperature of a 10% solution of $FeCl_3$ is raised every 24 h by 2.5 °C until pitting corrosion finally becomes visible. Such a CPT curve also goes up as the effective alloying index is increased. It is possible to determine critical pitting temperatures more quickly (in about 30 min) by the measurement of electrochemical noise.

Since the passive film can always be damaged in practice, it would really be more important to know whether such defects can be successfully repaired, rather than if pits are formed. Unfortunately, however, the determination of so-called repassivation potentials (or repassivation temperatures) is presently too inaccurate to permit their use in routine testing. Nevertheless, efforts continue to determine such values more exactly, because of their fundamental importance.

Intergranular Corrosion. Precipitation of a new phase occurs in a mixed crystal lattice if the solubility of one of the components is exceeded. This occurs preferentially at the grain boundaries, for thermodynamic reasons (lower energy). If the phase concerned is less corrosion resistant, and if it forms a continuous network, dissolution takes place particularly at the grain boundaries. In some cases, this can lead to the total decomposition of the material into individual crystals (grains), as can be the case, e.g., with the Al_3Mg_2 phase in aluminum/magnesium alloys, or the less noble β-phase in brasses.

When highly alloyed, Cr and Cr/Ni stainless steels are reheated (e.g., during welding), precipitation of chromium carbides ($Cr_{23}C_6$) can occur. The formation of this phase rich in chromium (up to 85%) leads to chromium depletion in the immediate vicinity (Fig. 3.118). In acid media, no stable passive film is formed if the chromium level sinks below a critical value of around 12%, which then results in extremely high rates of dissolution (up to 1 million times higher

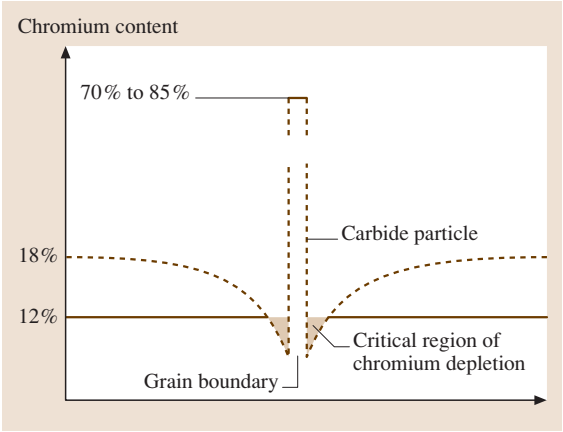

Fig. 3.118 Schematic representation of the distribution of chromium at a grain boundary in a sensitized stainless steel containing 18% chromium (after [3.106])

at the grain boundary than in the interior of the grains).

Figure 3.119 shows a photograph taken with an atomic force microscope (AFM). Strong dissolution can be seen to have taken place at the grain boundaries. The light-colored, protruding particles are the carbides which have been left behind.

The formation of a passive film is very dependent upon the electrochemical corrosion potential, which, in turn, is strongly influenced by the pH value of the solution. This results in an apparent paradox with passive steels, as a sensitized material can undergo severe intergranular corrosion in weakly acid media (beer, wine, hair shampoo) but exhibit little or no corrosion in a much more acid environment, where the potential is displaced to more positive values. In strongly oxidizing acids, however, where the potential is even higher, dis-

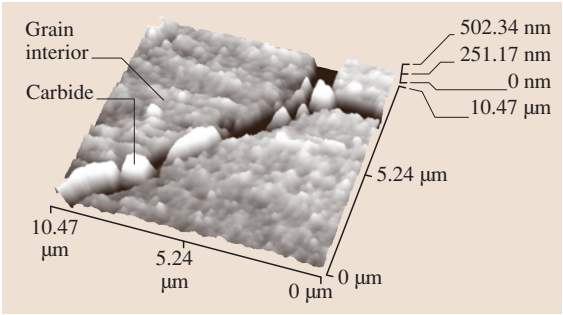

Fig. 3.119 AFM photograph of a highly alloyed stainless steel undergoing intergranular corrosion, leaving behind chromium-rich carbides (after [3.107])

solution of the chromium carbides themselves can take place, again leading to intergranular corrosion.

Stress–Corrosion Cracking. Stress corrosion cracking is a very dangerous form of attack, since it often leads to component failure without visible signs of damage at the metal surface. The preconditions for it to occur include a susceptible metal, a specific aggressive medium, and a critical level of stress. Internal stresses, such as that caused through prior cold working or heat treatment, can contribute to the required loading. As with pitting corrosion, stress corrosion cracking is observed in materials which are otherwise protected by surface layers. Those affected include unalloyed, low-alloy, and highly alloyed steels, as well as nickel-based alloys, aluminum, and brasses. A distinction is made between anodic and cathodic stress corrosion cracking, although mixed types are also often observed.

With anodic stress corrosion cracking, crack formation arises from a dissolution process, whereby localized defects, slip bands, phases susceptible to corrosion, and grain boundaries can all play an important role. Often, the crack forms at an incipient corrosion pit and the progress of corrosion involves alternating phases of crack propagation and broadening of the crack through dissolution. Localized embrittlement of material can occur ahead of the crack tip. Figure 3.120 shows schematically one example of the many possibilities leading to cracking.

The formation of atomic hydrogen plays a decisive role in cathodic stress corrosion cracking. This originates from the cathodic reaction according to (3.4), whereby compounds of sulfur, in particular, prevent the hydrogen atoms from recombining to molecular hydrogen. These hydrogen atoms are easily able to enter the metal and then form hydrogen gas, which cannot diffuse easily, or metal hydrides. In this way, dislocation movement is blocked and the metal becomes locally brittle (hydrogen embrittlement). Cracking of the material can then take place above a critical stress level.

The crack path in both types of stress corrosion cracking can follow the grain boundaries within the microstructure (intergranular), or propagate through the interior of the grains (transgranular), independent of the specific causes. Cathodic stress corrosion with transgranular cracking plays a special role with steels of higher strength. Without hydrogen, these would withstand much higher levels of stress, so that this particular type of corrosion often ultimately limits their use.

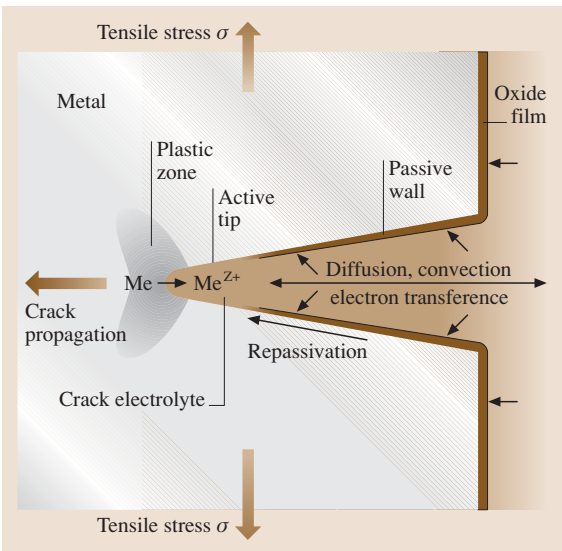

Fig. 3.120 Modeling of stress corrosion crack propagation in a passive metal by quasicontinuous, intermittent crack-tip-slip activation followed by deformation-enhanced dissolution of metal at the crack tip. Note the role of a plastic deformation zone at the crack tip and protection of the crack walls by repassivation, after crack growth has occurred (after [3.108])

Corrosion Fatigue. Corrosion fatigue can occur if a corrosion process occurs at the same time as cyclic mechanical loading. The combined effect is easily assessed in terms of the relevant *S*–*N* curve (Fig. 3.121).

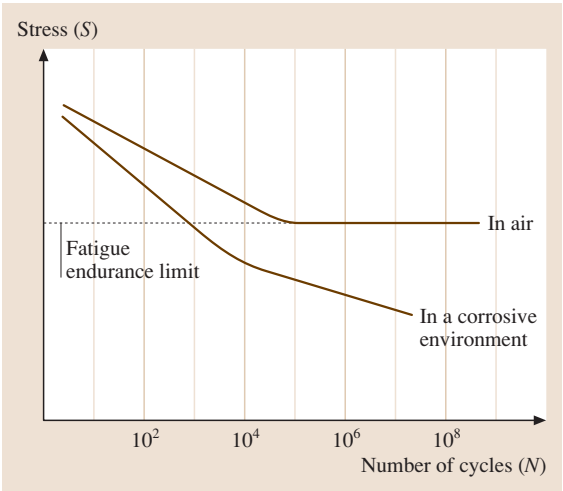

Fig. 3.121 Alteration of the cyclic *S*–*N* curve as a result of corrosion fatigue (after [3.106])

A corrosive environment leads to the absence of a true fatigue endurance limit. Instead, the fatigue strength can only be stated as a function of time (and accumulated loading cycles). The initial process of crack formation is comparable to that occurring in a non-corrosive environment: elements of the lattice structure become separated from the surface at slip bands as a result of localized plastic deformation. This results in the formation of microscopic notches, leading to stress concentrations, and later to cracks. In a corrosive environment, however, the cracks propagate more quickly. As a rule, they are transgranular in nature. All materials are basically affected and no specific corrosive medium is required. The damage results from the slip processes that are initiated by cyclic loading.

Erosion Corrosion. If the corrosion of metallic materials is stimulated by erosion processes at the metal surface, the damage mechanism is referred to as erosion corrosion or cavitation. Erosion corrosion can be observed in equipment containing flowing water, or steam, as a result of high flow rates and the presence of solid particles in the medium. The latter damage the microstructure by impacting the metal surface and thus input mechanical energy, which favors corrosion.

Cavitation corrosion refers to the situation when gas contained in water is abruptly released, or transformed into steam. The collapse of the resulting bubbles damages the metal surface by releasing soft or brittle components from the microstructure, thus stimulating the corrosion process. Cavitation corrosion is observed, particularly in steam boilers, degassing equipment, pumps, turbines, and valves.

Galvanic Corrosion. In practice, an attempt is often made to explain all corrosion phenomena by reference to the list of standard electrode potentials. However, the theory of galvanic corrosion elements derived from this has been unacceptable scientifically since the investigations of *Wagner* and *Traut* in 1938 [3.109]. It should be regarded only as a special case of the more universal theory of mixed potentials.

So-called galvanic corrosion occurs, in addition to normal corrosion, if two metals with different electrochemical potentials are connected together electrically. In this case, metal dissolution is accelerated at the less noble material (anode) and the consumption of electrons is favored at the more noble material (cathode). It is impossible to say what will be more or less noble just from the list of standard electrode potentials, since the addition of alloying elements and the formation of protective surface layers result in an entirely different order.

Table 3.11 Influence of area ratio on the corrosion rate of shiny nickel in contact with chromium in simulated rainwater of pH 2.5 (the less noble chromium, according to the list of standard potentials, forms the cathode here and is nobler than nickel as a result of passive film formation) [3.96]

Area ratio Cr/Ni for constant chromium area of 6.3 cm^2	Anodic current density of nickel dissolution (mA/cm^2)	Rate of nickel metal loss (mm/year)
1 : 1	0.0015	0.016
1 : 0.1	0.015	0.16
1 : 0.01	0.15	1.6
1 : 0.001	1.3	13.9
1 : 0.0001	6.8	72.8
1 : 0.00005	17	182

In practice, the contact resistances and the conductivity of the electrolyte are often more important than the potential difference. The area ratio of anode to cathode is also of great importance. Table 3.11 shows the effect of area on the current density using, as an example, passive chromium as the cathode and active nickel as the anode. From this it can be seen that the anode should be as large as possible and the cathode as small as possible. In practice, aluminum sheets (large anode) can be joined together with Monel rivets (70% Ni, 30% Cu) without leading to problems of galvanic corrosion. If one were to join copper sheets with aluminum rivets (small anode), however, the results would be catastrophic.

Microbiologically Influenced Corrosion. Corrosion caused by bacteria has increased in importance over recent years. Thus, damage to materials in the Earth (e.g., pipes and cables) has occurred as a result of the effects of micro-organisms (microbiologically influenced corrosion, MIC). One such example involves corrosion processes as a result of sulfate-reducing bacteria: in the presence of water, these can reduce sulfates and simultaneously lower the pH value with the formation of sulfuric acid. Traces of water are contained even in fuels such as oil and p.t.o., so that microbes can develop and disturb the electrochemical equilibrium. The resulting electrochemical reaction releases oxygen and thus permits electron consumption, leading to notch-like defects at the surface of the material. Although the suspicion is often raised that the bacteria themselves are directly active (*iron eaters*), this is not true. Instead, the attack is related to digestive products (e.g., acids), as well as to hindered access of the oxygen necessary for repassivation resulting from the formation of microbe colonies

Table 3.12 Influence of prior surface preparation on the lifetime of an alkaline-epoxy-based coating (consisting of one primer, two intermediate, and one final layers) exposed outdoors [3.96]

at the surface of the material. Clarification of the exact corrosion mechanism in an individual case can be complicated, since one is dealing with a living system and the local conditions can vary considerably (aerobic or anaerobic bacteria).

Corrosion under Coatings. The corrosion mechanism under coatings is still somewhat unclear and research is still needed into the effects of a series of influencing factors. As a rule, coatings are hydrophobic, i. e., water droplets do not wet the surface. This is only valid, however, for liquid water, where thousands of molecules band together to form small clusters. Although invisible, water vapor (not to be confused with steam, which also contains clusters) consists of separate molecules and determines the relative air humidity. Such water molecules can diffuse relatively easily through a coating, as can oxygen, carbon dioxide, and sulfur dioxide. If the coating adhesion is poor, cavities (or even rust particles) can exist between the metal surface and the coating and these permit local condensation of water and concentration of metal ions. Together with the water, the oxygen which diffuses into such cavities initiates the electron-consuming process with the formation of OH^- ions. These combine with the iron ions which have gone into solution to form rust. Since porous rust has a volume which is six to eight times greater than that of the corroded amount of metal, the coating is pushed away from the surface (formation of blisters). Larger amounts of water then collect in the resulting cavities and accelerate the processes already described. Table 3.12 illustrates the life expectancy as a function of the preparation of the surface prior to coating.

This makes it clear that the lifetime can be very different, even for the same coating system. With a firmly adhering coating, the water molecules still obtain access to the surface very quickly, but the locations at which they can condense remain so small that changes only become visible to the naked eye much later.

3.6.3 Corrosion (Chemical)

Basic Principles

With chemical corrosion, the material and the medium react directly with one another as a result of an overlap being formed between the electron paths of each of the partners. No increase in free electrons occurs in the metal. The products formed determine the continued evolution of the corrosion. The formation of protective layers is also desirable here, since these layers act as effective barriers to diffusion processes and, thus, hinder further reactions. The extent of corrosion can be determined either gravimetrically (weight change) or metallographically.

In contrast to the above, electrochemical corrosion leads to processes which take place in parallel at separate locations. Corrosion products (rust) are formed via secondary reactions, i. e., after the actual corrosion has occurred. The free electrons which are generated offer the possibility of direct measurement of the corrosion processes involved.

High-Temperature Corrosion

At high temperatures, the corrosion resistance of metallic materials decreases as a result of reactions with gases. The reaction product here is referred to as scale. It is a solid corrosion product which grows at the metal surface and forms a barrier to the reaction partners metal and gas. In order for this layer to grow, at least one of the partners must be mobile within the layer. Many oxides and sulfides contain cavities and vacancies within their microstructure and these locations permit metal cations to be transported towards the outside.

Scale formation is particularly important in practice with steels which are exposed to oxygen from the air, or to mixtures of common technical gases with steam or carbon dioxide. At low temperatures (200–400 °C), the initially high rate of reaction rapidly falls to very low values and growth of the protective layer versus time can be described by a logarithmic equation. In general, the resulting thin films ($< 0.1\,\mu m$), which are often described as tarnish layers, do not represent any significant damage to the material. They can, however, be detrimental upon subsequent exposure to water, i. e., in connection with electrochemical corrosion. At higher temperatures, the initial chemical reaction involves the

formation of thicker layers, free from pores, which grow with time according to a parabolic law. In this case, the diffusion speed of the ions and electrons is rate limiting. If the coverage is incomplete, however, as a result of the formation of pores and cracks, then either the reaction at the phase boundary metal/gas, or the supply of oxygen, become rate limiting. In these cases, layer thickening occurs in a linear manner with time, i. e., the metal is progressively destroyed (catastrophic corrosion). In oxygen or air at temperatures above 570 °C, iron forms a complex scale involving the following layers $Fe-FeO-Fe_3O_4-Fe_2O_3-O_2$. The proportion of wüstite (FeO) amounts to almost 90%, whereas magnetite (Fe_3O_4) represents 7–10% and the haematite layer (Fe_2O_3) only 1–3%. Figure 3.122 shows the relevant phase-stability diagram for iron and oxygen.

If slow cooling occurs below 570 °C, wüstite decomposes into iron and magnetite. The resulting layers are brittle and full of microcracks, both because of the differing density and the relative lack of *ductility* of Fe_3O_4 in comparison with FeO. Rapid cooling, as occurs, e.g., during hot-forming of steel plates, prevents this transformation and the resulting scale remains adherent. The oxidation rate of steels can be decreased by alloying with chromium, aluminum, and silicon.

Another set of damage mechanisms exists and leads, e.g., to carburization or decarburization of steels. Thus exposure of Cr/Ni stainless steels to gas atmospheres which can supply C results in carbide formation, which

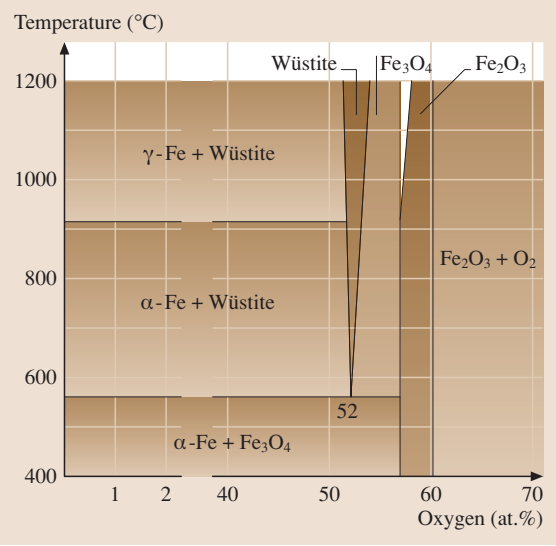

Fig. 3.122 Phase stability diagram for iron and oxygen (after [3.110])

continues to form within the body of the steel. Internal carburization is particularly detrimental for toughness at low temperatures. Particularly catastrophic carburization is possible for steels within an intermediate temperature range (400–600 °C) and is described as *metal dusting*. The material is transformed into a fine powder consisting of metal and carbon. After rapid oversaturation of the material with carbon, the process starts with the formation of an unstable carbide Me_3C (Me=Fe, Ni) at the surface and at grain boundaries. This is followed by decomposition of the carbide according to

$$Me_3C \rightarrow 3Me + C\,. \qquad (3.91)$$

The resulting, fine particles of metal act in a catalytic manner to accelerate the further uptake of carbon, so that voluminous carbon deposits grow on the metal surface. These loose deposits can be removed by the gas stream, leaving behind indentations resembling pitting corrosion.

Damage as a result of decarburization can occur in plants using pressurized hydrogen for the purposes of synthesis. Atomic hydrogen, formed as a result of thermal dissociation above 200 °C, becomes dissolved in the steel and reacts with iron carbides, producing methane

$$Fe_3C + 4H_{(Fe)} \rightarrow CH_4\,. \qquad (3.92)$$

This gas cannot escape, because of its molecular size, and leads to the build-up of high internal pressures in the metal. The mechanical properties of the steel are negatively affected by decarburization and embrittlement, with the result that inclusions, grain boundaries, and similar material separations can form the initiating points for brittle fracture.

In copper which contains oxygen, hydrogen reacts with copper oxide to form steam

$$Cu_2O + H_2 \rightarrow 2Cu + H_2O\,. \qquad (3.93)$$

This results in pores, which can become joined together to form networks of cracks. Such damage is known as *hydrogen sickness*.

More information regarding high-temperature oxidation can be found, e.g., in [3.111].

Corrosion of Glasses

Nonmetallic, inorganic materials are relatively resistant to attack at room temperature in most organic and inorganic solutions, in water, and in acids or weak bases. The extent of their resistance is dependent upon their chemical composition, the material microstructure, and

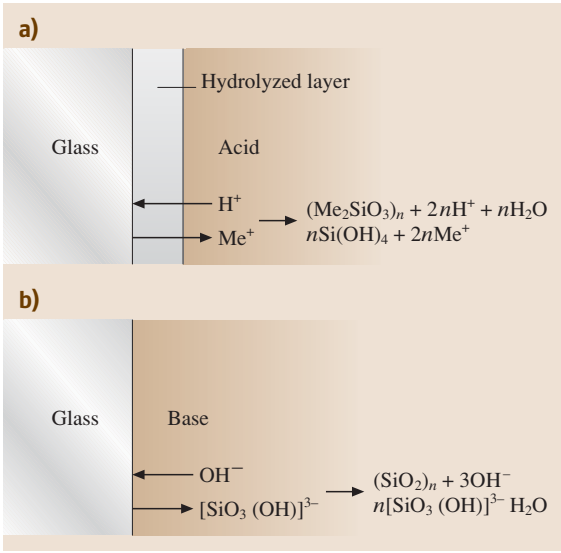

Fig. 3.123a,b Corrosion of glass by (a) acids, (b) bases (after [3.112])

the environmental conditions. Glass has no uniform composition, although it may appear relatively homogeneous from the outside. It contains various microscopic phases of different composition and is crystalline to different extents. Desired properties can be achieved by influencing the form and condition of these phases in a specific way. Thus normal glass, containing as its main component SiO_2, can be significantly attacked by hydrofluoric acid. However, special types of glass on the basis of P_2O_5 and Al_2O_3 exhibit good properties even in this medium.

The resistance of normal types of glass and enamel in acid media (apart from hydrofluoric acid) arises from the fact that the hydrogen ions in the acid are exchanged with migrant cations (Na^+, K^+, Li^+, Ca^{2+}). As this exchange proceeds, hydrolysis leads to the formation of a gelatinous layer rich in silica which limits the diffusion of ions, thus hindering corrosion and making the glass increasingly resistant to attack. This gelatinous layer only becomes damaged and allows further attack on the glass under very unfavorable conditions, e.g., during exposure to superheated steam or in heat exchangers, where additional chemical reactions involving carbon dioxide from the air can occur. Figure 3.123 shows schematically the mechanism of glass corrosion.

The resistance of the glass is very much lower in alkaline solutions (bases), since the OH^- ions can destroy the Si–O–Si links through chemical reactions producing low-molecular silicates, which dissolve in the medium. The loss of material follows a linear progression with time and can be appreciable, particularly in strong bases, at temperatures above 30 °C.

Even rainwater can lead to detectable corrosion of glass after long periods of time. Figure 3.124 shows the surface of an approximately 50-year-old pane of glass at high magnification. No amount of intensive cleaning can return the shine to this window.

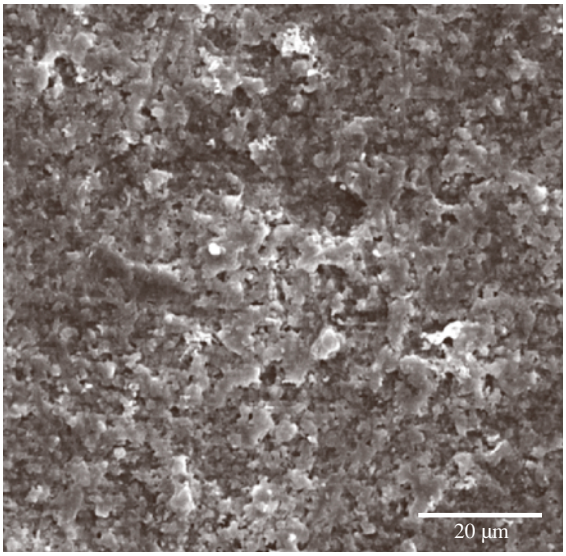

Fig. 3.124 Surface of a pane of glass as seen in the electron microscope after approximately 50 years of exposure outdoors

Corrosion of Polymers

Polymers are essentially resistant to attack in media such as the atmosphere, aqueous solutions, acids, and bases in which most metallic materials corrode. However, this does not mean that polymers show no corrosion in general. They lack resistance to attack in various organic solvents. Furthermore, they can exhibit damage due to corrosion in other media, the extent of which depends both on the chemical composition and structure of the polymer, as well as on the concentration of reactant in the medium concerned, the temperature, and the exposure time. In contrast to metals, the corrosion of plastic almost always begins with the entry of foreign molecules, i. e., with a physical process occurring in three steps: adsorption (wetting of the surface by the corrosive medium), diffusion (entry of the medium into the material), and absorption/swelling (uptake of the medium with uniform and complete penetration of

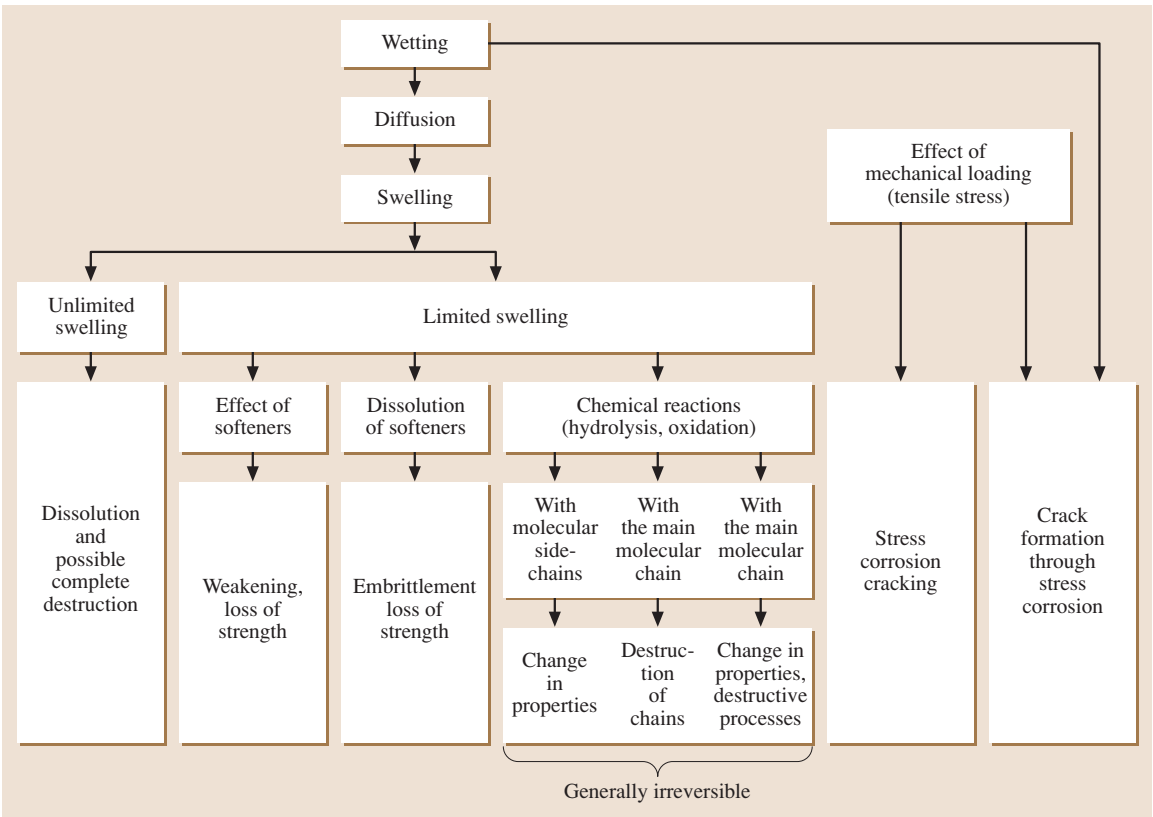

Fig. 3.125 Damage caused to plastics by liquid media

the material). Figure 3.125 shows the individual steps in the corrosion of polymers.

After the initial steps, chemical processes (chemisorption, oxidizing or reducing attack, hydrolysis, etc.) can occur and lead to considerable deterioration of the properties of the material. Attack on plastics usually occurs in a complex manner and is accompanied by further damage, such as the attainment of thermodynamic equilibria (late crystallization, recrystallization, relaxation of stress, and deformation). This takes place under the influence of thermal and/or radiation energy, as well as through biological effects. The irreversible change in properties which then occurs progressively with time is usually referred to as ageing. As with metals, stress corrosion cracking is also possible with plastics. Its occurrence again requires the presence of a specific, aggressive medium, as well as internal and/or external tensile stresses.

3.7 Materials in Mechanical Engineering

Engineering materials, in principle, may be divided into four main classes:

1. Metals
2. Ceramics and glasses
3. Polymers and elastomers
4. Composites

Materials belonging to one of these classes exhibit comparable properties, processing routes, and most often applications as well. The criteria for the material selection are rather complex and depend on the intended application purpose. To the main design criteria belong strength, stiffness, fracture toughness, formability, joinability, corrosion resistance, coefficient of thermal

expansion, cost, and last but not least recyclability. For structural applications in mechanical engineering metallic materials [3.113, 114] are still the most widely used group of materials; their order of importance is Fe, Al, Cu, Ni, and Ti. While the physical properties of materials belonging to different classes are given in Sect. 3.3, in Table 3.13 a comparison of the mechanical properties of some important metals and alloys, carbon fiber, and a polymer is shown.

3.7.1 Iron-Based Materials

Iron-based materials are the most widely used metallic materials, mainly because of their relatively inexpensive manufacturing and their enormous flexibility. Accordingly, the properties of Fe-based materials can be varied to a great extent, allowing precise adaptation to specific application requirements ranging from high-strength, high-temperature, and wear-resistant alloys for tools to soft or hard ferromagnetic alloys for applications in the electrical industries.

Pure iron, however, is only of minor importance in structural applications since its mechanical properties are simply inadequate. Alloying with carbon leads to the most important groups of constructional alloys, namely:

1. Steels with a carbon content of up to about 2.06% carbon (if not stated otherwise all compositions are giving in wt. %)
2. Cast iron, which practically contains 2.5–5% carbon

These Fe−C alloys exhibit outstanding properties, including widely variable mechanical properties: yield strengths ranging from 200 MPa to values exceeding 2000 MPa, hot and cold rolling ability, weldability, chip-removing workability, high toughness, high wear resistance, high corrosion resistance, heat resistance, high-temperature resistance, high Young's modulus, nearly 100% recyclability, and many more.

In the following sections the characteristic phases, microstructures, compositions, and applications of iron–carbon alloys are treated with emphasis on the fundamental background. For further reading, references such as [3.1, 118–122] and the online database [3.123] are recommended.

The Iron–Carbon Phase Diagram and Relevant Microstructures

Fe−C-based materials, in general, can be classified into two main categories:

1. Steels or steel castings, which are forgeable iron–carbon alloys with up to about 2.06% C
2. Gray iron or pig iron with more then 2.06% C (in practice 2.5–5%), which cannot be forged and are brought into final form only by casting

These two groups of Fe–C alloys divide the iron–carbon diagram (Fig. 3.126) into two parts, namely an eutectoid (steel) part and an eutectic (cast iron) part. In the thermally stable condition carbon prevails in the

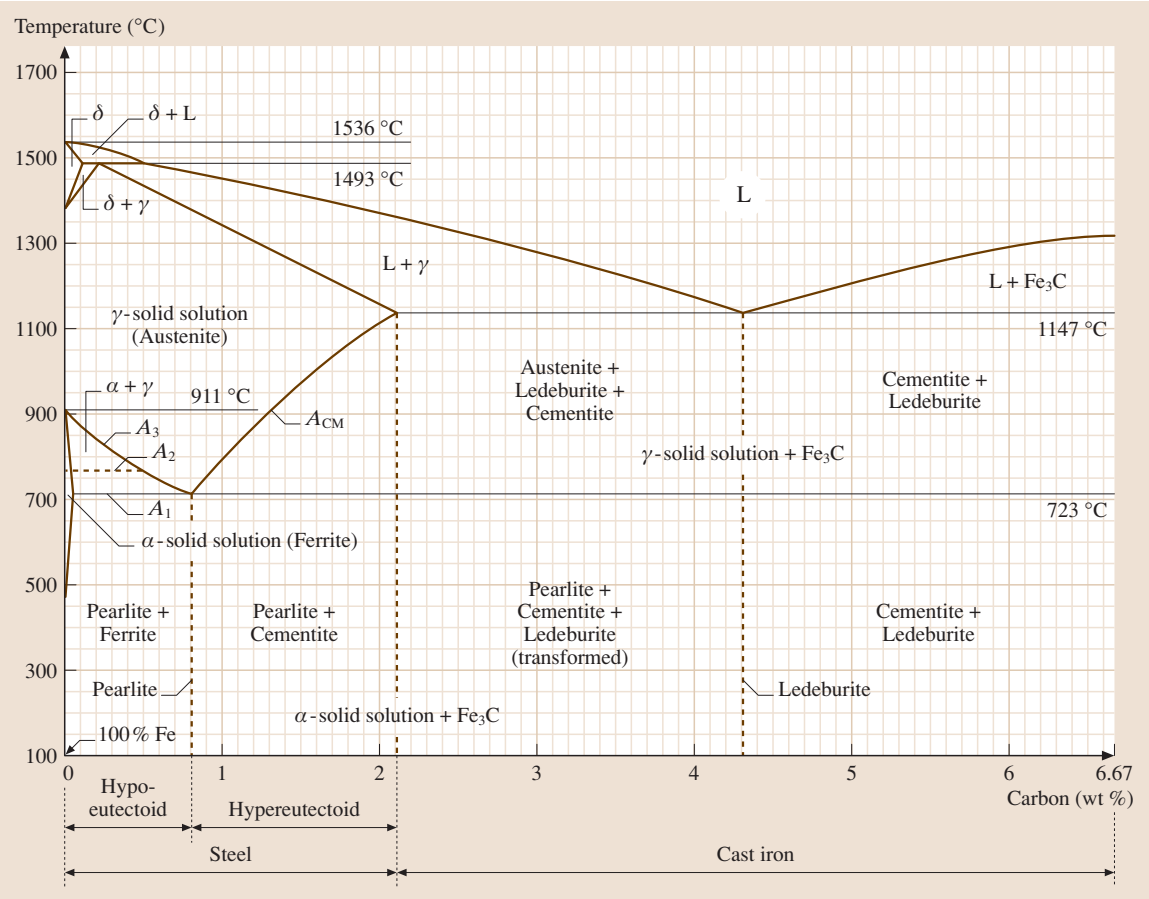

Fig. 3.126 The metastable Fe−Fe_3C (6.67%C) diagram

form of graphite. Although graphite or more precisely its shape and proportion plays a major role in adjusting the properties of cast irons, this equilibrium phase is usually not obtained in common steels. Instead, carbon in steels emerges in the form of metastable iron carbide (Fe_3C-cementite). Therefore, the metastable equilibrium (Fig. 3.126) between iron and iron carbide is relevant to the behavior of most steels in practice. A closer look at the Fe–Fe_3C phase diagram reveals the three fundamental ideal diagrams introduced in Sect. 3.1.2, namely a peritectic and a eutectoid system in the steel part and a eutectic system in the cast-iron part of the diagram.

Pure iron appears in three different allotropic forms for which the following notations are used:

- α-Fe with the bcc structure, which is stable at temperatures below 911 °C – note that from 769 °C (A_2 line) to lower temperatures α-Fe is ferromagnetic without a lattice transformation.
- γ-Fe with the fcc structure, which is stable between 911 °C and 1392 °C.
- δ-Fe with the bcc structure, which exists from 1392 °C to the melting point at 1536 °C.

With its significantly smaller atomic radius carbon occupies the interstitial lattice sites (compare Sect. 3.1.2) of the iron phases. The solubility, however, depends on the size of the lattice gap and therefore on the lattice type of the specific Fe phase (compare Fig. 3.126). These differences in the maximum solubility of carbon are the basis for the enormous variability of the mechanical properties of steels. In Table 3.14 phases and phase mixtures of the Fe–Fe_3C system, their corresponding (maximum) carbon content at different temperatures,

Table 3.14 Phases and phase mixtures of the Fe–Fe_3C diagram (SS: solid solution)

Phase and phase mixture	Maximum carbon content (in single-phase region) or percentage of particular phase in phase mixtures	Designation
α-Fe	0.02% (at 723 °C)	Ferrite
γ-Fe	2.06% (at 1147 °C) 0.8% (at 723 °C)	Austenite
δ-Fe	0.1% (at 1493 °C)	δ-Ferrite
Fe_3C	6.67%	Cementite
(α-Fe + Fe_3C)	88% α-SS + 12% Fe_3C	Pearlite (eutectoid)
(γ-Fe + Fe_3C)	51.4% γ-SS + 48.6% Fe_3C	Ledeburite I (eutectic)
(α-Fe + Fe_3C)	35.5% α-SS + 64.5% Fe_3C	Ledeburite II

and their microstructural nomenclature are summarized.

The intermetallic compound Fe_3C (*cementite*) or more accurately their microstructural appearance plays a crucial role for the adjustment of the mechanical properties of steels. Cementite with 6.69% carbon is based on an orthogonal lattice where dislocation glide at low temperatures is nearly impossible. It exhibits therefore a very high hardness (1400 HV) and brittleness. However, in the form of finely distributed particles or lamellas in the grain interiors it can hinder dislocations from glide very effectively. At a carbon content of about 0.8% at which the eutectoid reaction occurs a phase mixture of 88% α-Fe and 12% Fe_3C (eutectoid) is formed from γ-Fe(C) solid solution (compare Table 3.14). The typical arrangement of the eutectoid in contiguous lamellae (Fig. 3.127) is the result of fast decomposition and the designation *pearlite* is used for this microstructure.

Likewise the eutectic microstructure at about 4.3 wt. % C, i. e., a phase mixture of 51.4% γ-Fe and 48.6% Fe_3C, is called *ledeburite*. At carbon concentrations which vary from the exact eutectoid or eutectic composition, the microstructure contains more than one component. This is shown in Fig. 3.128 for *hypo-* and *hyper*-eutectoid steels.

On slow cooling of hypo-eutectoid compositions, i. e., of alloys containing less than 0.8% C, the austenite partly transforms to ferrite in the temperature range of 911–723 °C. Since the solubility of carbon in α-Fe is significantly lower than in γ-Fe the residual austenite simultaneously enriches in carbon along the A_3-line, until at 723 °C the remaining austenite, now exactly at the eutectoid composition, transforms to pearlite as a second microstructural component (Fig. 3.128). Hypereutectoid alloys with 0.80–2.06% carbon first form cementite at the γ-Fe grain boundaries on cooling in the temperature interval 1147–723 °C, while the austenite depletes in carbon. The carbon concentration of the austenite reaches in turn 0.8% at 723 °C and it transforms to pearlite on further cooling. The microstructural composition of Fe–C alloys in the thermodynamic

equilibrium can easily be derived from microstructure diagrams such as the one shown in Fig. 3.129.

Heat Treatments

Since a modification in the atomic configuration requires diffusion (Sect. 3.1.2) of the atoms to occupy the appropriate lattice sites, phase transitions in the solid state are typically time dependent. Therefore, the equilibrium phases of the iron–carbon phase diagram only appear upon slow cooling or after sufficiently long heat treatments. The microstructures shown in Fig. 3.128, on the other hand, arise only under specific cooling conditions. By altering the time–temperature path metastable phases as well as totally different microstructures can be formed. Heat treatment procedures differ with regard to the following parameters:

- Way of heating
- Holding temperature
- Holding time
- Way of cooling (for example, cooling in air, oil, water or furnace)

According to the way of cooling a principle division of the heat treatment procedures is widely used:

1. Annealing treatments (slow cooling close to equilibrium)
2. Hardening treatments (fast cooling)

In the following the main parameters and objectives of frequently used heat treatment procedures for steels are summarized using the above scheme.

Annealing Treatments. In Fig. 3.130 the temperatures and main parameters of frequently used annealing treatments of steels are shown [3.119].

Normalizing. Due to the heat flow during cooling of castings, in the heat-affected zone of welding joints as wells as after cold or warm rolling, the microstructure of steels can be extremely inhomogeneous. Normalizing, therefore, first of all serves to homogenize the steel and should result in a fine-grained microstructure (grain size $< 100\,\mu m$). To do so, the workpiece is austenitized by heating to temperatures 30–50 K above the A_3 line, i. e., into the region of the γ-Fe solid solution, or above the A_1 line in case of hypereutectoid steels. Subsequent cooling in air leads to complete new formation of fine-grained pearlitic–ferritic or pearlitic–cementitic microstructures (Fig. 3.131a) with high strength and high toughness. The strength and toughness of steels in the normalized condition strongly depend on the carbon content. As shown in Fig. 3.132 the strength reaches its maximum at about 1.0% carbon. Toughness, as characterized by the impact energy of Charpy tests, gives the steel a brittle behavior at carbon concentrations as low as 0.8%.

Spherodizing. The cold workability of normalized steels is normally not sufficient to gain the deformation degree desired. However, since the lamellar arrangement of α-Fe and Fe_3C in pearlite is energetically unstable, on heat treatment slightly below the A_1 transformation temperature (or in the case of hypereutectoid steels by oscillating around A_1 to accelerate spherodizing of the cementite network) the cementite lamellae rearrange to form stable spherical particles (Fig. 3.131b). Dislocation movement, which is restricted in pearlite to the region within the small α-Fe lamellae, is now possible in the whole grain interior and the steel can, therefore, be deformed more severely. After annealing, the workpiece is cooled slowly (furnace) to prevent heat stresses from arising.

Process Annealing. Cold deformation as well as hot deformation to a high degree result in the formation of a dense dislocation network, which hinders dislocation movement and therefore further material deformation. A high dislocation density, on the other hand, stores high levels of energy, which encourages complete new formation of the grain structure (recrystallization) upon annealing at temperatures exceeding $T_p = 0.4T_m$. As a consequence the strength and toughness of the recrystallized state reach levels which are close to the undeformed condition and the material can therefore be further deformed.

Coarse-Grain Annealing. Coarse grains are beneficial when the material is machined by chip-removing meth-

ods because short fragile shear chips are formed. Such a microstructure is the result of a heat treatment at temperatures between 950 and 1200 °C, i. e., in the austenitic region well above the A_3 line. On subsequent cooling in a furnace the coarse-grained γ-Fe solid solution is transformed to a coarse-grained ferritic–pearlitic microstructure. Since the accompanying decrease in toughness deteriorates the steel properties, a final heat treatment (hardening, tempering, etc.) must be made to retransfer the microstructure to a fine-grained state.

Stress-Relief Annealing. Stress-relief annealing serves to relieve stresses in the workpiece which are caused by cold deformation, microstructural transformations, thermal loading or chip-removal working. Stress-relief annealing is usually done at temperatures between 450 and 650 °C for several hours, followed by slow cooling. It does not lead to apparent changes to the microstructure nor does it change the mechanical properties significantly.

Diffusion Annealing. Diffusion annealing is done when segregations (local variations of the chemical composition) have to be compensated and requires temperatures as high as 1000–1300 °C and annealing times as long as 50 h. Since this treatment is very expensive, segregations should be prevented by optimizing the cooling conditions after casting.

Solution Annealing. Solution annealing is predominantly used for austenitic steels and serves to solve (large) precipitates in steels. Annealing at temperatures between 950 and 1200 °C and fast cooling results in a supersaturated solid solution at room temperature. Subsequent aging leads to the formation of small precipitates which lead to a significant strength increase at moderate toughness values.

While the annealing treatments introduced above lead to phase compositions which are close to the equilibrium with increasing cooling rate the transformation behavior of austenite can be completely different.

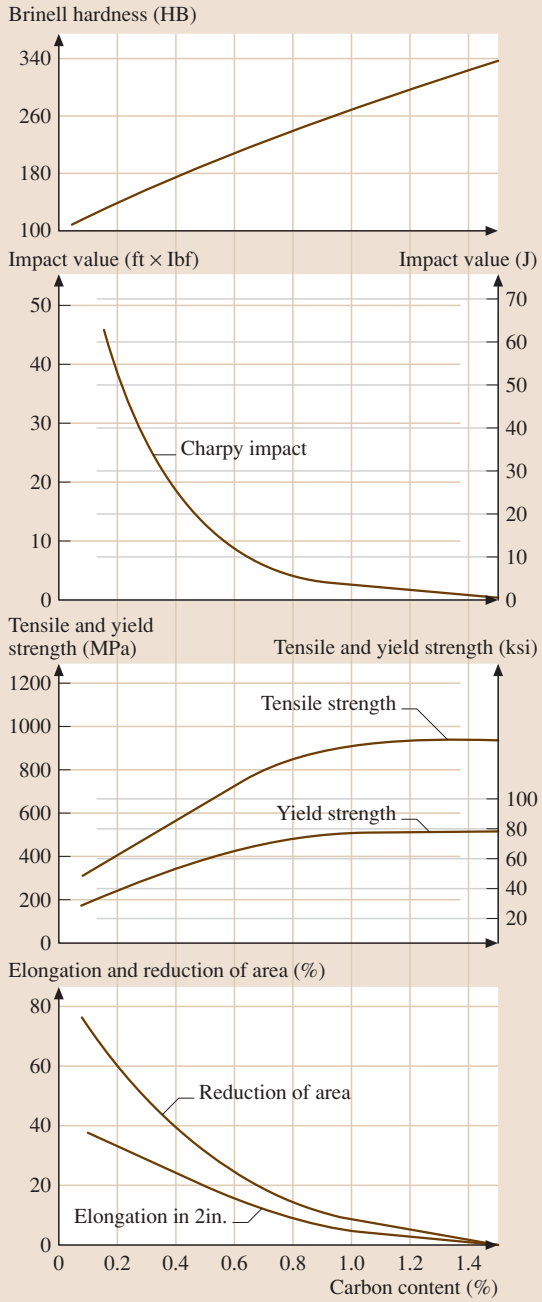

Fig. 3.132 Mechanical properties of Fe−C alloys in dependence on the carbon content (after [3.125])

Since the formation and growth of nuclei are diffusion-controlled processes fast cooling from the γ-Fe phase region may suppress the formation of the temperature

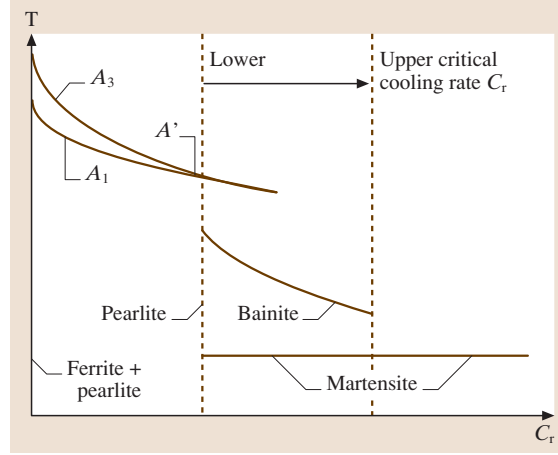

Fig. 3.133 Transition temperatures and products in steels as functions of the cooling rate (C_r)

equivalent equilibrium phases. On increasing cooling rates the transformation temperatures A_1 and A_3 decrease until they coincide at the point of the lower critical cooling rate (Fig. 3.133). At even faster cooling rates *bainite*, which consists of aggregates of plates of ferrite (so-called sheaves), separated by untransformed austenite, *martensite* (see below) or cementite are formed (for a more comprehensive compilation of bainite see [3.124]). Caused by the high cooling rate the diffusivity of Fe is reduced so strongly that the formation of cementite only occurs by diffusion of carbon, while iron transforms from fcc to bcc by a diffusionless shear process. When the cooling rate reaches the upper critical limit the diffusivity of carbon is completely suppressed as well. Due to the supersaturated solution of carbon in α ferrite a distorted body-centered tetragonal (bct) lattice, so-called martensite, is now formed as the product of a phase transition from the fcc γ-lattice. This results in very high strength of the steel but at the expense of low ductility.

The kinetics of the phase transitions from the γ-Fe phase region can be visualized in time–temperature transition (TTT) diagrams, obtained either under isothermal holding conditions or in continuous cooling transition (CCT) diagrams for varying (but fixed) cooling rates. One example for steels is given in Fig. 3.134 showing the CCT diagram of 42MnV7. Depending on the cooling rate, transition of γ-Fe leads to the formation of martensite, bainite or pearlite or a mixture of these at room temperature. The transformation quantity after crossing a transformation region is given in Fig. 3.134 as well as the

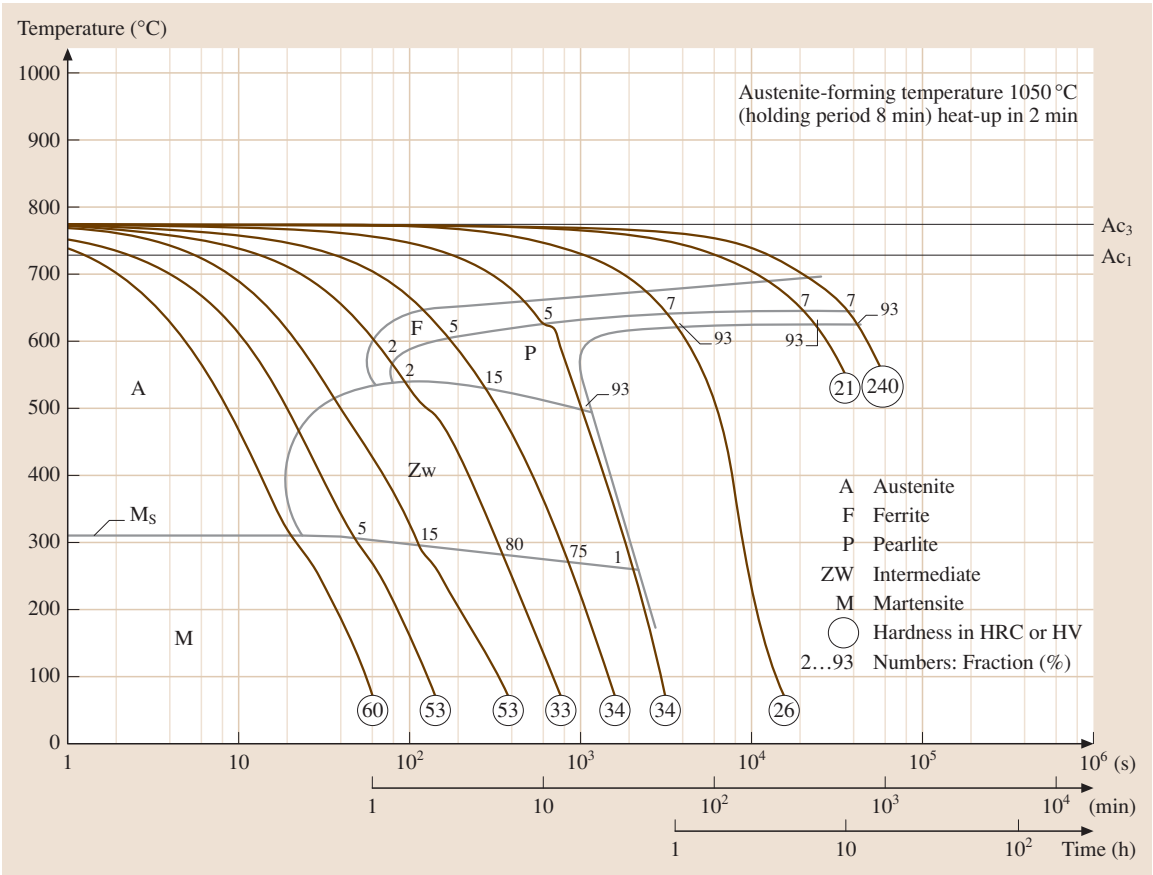

Fig. 3.134 Continuous-cooling-transition (CCT) diagram of 42MnV7

hardness values of the resulting microstructure at room temperature.

Hardening. The basis of hardening is the mechanism of martensitic transformation, which comprises a massive increase in material hardness. In the case of hypoeutectic steels austenitization is done above the A_3 line of the Fe−Fe_3C diagram; in the case of hypereutectic alloys annealing in the two-phase region γ-Fe + Fe_3C is usually sufficient. The distortion caused by the supersaturation of carbon in the α-ferrite increases with increasing carbon content. On the other hand, at least about 0.3% C are necessary to yield a significant increase in strength. The temperature to which the material has to be cooled from the austenite region (without any other nucleus formation to apply during cooling) to form martensite M_S (the *martensite start*) as well as the temperature where the whole microstructure consists of martensite M_f (the *martensite finish*) decrease with increasing carbon content (Fig. 3.135).

Therefore, hardening through the whole cross section of a workpiece with higher carbon content is only possible for low dimensions and the hardening depth can be increased by accelerated cooling or by alloying. The cooling media commonly used are oil, water, ice water or salt solutions. Alloying with Mn, Cr, Mo, and Ni in a concentration range of 1–3% can improve the through hardening capability of the steel. Thermal stresses caused by high temperature gradients superimpose onto transformation-induced stresses and can lead to hardening cracks. The crack sensibility can be reduced by warm-bath hardening, in which a temperature-balancing step above the M_S temperature is done before final quenching to martensite.

Tempering. To gain technically relevant properties, especially suitable toughness values, a final heat treatment

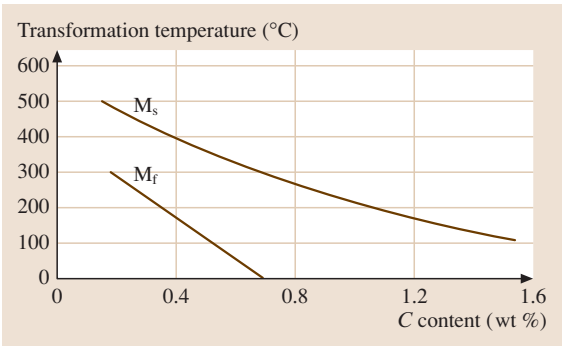

Fig. 3.135 Dependence of the martensite transformation temperatures on the carbon content (after [3.1])

after the hardening process step is required. This tempering step is done below the A_1 line and serves to reduce the brittleness of martensite by means of outdiffusion of carbon from the distorted ferrite lattice. In the temperature range up to about 300 °C, diffusion of carbon leads to a decrease of the lattice distortion which reduces the brittleness but does not lead to a significant change of the strength. This is assured by the formation of small metastable ε-carbides, and the disintegration of residual austenite. Tempering above 300 °C leads to disintegration of the remaining martensite into the formation of ferrite with finely distributed spherical cementite while the ε-carbide transforms to cementite as well. Consequently, the strength is lowered significantly and the toughness increases considerably. Tempering above 450 °C yields a homogeneous, fine-grained microstructure with high toughness and strength, as desired for many structural parts.

In the case of alloyed steels containing Mo, W, and/or V, i. e., tool steels or heat-resistant steels, tempering at temperatures between 450 and 600 °C leads to the formation of small, homogenously distributed carbide precipitates which counteract the strength decrease during annealing (so-called secondary hardening).

Selective Hardening. In many practical applications such as crankshafts, spigots, rolls or gears, high hardness and wear resistance may be required at the surface but at the same time high fracture toughness of the bulk part is required in order not to trade off fatigue strength. Therefore, for these applications, hardening is done only in the near-surface areas of a workpiece. Steels that are suitable for this treatment are plain carbon steels and low-alloy steels with carbon content of 0.3–0.7%. The following treatments are commonly used for direct hardening:

1. Flame hardening, in which the surface of the workpiece is heated to the austenitizing temperature with a gaseous oxygen flame
2. Induction heating, in which a high-frequency coil is used to heat the material surface utilizing the skin effect
3. Beam hardening (electron and laser beam), by which small areas of workpieces can be treated selectively
4. Dip hardening, which is especially suitable for pieces with curved surfaces for which other treatments would be too costly

In the case of steels with less than about 0.25% C the surface has to be enriched in carbon prior to hardening and the workpiece is heated to temperatures between 850 and 950 °C in a carbon-rich atmosphere. It has to be kept in mind that the enriched (up to 0.9% C) surface shows a lower transition temperature then the core with a lower carbon content. Therefore, hardening can be done either from the transition temperature of the core or of the surface. If only the surface region is austenitized, the core is not completely transformed to γ-Fe. This can lead to significant grain growth, and lower toughness values are expected. If, however, the core is fully austenitized, a fine-grained core with significantly higher toughness results after hardening. After surface hardening a tempering treatment at 150–250 °C is usually done.

Nitriding. Nitriding is a thermochemical treatment of steels. The surface area of steels is enriched in nitrogen (usually in an ammonia atmosphere). Nitriding is carried out at relatively low temperatures (495–565 °C) and no quenching is required after the process. Hence, this process leads to relatively little distortion but produces, on the other hand, a relatively shallow case (0.2–0.3 mm). In contrast to carbon-enriched surface layers, nitride layers provide significantly higher temperature resistance (up to 500 °C).

Steel Grades

Effect of Alloying Elements. Besides carbon as the main alloying element, steels generally contain further alloying additions [3.126]. A semantic distinction can be made between:

1. Residual elements, which are not intentionally added to the steel, but result from raw materials and steel-making practices
2. Alloying elements, which are added to cause changes in the properties of steels

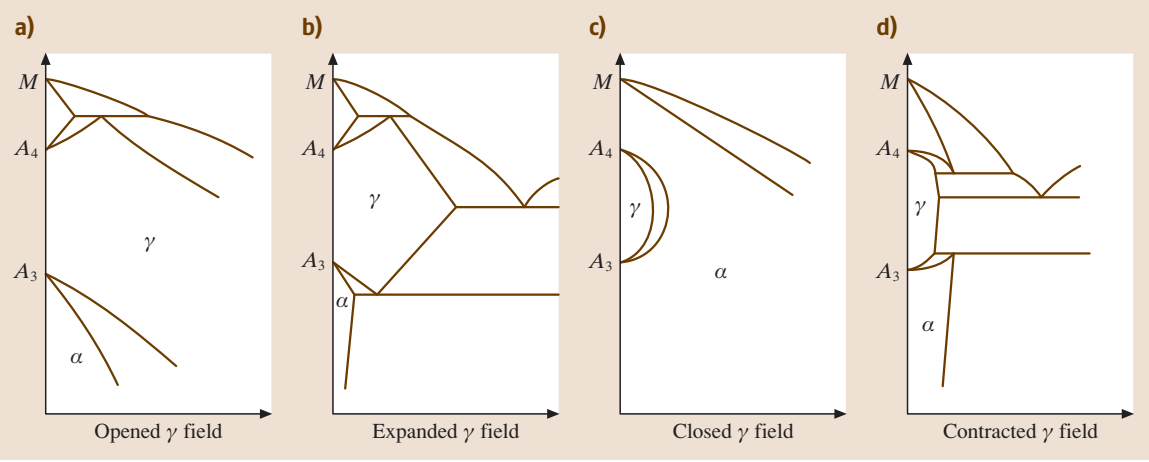

Fig. 3.136a–d Classification of iron alloy phase diagrams: **(a)** opened γ-phase field, **(b)** expanded γ-phase field, **(c)** closed γ-phase field, and **(d)** contracted γ-phase field (after [3.118])

To the residual elements in (1) belong predominantly phosphorus, sulfur, oxygen, hydrogen, manganese, and silicon. Phosphorus, sulfur, oxygen, and hydrogen are usually undesired, because they reduce ductility and toughness. Their content has to be reduced to a harmless level by secondary metallurgy. The only exception is the group of free-machining steels, where sulfur or phosphorus may be added deliberately to improve machinability. The effect of alloying elements of the group (2) can be separated into four different fundamental mechanisms:

a) Change of the phase equilibria in the Fe−C phase diagram
b) Solid solution hardening of elements such as Mn, Si, Ni, Co, Cu, and Al in Fe
c) Formation of carbides
d) Influencing the composition of oxides at surface

Alloying elements can influence the equilibrium diagram in two principal ways:

- By expanding (or opening) the γ-phase field and therefore facilitating the formation of austenite over a wider compositional range. These elements are referred to as γ-stabilizers (Fig. 3.136a,b).
- By contracting (or closing) the γ-phase field, which encourages formation of ferrite over a wider compositional range; these elements are termed α-stabilizers (Fig. 3.136c,d).

Consequently, elements such as Mn and Ni, which open the γ-phase field lead to a decrease of the eutectoid temperature, which facilitates hardening; others such as Ti and Mo lead to an increase of the eutectoid temperature (compare Fig. 3.137). However, most of the alloying elements in steels have in common that they help to decrease the carbon concentration in the eutectoid that provides better hardenability for low-carbon steel grades.

Alloying elements can be separated according to their impact on the iron–carbon phase diagram into four groups [3.118]:

- *Class 1*. These elements open the γ-phase field. To this group belong the most important alloying additions in steels: *manganese* and *nickel*. Cobalt and the inert metals ruthenium, rhodium, palladium, osmium, iridium, and platinum show a similar behavior. With a sufficient amount of nickel or manganese the formation of α-Fe under normal cooling conditions can be suppressed down to room temperature, allowing the formation of austenitic steels. At least 0.3% *manganese* is present in all commercial steel grades. It serves primarily to deoxidize the melt and counteracts the harmful influence of iron sulfide by the formation of manganese sulfide stringers. Excess content of manganese can partly dissolve in the iron lattice, leading to the mentioned solid-solution hardening effect and partly form Mn_3C. Through the opening of the γ-phase field the critical cooling rate is considerably decreased, allowing better hardenability of the steel. With increasing Mn content the amount of C in the steel can be reduced while retaining a constant strength level, which finally leads to improved ductility. The hot working capability is improved

at a Mn content of up to 2% since it reduces the susceptibility to hot shortness. However, if the manganese content is increased above 1.8% the steel tends to become air-hardened with resulting impairment of the ductility. Between 5 and 12% Mn the steel becomes martensitic even after slow cooling. At Mn contents above 12% and high C contents the austenite phase retains down to room temperature. Under impact loading such steels can be strongly cold worked at the surface while the core remains ductile.

In contrast to manganese *nickel* does not form any carbon compounds in steels. Up to a content of about 0.5% it is primarily an efficient ferrite strengthener. This is additionally intensified by a refinement of the pearlite lamellae. As in the case of manganese, with increasing Ni content and hence decreasing transition temperature, hardenability is improved (Fig. 3.138). The sudden drop in Ar_1 temperature at 8–10% nickel encourages the formation of martensite, while above 24% Ni this transformation is depressed below room temperature. As shown in the lower part of Fig. 3.138 the mechanical properties behave accordingly: while steels with more than 10% nickel have a high tensile strength the elongation drops from about 20% at nickel contents below 8% to about 10% in the martensitic region. Above 24% Ni and thus stabilization of austenite at room temperature, the tensile strength decreases and the material becomes ductile, tough, and workable. The effect of increasing Ni and C contents on the microstructure is shown in the *Guillet* diagram for a constant cooling rate in Fig. 3.138. Steels with high nickel content also show a low CTE. The so-called *Invar* alloy, containing 36% nickel, 0.2% carbon, and 0.5% manganese, has a thermal expansion coefficient which is nearly zero over the temperature range 0–100 °C. These alloys are therefore used in clocks, tapes, and wire measurements.

- *Class 2*. These elements expand the γ-phase field. The most important elements belonging to this group are carbon and nitrogen. *Copper*, zinc, and

gold show a similar effect. Cu in amounts exceeding 0.2% is beneficial to atmospheric corrosion resistance for carbon and low-alloy steels. Those steels are referred to as weathering steels and are used in the building industry. Furthermore, copper increases the yield strength and, at a content of more than 0.3%, age hardening is possible. However, copper exaggerates surface defects (grain boundaries), leading to a high surface sensitivity during hot rolling. It is therefore sometimes regarded as a *steel pester*.

- *Class 3*. These elements close the γ-phase field. Elements which restrict the formation of γ-Fe to a small area appearing like a loop include *silicon*, *aluminum*, beryllium, phosphor as well as the carbide-forming elements *titanium*, vanadium, molybdenum, tungsten, and *chromium*. In other words there are more elements which encourage the formation of bcc iron. Note that the normal heat treatment processes which are based on a $\gamma - \alpha$ transformation are no longer available.

When adding *chromium* to steel, most often its capability to increase the resistance to corrosion and oxidation is considered. However, chromium also improves the hardenability by decreasing the critical hardening rate. Furthermore, it raises the high-temperature strength and improves abrasion resistance in high-carbon compositions through carbide formation. Since the carbides are stable at high temperatures the solution anneal temperature has to be increased. In combination with nickel, chromium stabilizes austenite and a steel that superimposes the positive properties of chromium, i. e., high hardness and resistance to wear, and those of nickel, i. e., high strength, ductility, and toughness, is created. The effect of tempering a nickel–chromium steel on the room-temperature mechanical properties is shown in Fig. 3.139. Note that there is a distinct minimum in the Izod impact curve in the temperature range 250–450 °C, known as embattlement. This is caused by the grain boundary enrichment with alloying elements such as Mn and Cr during austenitization, which leads to enhanced segregation of embattling elements such as P, Sn, Sb, and As on slow cooling from 600 °C. This could be prevented by increasing the cooling rate during hardening. However, as shown in Fig. 3.139, Izod (2) addition of *molybdenum* significantly reduces the tempering embrittlement at intermediate temperatures and increases the high-temperature tensile

and creep strength of the steel. Ni–Cr–Mo steels are therefore widely used for ordnance and turbine rotors.

Aluminum, *silicon*, and *titanium* are commonly used as deoxidizers. Furthermore, aluminum and titanium can limit grain growth when added to steel in specific amounts. This is of vital for preventing grain coarsening during solution annealing prior to hardening. Titanium is, however, one of the strongest carbide formers (Fig. 3.140) and, since its

carbides are quite stable, they may not dissolve in austenite and can therefore have adverse effects on hardenability. It is used as a stabilizer in corrosion-resistant steels.

- *Class 4*. These elements contract the γ-phase field. This is observed when carbide-forming elements such as tantalum, niobium, and zirconium are present. Boron also belongs to this class of alloying additions. *Zirconium* is primary used in so-called high-strength low-alloy (HSLA) steels to improve their hot-rolling properties.

Classification and Designations. A variety of steel classification systems are in use; they subdivide, for example, with regard to chemical composition, application area, required strength level, microstructure, manufacturing methods, finishing method or the product form (a comprehensive comparison of steels standards is given in [3.127, 128]). Chemical composition is, however, by far the most widely used basis for classification and/or designation of steels. The most commonly used system of designation is those of the American Iron and Steel Institute (AISI) and the Society of Automotive Engineers (SAE), which are based upon a four- or five-digit number, where the first two digits refer to the main alloying elements and the latter two or three digits give the carbon content in wt. %.

The designation 1020 according SEA–AISI is used, for example, for a carbon steel with nominally 0.2 wt. % C, and the steel 10120 according to SEA–AISI contains 1.2 wt. % C. The various grades of carbon and alloy steels are given in Table 3.15.

The unified numbering system (UNS) for metals and alloys is being used with increasing frequency. It has been developed by ASTM and SAE and other technical societies, trade associations, individual users and producers of metals and alloys, and US government agencies. The system helps to avoid confusion, preventing the use of more than one identification number for the same metal or alloy. Each UNS designation consists of a single-letter prefix followed by five digits. The prefix usually indicates the family class of metals: for example, T for tool steel, S for stainless steel, and F for cast irons, while G is used for carbon and alloy steels. Existing designation systems, such as the AISI–SAE system were incorporated into the UNS system wherever feasible. More information on the UNS system and an in-depth description can be found in SAE J1086 and ASTM E 527. Table 3.16 gives an overview of the main groups of UNS designations for iron-based materials.

The American Society for Testing and Materials (ASTM) standard contains full specifications of specific products, such as A 574 for alloy steel socket-head cap screws, and is oriented towards the performance of the fabricated end product. Theses commonly used steels are not initially included in the SAE–AISI designations.

From a user's viewpoint steels may generally be divided into two main categories, namely *standard steels* and *tool steels*. It is useful to further subdivide *standard steels* according to their chemical composition into three major groups:

1. Carbon steels
2. Alloy steels
3. Stainless steels

Carbon Steels. Carbon steels contain less than 1.65% manganese, 0.6% silicon, and 0.6% copper. According to the SAE standard J142 *General Characteristics and Heat Treatments of Steels* plain carbon steels of the 10xx and 15xx series in Table 3.15 are divided into four groups [3.125]:

- Group I steels with a carbon content of less than 0.15% provide enhanced cold formability and drawability. These steels are therefore used as cold-rolled sheets in automobile panels and appliances and are suitable for welding and brazing. It should however be noted that these alloys are susceptible to grain growth upon annealing after cold working and, as a consequence, exhibit a tendency to embrittlement (strain age-embrittlement).
- Group II steels with carbon contents of 0.15–0.3% show increased strength and hardness and are less suitable for cold forming. The steels are applicable for carburizing or case hardening. As shown above, increasing manganese content supports the hardenability of the core and case, and intermediate manganese levels (0.6–1.0%) are preferential for machining. Carburized plain carbon steels are used for parts which require a hard wear-resistant surface and a *soft* core, for example, small shafts, plungers, and lightly loaded gears.
- Group III steels with medium carbon content of 0.3% to nearly 0.55% can be directly hardened by induction or flame hardening or by cold working. These steels are found in automotive applications and can be used for forgings and for parts which are machined from bar stock.
- Group IV steels with high carbon levels of 0.55% to nearly 1.0% offer improved wear characteristics and high yield strengths and are generally heat treated before use. Since cold-forming methods are not practical for this group of alloys, application parts such as flat stampings and springs are coiled from small-diameter wire. With their good wearing

properties typical applications are found in the farm implement industry as plow beams, plow shares, scraper blades, discs, mower knives, and harrow teeth.

The so-called *free-machining grades* are either resulferized (group 11xx steels) or resulferized and rephosphorized carbon steels (group 12xx). These additives enhance their machining characteristics and lower machining costs.

Chemical compositions as well as the mechanical properties of some carbon steels are given in Table 3.17.

Alloy Steels. Alloy steels constitute a category of ferrous metals that exceed the element limits for carbon steels. They contain elements not found in carbon steels such as nickel, molybdenum, chromium (up to 3.99%), cobalt, etc.. The primary function of the alloying elements is to increase the hardenability and to optimize the mechanical properties such as toughness after the final heat treatment. Table 3.18 summarizes the mechanical properties of selected alloy steels in the normalized, annealed, and quenched-and-tempered condition. In the following the alloy steels are divided into five major groups according to their application area [3.125].

Structural steels according to the SAE–AISI system include *carburized steel grades*, *through-hardening grades*, and *nitriding grades*.

Carburizing grades with low alloying combinations such as SAE–AISI 4023 or 4118 have better core properties than plain carbon steels and are hardenable in oil in small cross-sections, resulting in less distortion compared with water-quenched alloys. These alloys are applied as cam shafts, wrist pins, clutch fingers, and other automotive parts. For applications requiring higher core and case hardness such as for automotive gears, universal joints, small hand tools, piston pins, bearings, etc. higher-alloy carburizing steels such as Ni−Mo (SAE–AISI 4620), plain Cr (SAE–AISI 5120) or Ni−Cr−Mo (SAE–AISI 8620) steels are used. Aircraft engine parts, truck transmissions and differentials, rotary rock-bit cutters, and large antifriction bearings are made from high-alloy steels as SAE–AISI 4820 and 9310.

Through-hardening grades in principle contain higher carbon levels than carburized grades. In this group the lower-alloy steels are used for applications

in small sections or in larger sections that may not have optimal properties but allow weight savings due to the higher strength of the alloys. Typical examples are manganese steels (SAE–AISI 1330–45), which are used for high-strength bolts, molybdenum steels (SAE–AISI 4037–4047), and chromium steels (SAE–AISI 5130–50), which are used for automotive steering parts, and low-Ni−Cr−Mo steels (SAE–AISI 8630–50), which are used for small machinery axles and shafts. Heavy aircraft or truck parts or ordnance materials require higher-alloy structural steels, such as SAE–AISI 3430 or 86B45. There are several constructional alloy steels which are used for specialized applications; for example, SAE–AISI 52100 steels are used almost exclusively for ball-bearing applications and the chromium steels SAE–AISI 5150 and 5160 were developed for spring steel applications.

Steels that belong to the *nitriding grades* are in most cases either medium-carbon and chromium-containing low-alloy steels, which are covered by the SAE–AISI (for example, 4100, 4300, 5100, 6100, 8600, 9300, and 9800 group) or Al-containing (up to 1%) low-alloy steels, which are not described by SAE–AISI designations but have simple names such as "Nitralloy". Typical applications for nitride grades include gears designed for low contact stresses, spindles, seal rings, and pins.

Low-carbon quenched-and-tempered steels typically contain less than 0.25% C and less than 5% alloy additions. Economical points of view have driven the

yield strengths (approximately 340–900 MPa). In addition, they have two to six times higher corrosion resistance than that of plain carbon steels. Depending on the final treatment these steels could be either martensitic, bainitic, and, in some compositions, ferritic. These steels are not covered by SAE–AISI designations but most of them can, however, be find in ASTM specifications such as A514, A517, and A543. Thanks to the high strength and toughness values these steels can be applied at lower final costs than plain carbon steels, which leads to a wide variety of applications. They are used as major members of large steel constructions, pressure valves, earth-moving, and mining equipment.

Ultrahigh-strength steels are a group of alloy steels with yield strengths in excess of 1300 MPa; some have plain-strain fracture toughness levels exceeding 100 MPa$\sqrt{\text{m}}$. Some of these steels are included in the SAE–AISI designation system and have medium carbon contents with low-alloy additions. Examples are steels in the SAE–AISI 4130 series, the higher-strength 4140, and the deeper hardening higher-strength 4340 steels. Starting form the 4340 alloy series numerous modifications have been developed. Addition of silicon, for example, reduces the sensitivity to embrittlement on tempering at low temperatures (required to keep high strength levels). Addition of vanadium leads to grain refinement, which improves the strength and toughness of the material. Medium-carbon alloys can be welded in the annealed or normalized condition, requiring a further heat treatment to retrieve the desired strength. If high fracture toughness as well as high strength is specifically desired, as for aircraft structural components, pressure vessels, rotor shafts for metal-forming equipment, drop hammer rods, and high-strength shock-absorbing automotive parts, high nickel (7–10.5%) and Co (4.25–14.50%) contents are used as primary alloying elements. While offering a plane-strain fracture toughness of 100 MPa$\sqrt{\text{m}}$ the HP-9-4-30 steel can have a tensile strength as high as 1650 MPa. Furthermore, the steel can be hardened to martensite in sections up to 150 mm thick. The AF 1410 steel (developed by the US Air Force) has an ultimate tensile strength (UTS) of 1615 MPa and a K_{IC} value of 154 MPa$\sqrt{\text{m}}$.

The group of *alloy steels for elevated- or low-temperature applications* includes two different alloying systems. For high-temperature applications chromium–molybdenum steels offer a good combination of oxidation and corrosion resistance (provided by

the chromium content of up to 9%) on the one hand and high strength at elevated temperatures (provided by the molybdenum content of 0.5–1.0%) on the other. These steels can be applied at temperatures up to 650 °C for pressure vessels and piping in the oil and gas industries and in fossil-fuel and nuclear power plants. In low-temperature service applications such as storage tanks for liquid hydrocarbon gases and structures and machinery design for use in cold regions, ferritic steels with high nickel content (approximately 2–9%) are typically used.

Another important category of alloy steels are the *high-strength low-alloy steels* (HSLA). HSLA steels, or microalloyed steels, are designed to meet specific mechanical properties rather than a chemical composition. So the chemical composition can vary for different end-product thicknesses with still retaining specific mechanical properties. The low carbon content of these steels (0.05–0.25%) allows good formability and excellent weldability. Further alloying elements are added to meet the application requirements (Table 3.19), resulting in a division into six categories, as follows:

- Weathering steels, where small amounts of copper and phosphorous are added to improve atmospheric corrosion resistance
- Microalloyed ferritic–pearlitic steels, with small amounts (less than 0.1%) of carbide-forming elements such as niobium, vanadium or titanium which enable precipitation strengthening and grain refinement
- As-rolled pearlitic steels, with high strength, toughness, formability, and weldability, which have carbon, manganese, and further additions
- Acicular ferrite (low-carbon bainite) steels (less than 0.08% C), which offer an excellent combination of high yield strength, weldability, formability, and good toughness
- Dual-phase steels, with martensitic portions finely dispersed in a ferritic matrix. These steels have high tensile strength and sufficient toughness
- Inclusion-shape-controlled steels, in which the shape of sulfide is changed from elongated stringers to small, dispersed, near-spherical globules to improve ductility and toughness; elements which are suitable are, e.g., Ca, Zr, and Ti

The allocation to a specific group is not rigorous; many of these steels have properties which would also allow allocation to other groups mentioned.

Stainless steels. Stainless steels in general contain at least 12% chromium, which forms a thin protection layer at the surface (Cr−Fe−oxide) when exposed to air [3.129]. As shown above, chromium stabilizes the ferrite to remain stable up to the melting point, presuming, however, a low carbon content. Stainless steels can be differentiated depending on their crystal structure or the acting strengthening mechanisms according to Table 3.20. Ferritic stainless steels are relatively inexpensive and contain as much as 30% chromium with typically less than 0.12% C. They show good strength and intermediate ductility. Martensitic stainless steels typically contain less than 17% chromium to contract the austenitic region not too strongly but have a higher C content of up to 1.0%. These alloys are used for high-quality knifes, ball bearings or fittings.

Austenitic stainless steels are formed by the addition of nickel, offer high ductility, and are intrinsically not ferromagnetic. These alloys are well suited for high-temperature applications because of their high creep resistance and, thanks to their high toughness at low temperatures, for cryogenic service as well.

Precipitation-strengthened stainless steels contain additions such as Al, Nb or Ta, which form precipitates such as Ni_3Al during heat treatment and can have very high strength levels.

Stainless steels with duplex microstructure consist of about 50% ferrite and austenite each. They show an ideal combination of strength, toughness, corrosion resistance, formability, and weldability, which no other stainless steel can supply.

Tool steels. *Tool steels* are made to meet special quality requirements, primarily due to their use in manufacturing processes as well as for machining metals, woods, and plastics [3.130]. Some examples are cutting tools, dies for casting or forming, and gages for dimensional tolerance measurements. Tool steels are very clean ingot-cast wrought products with medium (minimum 0.35%) to high carbon content and high alloy (up to 25%) contents, making them extremely expensive. They must withstand temperatures up to 600 °C and should in addition have the following properties:

- Generally a high hardness to resist deformation.
- Resistance to wear for economical tool life, which depends directly on hardness; this can be increased by alloying with carbide-forming elements such as W and Cr.
- Dimensional stability. Dimensional changes of tools can be caused by microstructural alteration, by

exceeding the elastic limit, by transformation of the remaining austenite, and by changes of the grain dimensions. The highest dimensional stability is exhibited by ledeburitic cut steels with 12% chromium, which are used for precise cutting and punch tools.

- Working capability. In order to guarantee fault-free operation tools must have a certain working capability, meaning that they should be able to collect elastic distortion energy to a certain degree. Therefore, steels with high toughness and at the same time high yield strength are required.
- Through hardening. The through hardening capability can be improved by alloying with carbide formers which additionally increase wear resistance: Cr, Mo, and Mn.

Tool steels may be categorized into five principal groups; compositions and application examples are given in Table 3.21:

1. Cold-work tool steels, which include the oil-hardening O alloys, the water-hardening W alloys, the high-chromium class D (stainless steel), and the medium-alloy air-hardening class A alloys. Water-hardening grades have high resistance to surface wear but are not suited for high-temperature applications.
2. Shock-resistant tool steels in the S group of alloys, which are the toughest of the tool steels due to the presence of only 0.5% C and low-alloying additions.
3. Hot-work tool steels are class H alloys and include chromium, tungsten, and molybdenum alloys.
4. High-speed steels are either tungsten (T class) or molybdenum (M class) alloys. They have a high hardness of 62–67 HRC and maintain this hardness at service temperatures as high as 550 °C.
5. Special-purpose tool steels are low-alloy (L) or mold tool steels (P).

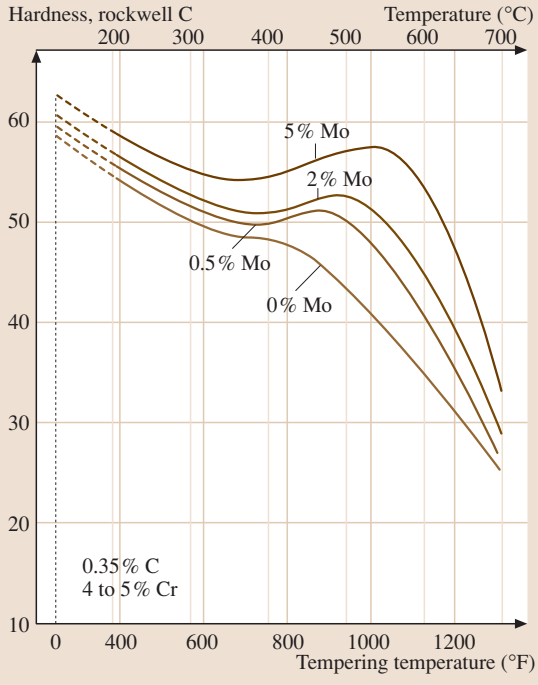

Fig. 3.141 Influence of molybdenum content on the occurrence of a secondary hardening maximum during tempering (after [3.131])

From the compositions given in Table 3.21 it is obvious that the main alloying elements in tool steels are:

1. Chromium to increase hardenability and, if alloyed in excess, forms $Cr_{23}C_6$ for high wear resistance
2. Molybdenum and tungsten, which are strong hard carbide formers $(Mo\text{-}W)_6C$ that can be dissolved in austenite, and precipitate as fine particles in martensite upon annealing (secondary hardening, see Fig. 3.141). Furthermore, they resist growth at low red temperatures.
3. Vanadium, which forms the hardest carbide V_4C_3, and which resists solution in austenite and remains unchanged through heat-treatment cycles.

Steel Castings and Cast Iron

Steel castings and cast iron are preferable for the manufacture of complex geometries at relatively low costs because expensive reworking steps are not necessary or only a few process steps are required to reach the final product [3.132]. Against this advantage there are two important restrictions, namely:

1. The appearance of cast defects and, in conjunction
2. Inferior mechanical properties compared with components prepared by deformation

Iron-carbon cast materials can be roughly divided according to their carbon content into:

1. Steel castings ($C < 2\%$)
2. Cast iron ($C > 2\%$)

Steel castings have a better combination of high strength and ductility compared with cast iron. However, because of their high melting point and strong shrinkage (about 2%) upon cooling the castability of steel castings is poor and the affinity of forming cavities is more pro-

nounced. Therefore, steel castings are only used when high strength and toughness are a must, as in the case of permanent magnet castings and manganese hard castings. A far more broad application spectrum exists for cast irons, which are concentrated on in the following. Cast iron is a very cost-efficient constructional material. The precipitation of carbon (as graphite) during solidification counteracts the normal shrinkage of the solidified metal.

Classification of Cast Iron. Cast irons solidify by the eutectic reaction and are generally ternary alloys of Fe with 2–4% C and 0.5–3% Si. With increasing contents of C and Si and decreasing cooling rate the formation of the stable graphite instead of the unstable cementite is favored. Furthermore, high carbon content and silicon give cast irons excellent castability with melting points appreciably lower than those of steel. Pattern-making is no longer a necessary step in manufacturing cast-iron parts. Many gray, ductile, and alloy-iron components can be machined directly from bars that are continuously cast to near-net shape. Not only does this *parts without patterns* method save the time and expense of pattern-making, but continuous-cast iron also provides a uniformly dense, fine-grained structure, essentially free from porosity, sand, or other inclusions. Cast irons are usually not classified according to their chemical composition. The microstructure of the final product depends strongly upon foundry practice and the shape and size of the castings, which influence the cooling rate; so several entirely different types of iron may be produced starting with the same nominal composition. Thus, cast irons are usually specified by their mechanical properties. A principal classification can be made concerning their microstructure, which depends on the casting conditions:

1. Gray cast iron
2. Ductile cast iron
3. White cast iron
4. Compacted graphite iron
5. Malleable cast iron
6. High-alloy cast irons

Gray cast iron is formed when excess carbon graphitizes during solidification to form separate graphite flakes. The resulting microstructure depends on the cooling rate from the eutectoid temperature downwards (region II in Fig. 3.142). If cooling is fast, pearlite (α-Fe + Fe_3C) is formed from the γ-Fe. If the cooling rate is slow ferrite is formed during transformation and

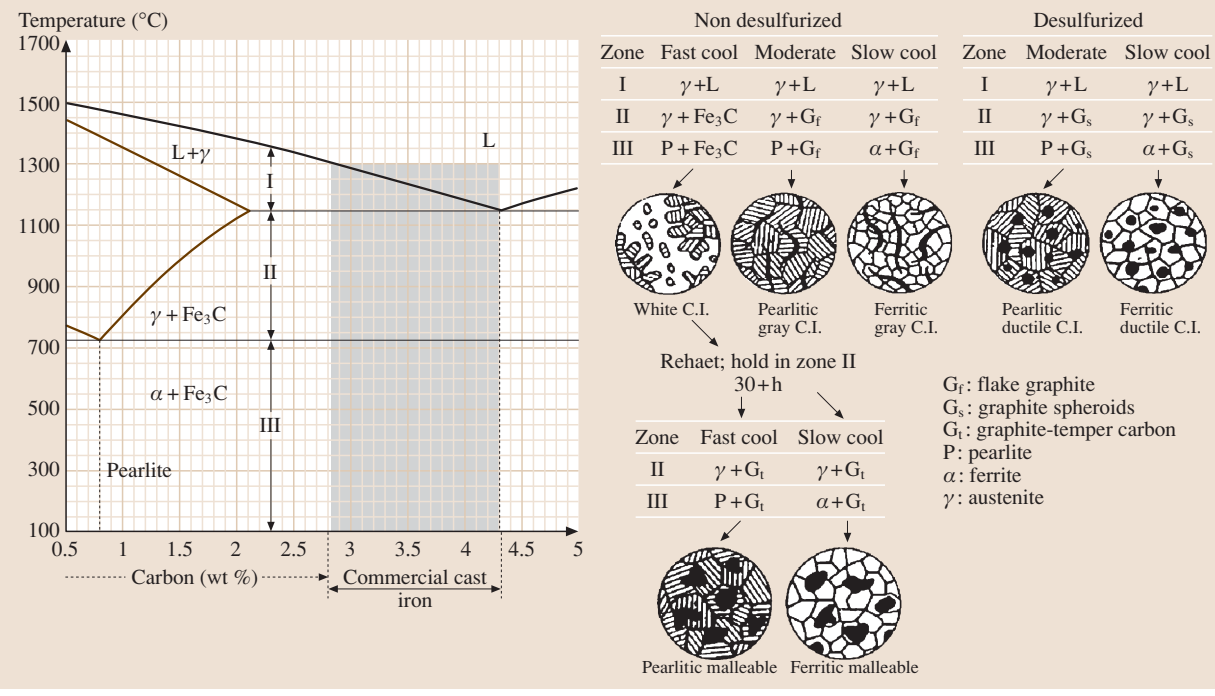

Fig. 3.142 The influence of the casting conditions on the resulting microstructure of cast irons (after [3.133])

Table 3.22 Mechanical properties of forged steel, pearlitic ductile iron, and ADI [3.134]

Mechanical property	Material

Impact strength (ft-lb) (J)	130	40	120

the material has a lower strength compared with the pearlitic gray cast iron. Depending on the cooling rate a mixture of ferrite (surrounding the graphite flakes) and pearlite may be formed as well. The flake-type shape of the graphite in gray cast iron leads to generally brittle behavior. Furthermore, the impact strength of gray cast iron is low and it does not have a distinct yield point. On the other hand, excellent damping against vibrations, excellent wear resistance, and acceptable fatigue resistance are desirable properties of gray cast iron. Typical applications are engine blocks, gears, flywheels, brake discs and drums, and machine bases.

In *ductile iron* the form of the graphite is nodular or spheroidal instead of flake type. This is achieved by the addition of trace amounts of Mg and/or Ce which react with sulfur and oxygen. However, in ductile iron the impurity level has to be controlled more precisely than in gray cast iron since it affects nodule formation. Ductile cast iron exhibits improved stiffness and shock resistance. It has good machinability and fatigue strength as well as high modulus of elasticity, yield strength, wear resistance, and ductility. Damping capacity and thermal conductivity are lower than in gray iron. By weight, ductile gray iron castings are more expensive than gray iron. Ductile iron is used in applications such as valve and pump bodies, crankshafts, in heavy-duty gears or automobile door hinges, and nowadays with increasing frequency also as engine blocks.

Austempered ductile cast iron (ADI) is a subgroup of the ductile iron family but could be treated as a separate class of engineering materials. In contrast to the former, the matrix of this spheroidal graphite cast iron is bainitic (not pearlitic). This microstructure is obtained by isothermal transformation of austenite at temperatures below that at which pearlite forms. In terms of properties, the bainitic matrix has almost twice the strength of pearlitic ductile iron while retaining high elongation and toughness. While exhibiting superior wear resistance and fatigue strength the castability of ADI is not very different from that of other ductile irons, but heat treatment is a critical issue to fully exploit its beneficial properties. For example, the yield strength of ADI is more than three times that of the best cast or forged aluminum. In addition ADI castings weigh only 2.4 times more than Al alloys and are 2.3 times stiffer. ADI is also 10% less dense than steel. Furthermore, for a typical component, ADI costs 20% less per unit weight than steel and half that of Al. A comparison of forged steel, pearlitic ductile iron, and ADI is shown in Table 3.22.

White cast irons are formed trough fast cooling and consist of Fe_3C and pearlite. The origin of this designation is the white-appearing crystalline fracture surface. While having an excellent wear resistance and high compressive strength the principal disadvantage of white cast iron is its catastrophic brittleness. Therefore in most applications white cast iron is only formed on the surface of cast parts, while the core consists of either grey cast iron or ductile iron. Examples of the application of white cast iron are mill liners and shot-blasting nozzles as well as railroad brake shoes, rolling-mill rolls, and clay-mixing and brick-making equipment, crushers, and pulverizers.

Compacted graphite iron (CGI), also known as vermicular iron, can be considered as an intermediate between gray and ductile iron, and possesses many of the favorable properties of each. CGI is difficult to produce successfully on a commercial scale because the alloy additions must be kept within very tight limits. The advantages of CGI compared with gray cast iron are its higher fatigue resistance and ductility, which are at the same level as those of ductile iron. Machinability, however, is superior to that of ductile iron and its damping capacity is almost as good as that of gray iron. This combination and the high thermal conductivity of CGI suggest applications in engine blocks, brake drums, and exhaust manifolds of vehicles.

Malleable iron is white iron that has been converted by a two-stage heat treatment to a condition in which most of its carbon content is in the form of irregularly shaped nodules of graphite, called temper carbon. In contrast to white iron it is malleable

and easily machined. The matrix of malleable cast iron could be ferritic, pearlitic, or martensitic. Ferritic grades are more machinable and ductile, whereas the pearlitic grades are stronger and harder. Malleable-iron castings are often used for heavy-duty bearing surfaces in automobiles, trucks, railroad rolling stock, and farm and construction machinery. The applications are, however, limited to relatively thin-sectioned castings because of the high shrinkage rate and the need for rapid cooling to produce white iron.

High-alloy irons are ductile, gray, or white irons that contain 3% to more than 30% alloy content. Properties achieved by specialized foundries are significantly different from those of unalloyed irons. These irons are usually specified by chemical composition as well as by various mechanical properties. White high-alloy irons containing nickel and chromium develop a microstructure with a martensitic matrix around primary chromium carbides. This structure provides high hardness with extreme wear and abrasion resistance. High-chromium irons (typically, about 16%) combine wear and oxidation resistance with toughness. Irons containing 14–24% nickel are austenitic; they provide excellent corrosion resistance for nonmagnetic applications. The 35% nickel irons have an extremely low coefficient of thermal expansion and are also nonmagnetic and corrosion resistant.

3.7.2 Aluminum and Its Alloys

General Properties

Despite the ten times higher costs for the preparation of primary aluminum compared with that of pig iron, aluminum-based materials are today the second most widely used metallic materials. For structural applications in mechanical engineering their most important advantage is an excellent combination of intrinsically good corrosion and oxidation resistance and high specific strength (strength-to-density ratio; compare Table 3.13) when compared with stainless steels. However, with strength values as low as 45 MPa (1199-O), technically pure aluminum is very soft and requires the addition of alloying elements for most applications. In doing so the strength can be increased manyfold to almost 700 MPa (alloy 7055-T77). Because the specific stiffness (stiffness-to-density ratio) of aluminum alloys ($E \approx 70$ GPa) is comparable to that of steels ($E \approx 210$ GPa), components must have significantly larger dimensions (volume) in order to achieve a stiffness equal to that of their steel counterparts. However, various constructive arrangements, such as tabular or box-shaped hollow sections, locally strengthened rips, flanges welts, and coils, are known and can be used as an alternative to larger components. In contrast to steels Al does not exhibit an endurance limit in fatigue. Moreover, the low hardness of aluminum leads to generally poor wear resistance.

Further important properties, which contribute to the still growing application of aluminum and aluminum alloys, are their high electrical and heat conductivity as well as their good formability. Furthermore, the high chemical affinity of aluminum to oxygen leads to a very acceptable corrosion and oxidation resistance but causes at the same time the high production costs mentioned. To manufacture primary aluminum based on aluminum oxide a costly reduction (mostly smelting electrolytic reduction) is necessary. Bauxite with hydrated forms of aluminum oxide serves as the primary mineralogical source of alumina since its reduction is economically most efficient amongst the different types of aluminum ores.

Al alloys can be very well machined by chip removal, and additions of Pb can prevent the formation of long chips in the case of pure aluminum or soft Al alloys. Joining of Al-based components can be done by all common procedures. Fusion welding is predominantly done by inert gas welding. Adhesion joints are also gaining importance. Aluminum and its alloys do not show a sharp ductile-to-brittle transition temperature; rather they remain ductile even at very low temperatures. Comprehensive treatments of Al-based materials are given in [3.135–137].

Pure Aluminum

Commercial-purity aluminum, mainly manufactured by modified Hall–Héroult electrolysis, usually reaches a purity of 99.5–99.8%. On further electrolytic refinement (the three-layer method [3.135]) of commercially pure aluminum or secondary aluminum, superpurity aluminum (99.95–99.99%) can be prepared. Finally, for special purposes, aluminum can be further purified by zone melting to result in extreme purity aluminum of up to 99.99995%. Classification of pure aluminum is given in Table 3.23 of [3.135].

In the annealed condition aluminum possesses only low strength at room temperature. By cold deformation, however, it is possible to improve its strength significantly, whereas the elongation is reduced considerably (Fig. 3.143).

Traditionally, pure aluminum is used in wrought condition for electrical conductors (EC-aluminum). Further important applications of aluminum are as foils for the food processing industries and in packaging practice (alloy 1145), as case components, boxes in tool-building, in the building industry as well as claddings, and to improve resistance to corrosion with heat-treatable Al alloys.

Aluminum Alloys

The major alloying elements of aluminum are copper, manganese, magnesium, silicon, and zinc. Depending on the production route to its final form, aluminum alloys may in principle be divided into wrought alloys and cast alloys. The wrought alloys can be classified into two main groups:

1. Age-hardenable alloys
2. Non-age-hardenable alloys

The nomenclature used for wrought alloys consists of four digits 2xxx-8xxx where the last two digits are the alloy identifier (Table 3.24). The second digit indicates certain alloy modifications (0 stands for the original alloy). A second designation is usually used, and describes the final temper treatment (Table 3.25).

Aluminum responds readily to strengthening mechanisms (Sect. 3.1) such as age hardening, solution hardening, and strain hardening, resulting in 2–30 times higher strength compared with pure aluminum (Table 3.26). Age hardening is the most effective hardening mechanism. It is based on the fact that the solubility of certain elements increases on increasing temperature. In the case of Cu as the alloying element, maximum solubility is reached at about 550 °C (Fig. 3.144). For age hardening the material is solution annealed in the single-phase region, quenched to room or low temperature, and finally age hardened at higher temperatures (100–200 °C) to facilitate the formation of small precipitates. On further age hardening the precipitates continue to grow, resulting in overaging (Fig. 3.144), which is accompanied by a loss in material strength.

The strength increase $\Delta\sigma$ is inversely proportional to the separation distance l of the precipitates and is giving in the peak aged condition (Fig. 3.145) by $\Delta\sigma \sim 2Gb/l$ (G – shear modulus; b – Burger vector).

However, on further annealing the precipitates can grow by Ostwald ripening, i. e., small precipitates are consumed and larger particles grow continuously at their expense. This process results in severe strength decrease when the material is exposed to high temperatures during service (Fig. 3.146).

Depending on the alloying additions, different strengthening mechanisms are activated:

- 2xxx: Precipitation of Cu-rich phases allows the formation of high-strength alloys at the expense of weldability. Precipitation from the α-solid so-

lution appears in the following order: $\alpha_{ss} \rightarrow \alpha + GP-I \rightarrow \alpha + GP-II \rightarrow \alpha + \theta' \rightarrow \alpha + \theta$. As shown in Fig. 3.147 the highest strength is reached when coherent GP–II zones have been formed, where Orowan by-passing and precipitation cutting require almost the same amount of energy.

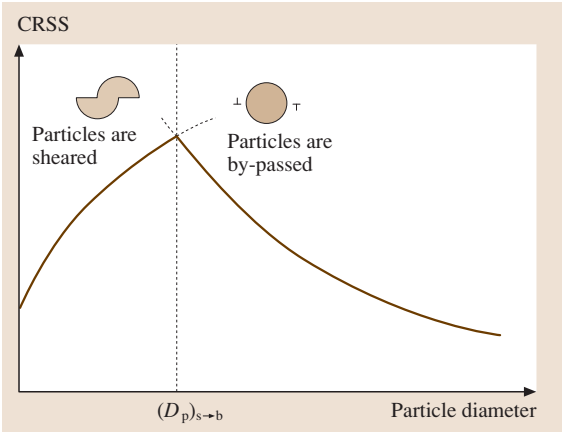

Fig. 3.145 Change in critical resolved shear stress (CRSS - at which dislocations glide freely in single crystals) as a function of particle (precipitate) size. Maximum strength is obtained where dislocation interaction changes from shearing to Orowan by-passing. In the peak aged condition the average particle size corresponds to D_p and particle size variation should be marginal (after [3.135])

- 3xxx: These alloys are single-phase alloys except for the presence of inclusions or intermetallic compounds. Their strength is achieved by solid solution of Mn and is not as high as for 2xxx alloys but they exhibit excellent corrosion and oxidation resistance and are weldable.
- 4xxx: The high strength of this group of wrought alloys is achieved via solid solution of Mg and in the case of the presence of Si by the formation of finely dispersed Mg_2Si particles as well.
- 5xxx: These alloys are strengthened by a solid solution of Mg and contain a second phase: Mg_2Al_3 particles, a hard and brittle intermetallic compound. The corrosion resistance of these alloys is almost comparable to that of pure Al.
- 6xxx: Alloys belonging to this group show a good balance of their properties. They are moderately heat treatable and show moderate corrosion resistance and weldability. $\alpha_{ss} \rightarrow \alpha + GP$ zones $\rightarrow \alpha + \beta\ (Mg_2Si) \rightarrow \alpha + \beta\ (Mg_2Si)$.
- 7xxx: The highest strength levels of commercial aluminum alloys are attained by the members of this group, which are strengthened by addition of Mg and Zn. The alloys are age hardenable by the formation of $MgZn_2$ particles in the following sequence: $\alpha_{ss} \rightarrow \alpha + GP$ zones $\rightarrow \alpha + \eta\ (MgZn_2) \rightarrow \alpha + \eta\ (MgZn_2)$. Most alloys of this group are not weldable. An exemption is the alloy 7005, which is used as a standard alloy for bike frames.

Mechanical properties and some typical applications of selected aluminum alloys are given in Table 3.27.

Cast aluminum alloys are developed to have good fluidity and feeding ability during casting. Their designation (Table 3.24) is based on three major digets 2xx-9xx, giving the alloy group, and a further digit following a dot, which indicates the material form (casting/ingot). The most widely used casting alloys belong to the 300 series (319 and 356), where hardening is done by Cu or Mg_2Si precipitation. Examples of casting alloys are giving in Table 3.28.

3.7.3 Magnesium and Its Alloys

General Properties

Magnesium is the lightest structural metal with a density close to that of polymers (plastics). It is therefore not surprising that Mg alloys are especially found in applications where the weight of a workpiece is of paramount importance, as generally is the case in the transportation industry. In recent years magnesium cast alloys have particularly becoming increasingly important and have partly replaced well-established Al-based alloys. The main reason is the excellent die-filling characteristics of magnesium, which allows large, thin-walled, and unusually complex castings to be produced economically. Magnesium can be cast with thinner walls (1–1.5 mm) than plastics (2–3 mm) or aluminum (2–2.5 mm) and, by designing appropriately located ribs, the stiffness disadvantage of magnesium versus aluminum can be compensated without increasing the wall thickness of an overall magnesium part.

Further positive properties to be noted are the excellent machinability, high thermal conductivity (Sect. 3.4), and the good weldability. However, Mg alloys suffer from poor corrosion resistance and the manufacturing costs are comparatively high. With its hexagonal close-packed crystal structure the room-temperature deformation behavior of Mg alloys is moderate, resulting in poor cold workability. Thus, all current applications are manufactured through casting. Furthermore, Mg is a very reactive metal and readily oxidizes when exposed to air. Since pure Mg is only of minor importance for structural applications it appears almost always in the alloyed condition with additions such as Al and Zn. A comprehensive treatment of Mg and its alloys is given in [3.141].

Magnesium Alloys

Major alloying elements of Mg are Al, Zn, and Mn, while elements such as Sn, Zr, Ce, Th, and B are occasionally of importance. Impurities in Mg alloys are commonly Cu, Fe, and Ni. Mg designation is based on the main alloying elements (such as AZ for aluminum and zinc) followed by the amount of additives and a letter that indicates the amount of variations with

respect to the normal alloy (Table 3.29). When referring to mechanical properties it is useful to indicate the temper treatment as well (Table 3.30). The alloy AZ91A, for example, is a Mg-based alloy with nominally about 9% Al and 1% Zn, while the letter A indicates that only minor changes to the normal alloy were carried out.

An overview of the general effect of certain alloying additions is given in Table 3.31 [3.1, 141–143]. The addition of up to 10% aluminum (Mg−Al alloys) increases the strength (age hardenable), castability, and corrosion resistance. During precipitation heat treatment the intermetallic phase $Mg_{17}Al_{12}$ is formed, and is usually not finely distributed enough to lead to a strong strengthening effect. The supplementary addition of zinc (Mg−Al−Zn alloys) improves the strength of Mg−Al alloys by refining the precipitates and by solid-solution strengthening. The frequently used alloy AZ91, for example, offers yield strength and ductility levels which are comparable to its aluminum counterpart A380. However, in terms of high-temperature creep resistance (application limited to about 125 °C), fatigue strength, and corrosion resistance the alloy AZ91 is inferior to Al alloys. Its application is therefore restricted to nonstructural components such as

brackets, covers, cases, and housings. With the development of the low-impurity AZ91D alloy (Fe < 0.005%; Ni < 0.001%, Cu < 0.015%) corrosion resistance has been improved dramatically. For structural applications where crashworthiness is important such as instrument panels, steering systems, and seating structures, magnesium die-cast alloys with small amounts of manganese (Mg−Al−Mn alloys) such as AM50 or AM60 are used as they offer higher ductility (elongation to failure: 10–15%). These alloys are less expansive than Al alloys. The poor high-temperature creep resistance of Mg alloys is the reason why these alloys are rarely found in automotive powertrains. The high operating temperatures (transmission cases: 175 °C, engine blocks: > 200 °C) are already a challenge for aluminum alloys, which have higher creep resistance. For this application Mg alloys containing rare-earth elements are under development to improve creep resistance by precipitation strengthening (some examples such as QE22 and WE43 are given in Tables 3.32,3.33 [3.1, 141–143]).

3.7.4 Titanium and Its Alloys

General Properties

With a density below 5 g/cm^3 (Table 3.13) titanium, like aluminum and magnesium, belongs to the light structural materials. However, in contrast to Al and Mg it also offers a high melting point of $T_s = 1670\,°C$, which is even higher than that of pure iron. Furthermore, amongst the materials which are under consideration for light structural constructions, Ti-based alloys have the highest specific strength (Table 3.13) and excellent corrosion resistance in oxidizing acids, chloride media, and most neutral environments. Titanium is well known for its biocompatibility, low thermal conductivity ($\kappa = 21\,W\,m^{-1}\,K^{-1}$), and low thermal expansion coefficient ($\lambda = 8.9\times10^{-6}\,K^{-1}$). Beside a slightly lower specific stiffness compared with iron-based materials the most annoying disadvantage of Ti and its alloys is the high manufacturing cost, which is about six times that of aluminum and ten times that of stainless steels. Therefore, Ti alloys are primary used in areas where strength-to-weight ratio and elevated-temperature properties are of prime importance, i. e., in aerospace applications (compare Fig. 3.148 [3.144]).

As an allotropic material, Ti undergoes a structural phase transformation at 883 °C from a (almost) closed-packed hexagonal structure (α) to a body-centered cubic high-temperature phase (β). By alloying additions and applying appropriate heat treatments titanium alloys can be age hardened to form a two-phase ($\alpha+\beta$) alloy. The solubility of interstitials such as O, N, C, and H is very high, allowing on the one hand strength to be increased by solid-solution hardening, but also leading on the other hand to a severe reduction of toughness when the material is penetrated by gases. Comprehensive treatments on Ti and its alloys can be found in [3.142, 145, 146].

Commercially Pure and Low-Alloy Grades of Titanium

Commercially pure grades of titanium in the purity range 99.0–99.5% can actually be considered as α-phase alloys since they contain certain levels of O, N, C, and Fe, resulting from the manufacturing process. Furthermore, oxygen may be added deliberately for solid-solution strengthening. Interstitials in titanium are very effective strengtheners; a 0.1% oxygen equivalent (% O equivalent = % O + 2% N + 0.67% C) in pure titanium increases strength by about 120 MPa. However, interstitials counteract fracture toughness; some applications, especially at low temperatures, may there-

fore require titanium grades with extra-low interstitials (ELI). While having an hcp structure Ti exhibits surprisingly high room-temperature ductility and can be cold-rolled to > 90% without crack formation. This behavior is attributed to the relative ease of activating slip systems and the availability of twinning planes in the crystal lattice. The chemical composition and the mechanical properties of commercial pure and low-alloy grades of titanium are given in Table 3.34.

hexagonal α-phase is stabilized by the impurities O, N, and C as well as by Al and Sn (Table 3.35), whereas elements such as V, Mo, and Cr expand the β-phase stability region (the Ti-rich part of the Ti−Al and the Ti−Mo phase diagram are shown in Fig. 3.149 [3.147]).

By varying the alloying content pure α- or β-phase alloys can be stabilized at room temperature as well as a mixture of both phases. The α-phase Ti alloys have a high solid solubility at room temperature and are weldable. The most widely used α-Ti alloy is Ti-5Al-2.5Sn (Table 3.36). While offering the highest strength levels of the Ti alloys and the ability of cold working, the usage of β-phase alloys is rather limited compared with pure α- or $\alpha+\beta$-alloys. Besides costs, the reasons for this include the higher density, caused by the addition of V or Mo, the low ductility in the high-strength condition, and the poor fatigue performance in thick sections, which is caused by segregations at grain boundaries. The most widely used group (about 60%) of Ti alloys are two-phase $\alpha+\beta$-alloys, with Ti-6Al-4V being the most prominent representative. These alloys are heat treatable and allow large variations of the mi-

intermetallic compounds in the Ti−Al system are attractive candidates for high-temperature applications (see, for example, [3.148]), mainly because of their unique combination of very low density and high melting point (above 1350 °C). The most promising alloys are Ti-rich two-phase (γ-TiAl and α_2-Ti_3Al) Ti–Al alloys with lamellar or duplex microstructures, which are adjusted by adequate heat treatments (Fig. 3.150). Additions such as Cr and Nb lead to further enhancement of the mechanical properties and allow elongations of up to about 3%, and room-temperature toughness values of 10–35 MPa$\sqrt{\text{m}}$ underline their principal suitability as constructional materials.

Ti–Ni Shape-Memory Alloys

Ti–Ni alloys are the most prominent representatives of shape-memory alloys [3.150]. The shape-memory effect, allowing the return of a highly deformed material to its starting shape, is based on a reversible martensitic transformation. In the case of Ti–Ni this transition is provided by a transition of the cubic, high-temperature B2 structure to the monoclinic low-temperature B19 structure upon cooling or by deformation. The transformation start (M_s) temperatures can be varied between −200 and 110 °C by altering the Ni content. Therefore, the transformation can be reversed either on heating or on releasing the stress isothermally. For further reading see [3.1, 150].

3.7.5 Ni and Its Alloys

General Properties

Due to its similarity to Fe with respect to the most relevant physical (and chemical) properties such as density, Young's modulus, melting point, thermal conductivity, and CTE (Sect. 3.4), it is straightforward to conclude that nickel is one of the major alloying elements in Fe-based alloys. Since Ni possesses a fcc crystal structure it stabilizes the austenite in Fe-based alloys at higher concentrations. In fact, over 60% of the annual Ni con-

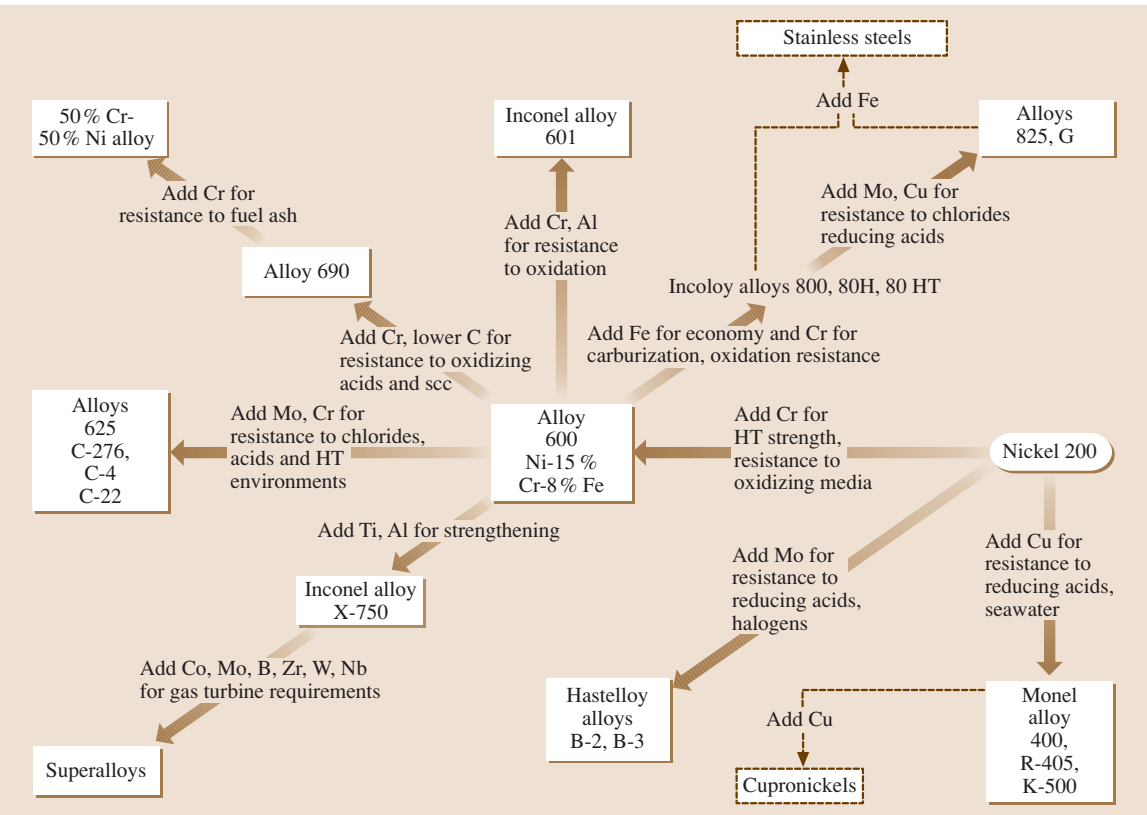

Fig. 3.151 Effects of alloying additions on the corrosion resistance of nickel alloys (HT denotes high temperature) (after [3.1])

sumption is devoted to alloying of stainless steels and a further 10% is used in (ferritic) alloy steels.

Nickel forms extensive solid solutions with many other elements: complete solid solutions with Fe and Cu (such as those exemplified with the phase diagrams in Figs 3.30,3.31) and limited solid solutions with < 35 wt. % Cr, < 20 wt. % Mo, < 10 wt. % Al, Ti, to mention the most important ones. Based on the fcc crystal structure Ni and its solid solutions show high ductility, fracture toughness, and formability.

Alloys of Ni−Fe show ferromagnetism over a wide range of compositions which, in combination with other intrinsic properties, gives rise to alloys with soft magnetic [3.59] and controlled thermal expansion properties (*Invar alloy*, Sect. 3.4.1). Ti–Ni shape-memory alloys are briefly discussed in Sect. 3.7.4. Finally, nickel plating is widely used for decorative applications. Most frequently, electroless deposition of either nickel–phosphorous or nickel–boron binary solutions is carried out by autocatalytic reduction of Ni ions from aqueous solutions. For more details see [3.151].

Besides these functional applications, structural applications of nickel and its alloys can be essentially grouped into two categories, namely:

1. Corrosion-resistant alloys
2. High-temperature alloys

as will be described briefly in the following two subsections. A survey on commonly used alloying additions in nickel and their effects on properties and applications is shown in Fig. 3.151.

Corrosion-Resistant Alloys

The main application of commercially pure nickel is to combine corrosion resistance with outstanding formability. The 200 alloy series typically contains minor amounts of less than 0.5 wt. % Cu, Fe, Mn, C, and Si. According to Fig. 3.148 the intrinsically good corrosion resistance of nickel 200 can be substantially improved by high alloying in solid solution with

- Cu for increased resistance against seawater and reducing acids, leading to the Monel alloys (e.g., 400, K-500)
- Mo for increased resistance against reducing acids and halogens, leading to the Hastelloy alloys (B2, B3)
- Cr for increased high-temperature strength and resistance to oxidizing media, leading to alloy 600 (which also possesses about 8 wt. % Fe, mainly for economical reasons)

Alloy 600 can be considered as the base alloy for a series of further high-alloyed Ni-base alloys for various applications in aggressive environments, as displayed in Fig. 3.151. An extensive compilation of chemical compositions and mechanical properties may be found in [3.1] while some typical examples for Ni alloys are listed in Table 3.38 together with their corresponding field of application.

Ni-Based Superalloys

The term *superalloy* is generally used for metallic alloy systems which may operate under structural loading

conditions at *elevated temperatures* above 1200°F (or around 650 °C correspondingly). Note, that this is synonymous with operating under creep conditions since $T_{app} > 0.5T_m$ (Sect. 3.3.2). As displayed in Fig. 3.152 superalloys can be grouped into three main subcategories according to the strengthening mechanism (Sect. 3.1.2) employed. One distinguishes:

1. Solid-solution-strengthened iron, nickel, and cobalt alloys
2. Carbide-strengthened cobalt alloys (see next section) and most prominently
3. Precipitation-strengthened nickel and nickel–iron alloys

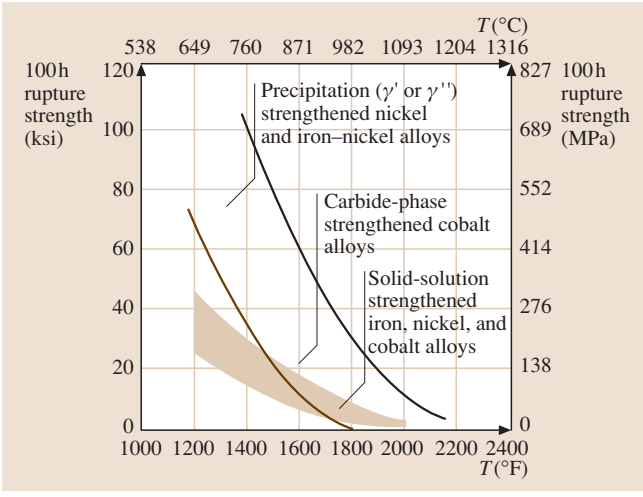

Fig. 3.152 Temperature dependence of the 100 h stress-rupture characteristics of wrought superalloys (after [3.1])

The paramount importance of the latter group regarding high-temperature creep strength stems from alloying with Al and Ti, which leads to the formation of a coherent ordered intermetallic γ'-$Ni_3(Al, Ti)$ phase. This $L1_2$ crystal structure has a superlattice structure with regard to the disordered fcc structure of the γ phase. The binary Al−Ni phase diagram (Fig. 3.153) clearly demonstrates that the γ' phase is stable up to its melting point close to 1400 °C. Since the γ phase exhibits a decreasing solubility for Al with decreasing temperature, precipitation strengthening by age hardening can be carried out in analogy to the Al−Cu system (Fig. 3.143). Maximum fractions of γ' phase exceed 60% by volume in single-crystal cast alloys such as CMSX 4 (Fig. 3.154). The pronounced hardening effect of the precipitate phase is mainly due to the γ/γ' lattice mismatch which causes dislocation reactions at the interphase and an anomalous temperature dependence of strength of the γ' phase [3.17]. The strength anomaly is also the reason why forming and machining operations of wrought superalloys require special attention and tools and restrict γ' volume fractions to below 50%.

Another major alloying element is carbon which forms carbides (of type MC, M_7C_3, $M_{23}C_6$, M_6C) with Ti, Cr, Nb, Mo, and W in order to stabilize the microstructure (grain structure) against creep deformation. The latter *heavy* elements are added also for γ matrix solid-solution strengthening since they segregate preferentially there. This effect has been further accen-

tuated recently with noble elements such as rhenium and ruthenium (Fig. 3.154). Finally, Cr is deliberately added in large concentrations of > 10 wt. %, typically around 20 wt. %, for chromia scale formation and protection against oxidation up to about 1000 °C.

A compilation of the most commonly employed wrought and cast Ni-based superalloys and their chemical composition can be found in [3.1]. Data for mechanical properties as a function of temperature are also extensively tabulated in [3.1], some characteristic examples for superalloys and their field of application are also listed in Table 3.38. Figure 3.155 illustrates some typical results of long-term stress rupture tests, demonstrating the suitability of Ni-based superalloys for applications in gas turbines and related power-generation applications.

3.7.6 Co and Its Alloys

General Properties

Due to their neighborhood in the periodic table, there are many analogies between Co and Ni. Like

Fig. 3.154 TEM micrograph of a second-generation Ni-based single-crystalline superalloy CMSX 4 (Courtesy of U. Glatzel, University of Bayreuth, Germany) ◀

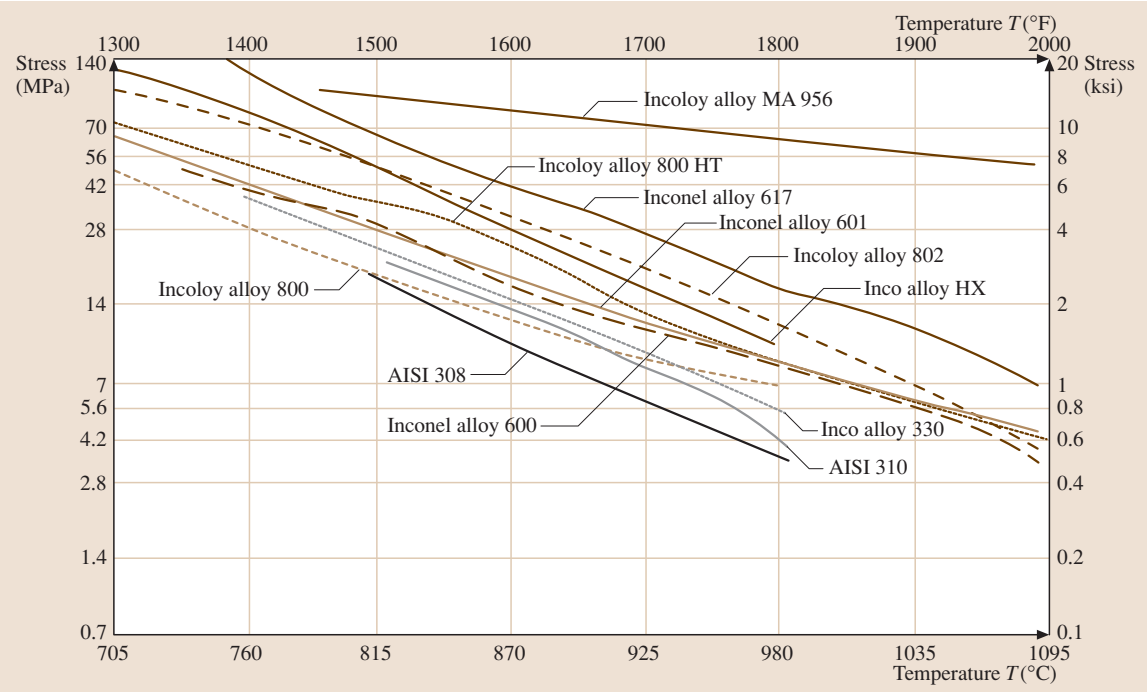

Fig. 3.155 Rupture strength (10 000 h) of Ni-based superalloys in comparison with selected stainless steels (after [3.1])

Ni cobalt also possesses physical properties which are similar to Fe [3.1]. However, at room temperature it exhibits a hexagonally closed-packed crystal structure like Mg, which undergoes an allotropic transformation at into an fcc crystal structure above approximately 660 K. Therefore, wrought deformation requires elevated temperatures and structural applications rely on the intrinsically high hardness of Co alloys, mainly manufactured via casting or powder-metallurgical technologies. Besides its use as an alloying element in steel, Co is frequently used as a component for many inorganic compounds such as a colorizer for glass and ceramics or in battery applications. While applications as surgical implant alloys and corrosion-resistant alloys are not treated further here, Co-based alloys may be grouped according to their field of application into the following three main categories.

Co-Based Hard-Facing Alloys

Co-based alloys with a carbon content in the range 1–3 wt. % C are widely used as wear-resistant hard-facing materials and weld overlays. In analogy to Ni-base alloys carbides of the type $M_{23}C_6$, M_6C and MC are formed depending on composition and heat treatment and *heavy* elements such as Mo, Ta, and W are deliberately added for solid-solution strengthening. Finally, a high Cr content of typically > 15 wt. % provides oxidation and hot corrosion resistance by chromia scale formation. In order to provide the necessary wear resistance under abrasive conditions, the microstructure of hard-facing Co-based alloys consists of a rather coarse dispersion of hard carbide phases embedded in a tough Co-rich metallic matrix. Due to the high C content of up to 3 wt. % the carbide volume fraction can exceed 50%. As a consequence of this, hot hardness values can exceed 500 HV at 650 °C (1200°F) and compressive strength can approach 2000 MPa trading off, however, for tensile ductility (< 1%) and UTS (around 800 MPa). Among some others, the most commonly known family of hard-facing Co-based alloys is designated *stellites*. For further details see [3.1] and Chap. 5 on tribology.

Co-Based Superalloys

Both wrought and cast Co-based superalloys differ significantly in chemical composition from their hard-facing counterparts as follows. First, they are based on the high-temperature face-centered cubic crystal structure, which is stabilized between RT and the melting

point by alloying with > 10 wt. % Ni. Second, for enabling wrought deformation the carbon content is reduced to values below 0.5 wt. %, which forms fine and homogeneously distributed carbides for dispersion strengthening. Finally, like for many Ni-based superalloys, in some Co-based superalloys the addition of Al and Ti serves to form the coherent ordered $Co_3(Al,Ti)$ phase, thus leading to precipitation strengthening by age hardening. These (often investment-cast) alloys are used in the very hot parts of gas turbines because of their excellent oxidation resistance. By contrast, they are inferior to Ni-based superalloys regarding creep strength (Fig. 3.152). A survey of the temperature dependence of the 1000 h rupture stress of typical Co-based superalloys is displayed in Fig. 3.156.

Cemented Carbides

Cemented carbides, also called *hardmetals*, can be considered as powder-metallurgically manufactured composite materials consisting of (rather coarse) carbide particulates embedded in a metallic Co-based matrix (*binder*). Most commonly, tungsten carbide (WC) is used for the particulates while the elements Ta, Nb, and Ti are deliberately added for economical reasons and to form complex multigrade cemented carbides. Then, the term *cermets* is used occasionally. Cobalt is the element of choice for the binder since it wets the carbides particularly well. Usually, Ni is added to the binder phase to increase corrosion and oxidation resistance. The main field of application is as grinding and turning tools for *difficult-to-machine* materials. Table 3.39 lists selected relevant hardmetals and their main properties.

3.7.7 Copper and Its Alloys

The most striking evidence of the presence of copper in constructions is that as rooftops, where it is distinctively marked (after 10–15 years) by a green-colored layer of copper acetate, which prevents further

corrosion (the statue of liberty is referred to as a prominent example). Copper and copper alloys have been in use for about 11 000 years, with Cu–Sn (bronze) probably being the first alloy of all. They generally have good corrosion resistance, excellent electrical and thermal conductivity, and their fabrication is easy due to the excellent formability (ductility). The favorable combination of electrical, mechanical, and corrosion properties aided the establishment of Cu as a structural material. On the other hand, Cu is susceptible to hydrogen embrittlement and stress corrosion cracking and has a relatively low strength-to-weight ratio. Comprehensive treatments and data of copper and copper alloys are given in [3.152–154]. The designation system of Cu alloys is given in Table 3.40.

Pure Copper

With its high electrical conductivity pure copper is primarily used for cables, wires, electrical contacts, and other electrical devices. A conductivity of 100% IACS

(International Annealed Copper Standards) corresponds to a resistivity of 1.72438 μ Ω cm. However, the properties of Cu are subject to dramatic changes with varying alloy content, i. e., the conductivity decreases substantially with increasing impurity content. Small oxygen additions of up to about 0.04% (electrolytic tough pitch copper) can bind metallic impurities to form oxides and therefore lead to an increase of the conductivity (Table 3.41), on the one hand. On the other hand, the presence of oxygen in Cu diminishes weldability, since hydrogen diffuses into the metal and interacts with oxide to form steam, which leads to cracking. For torch welding and brazing copper must be deoxidized, for example, by the addition of a small amount of phosphorus, which, however, lowers the electrical conductivity substantially but allows the material to be used in plumbing devices.

Copper Alloys

Elements which are solid-solution strengtheners in copper include Zn, Sn, Al, and Si, whereas Be, Cd, Zr, and Cr are suitable for age hardening. *Age-hardenable* alloys with small amounts of alloying additions (up to about 3%) can reach very high strength levels (yield stress $R_{pO.2} > 1300$ MPa at RT in the case of copper beryllium), offer high stiffness, and are nonsparking.

The term *brass* has been established for binary Cu−Zn alloys (Fig. 3.157) but is nowadays used for alloys containing additional components such as Pb, Fe, Ni, Al, and Si as well. Brasses are less expensive than pure Cu and can have different microstructures which depend on Zn content. Pure α-(Cu) solid solutions (up to about 38% Zn) are cold-working alloys. On increasing Zn content the natural color of brass changes form copper-like red (5% Zn) to yellow–gold (40% Zn) (Table 3.42). The *Muntz metal brass* is a binary $\alpha+\beta$ alloy with high strength and still reasonable ductility.

The most important properties of selected commonly used brasses are summarized in Table 3.43.

Wrought products of brasses and bronzes are used in automobile radiators, heat exchangers, and home heating systems, as pipes, valves, and fittings in carrying potable water and as springs, fasteners, hardware, small gears, and cams, to give a few examples. Cast leaded red and semi-red brasses find their application as lower-pressure-rating valves, fitting, and pump components as well as commercial plumbing fixtures, cocks, faucets, and certain lower-pressure valves. General hardware, ornamental parts, parts in contact with hydrocarbon fuels, and plumbing fixtures are made from yellow leaded brass, and high-strength (manganese-containing) yellow brass is suitable for structural, heavy-duty bearings,

hold-down nuts, gears, valve stems, and some marine fittings.

Bronzes are Cu−Sn- (Fig. 3.158), Cu−Al-, and Cu−Si-based alloys. Tin and aluminum are the most effective solid-solution strengtheners in copper. Cast products of tin bronzes are used as high-quality valves, fittings, and pressure vessel for applications at temperatures of up to 290 °C, special bearings, pump parts, gears, and steam fittings. Aluminum and silicon bronzes have very good strength, excellent formability, and good toughness. They are used as gears, slides gibs, cams, bushings, bearings, molds, forming dies, combustion engine components, valve stems, spark-resistant tools, and in marine applications such as propellers, impellers, and hydrofoils. The properties of some broadly used bronzes are given in Table 3.43.

Copper–nickel alloys show excellent corrosion resistance against seawater. Accordingly, they are used in shipboard components, power plants in costal areas, and saline-water conversion installations. Since Ni in Cu leads to a drastic decrease in electrical and thermal conductivity Cu−Ni alloys are also suitable for cryogenic applications.

3.7.8 Polymers

Polymers (polymer materials, polymeric materials, solid polymers, macromolecular materials) consist of very large molecules (chain molecules, macro molecules) which are synthesized from small molecules (monomers, monomer units) by a chemical reaction called polymerization (polyethylene, polyvinylchloride, polyurethane) or they are modified natural products (modified silk, regenerated cellulose) [3.155, 156].

The polymerization reactions can be classified into four groups [3.157]. *Chain polymerization* proceeds by the reaction of a monomer unit with the reactive site at the end of a polymer chain. These are mostly reactions via a radical mechanism [3.158]. The terminus *condensation chain polymerization* is used in

cases where a low-molar-mass byproduct is formed during polymerization. In *polycondensation* already generated polymer chains react with each other or with a monomer unit whereby a low-molar-mass byproduct is generated, for example, water as a byproduct in the reaction of an −OH group (alcohol group) with a −COOH group (organic acid group) resulting in an ester group. During *polyaddition*, growth of the polymer chains proceeds by an addition reaction between molecules of all degrees of polymerization or monomer units.

The annual world production of polymer materials is about 150–200 Mt. Some polymer materials are produced in amounts of more than 1 Mt/year (polypropylene about 14 Mt/year, which is about the same amount as for cotton), whereas others are polymer materials for special purposes with only small production volumes. Beside the use of bulk polymers as engineering materials a great amount of polymers is fabricated in the shape of fibers for manufacturing fabric, packaging films, paintings, thermal isolation materials (foam), and, for example, artificial leather.

Chemical Composition and Molecular Structure

For the presentation of polymer molecules the monomer unit is enclosed in brackets [ ] and an index (n) shows that a certain number of monomer units react to form the backbone of the polymer molecules. The polymerization of ethylene to polyethylene, for example, is written as $n CH_2{=}CH_2 \rightarrow [-CH_2-CH_2-]_n$, where the last part represents the whole molecule $CH_3-CH_2-CH_2...CH_2-CH_2-CH_3$, with n being between some hundreds and some millions.

Most of the polymers which are used as engineering materials are organic polymers with backbones (main chains) consisting of C−C bonds, or they contain bondings between C and other chemical elements (Table 3.44). Polymers with a backbone containing no carbon atoms are regarded as inorganic polymers. For most polymers common abbreviations are used and trademarks exist (Table 3.44).

Polymer materials can be classified, e.g., by their specific molecular structure and the resulting mechanical properties at different temperatures into *thermoplastics*, *elastomers*, and *duromers* [3.159].

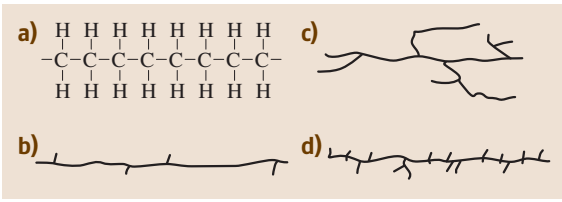

Fig. 3.159a–d Examples of linear polymer molecules: **(a)** theoretical backbone with carbon–carbon bonds; no side chains, **(b)** backbone with only a few small side chains, ≈ 10 side chains/1000 C atoms, example: high-density PE; **(c)** backbone with longer side chains/branches, example: low-density PE; **(d)** a great number of side chains attached to the backbone, example very low-density PE

Thermoplastics. *Thermoplastics* show good strength and high Young's modulus at RT and they are plastically deformable at elevated temperatures, in most cases above 100 °C. They consist in their simplest molecule structure of linear molecules with no branches (Fig. 3.159). In technical products small (e.g., $-CH_3$ groups) or larger side chains (short −C−C− chains) are attached to the main chain, forming a branched polymer. The degree of branching determines the density of solid polymers, because with increasing branching the possibility of a dense arrangement of the macromolecules decreases.

A typical example is polyethylene, with a density of 0.91–0.94 g/cm^3 for the strong branched low-density PE (LDPE) and a density of 0.94–0.97 g/cm^3 for the weakly branched high-density PE (HDPE). Regarding thermoplastics, within chain molecules there exist very strong intramolecular covalent bondings (bonding energy of the −C−C-bonding: 348 kJ/mol), whereas between neighboring molecule chains only weak intermolecular bonds with small bonding energies are present (Van der Waals bond: 0.5–5 kJ/mol, hydrogen bond: ≈ 7 kJ/mol). Therefore the chain molecules can, already around room temperature (rubber-like polymers, elastomers) or at elevated temperatures (thermoplastics), shifted with respect to each other, and such polymer solids can be deformed elastically or plastically. The molecular structure of thermoplastics can be distinguished by the kind of atoms building the backbone and by the kind of atoms or chemical groups attached to the backbone (Table 3.45). The side groups determine the polymer properties to a large extent, because they influence the strength of the intermolecular bonding.

Another significant parameter that determines the properties of polymer solids results from the mean size of the macromolecules (degree of polymerization, mean chain length, mean molar mass), and, because the polymer molecules show no unit length, the deviation of the molecule size, which depends on the production parameters.

Elastomers. *Elastomers* (rubber-like polymers) consist, similarly to thermoplastics, of linear molecules, but the molecule chains are bridged by small-molecule segments via covalent bondings. The molecules can therefore undergo a strong elastic deformation at *room temperature*. This effect is due to the stretching of the molecules out of the disordered state if a load is applied, and a re-deformation into the random tangle of molecules due to the increased entropy, after the load is released.

Duromers. *Duromers* consist of a three-dimensional molecule network, bridged by covalent bondings. Even at elevated temperatures they undergo no plastic deformation and can, in most cases, be heated up to their decomposition temperature without any elastic or plastic deformation. Most duromers are thermosets (phenolics, unsaturated polyesters, epoxy resins, and polyurethanes) which solidify by an exothermal chemical reaction (curing). Thermosets are obtained by moulding a thermoplastic material into the desired shape, which is then cross-linked. The curing reaction can be initiated at room temperature (RT) by mixing the components, or it starts at an elevated temperature, or irradiation by energetic radiation (ultraviolet light, laser beam, or electron beam) is applied.

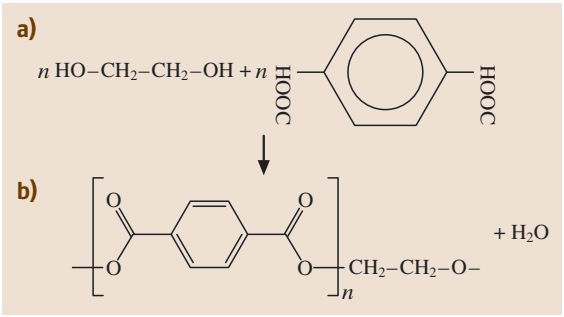

Fig. 3.160 PET formation by polycondensation of ethylene glycol with terephthalic acid

Most polymers are formed by chain polymerization from one type of monomer (PE, PP, PVC, PS). For example, PE is obtained by polymerization of ethylene: $n(CH_2{=}CH_2) \rightarrow -[-CH_2-CH_2-]_n$. Another possibility is that two different monomers containing different types of chemical groups react with each other (PA, PC, PET, polyurethane), thus forming a polymer unit built by two molecules; for example, PET is obtained by polycondensation of ethylene glycol with terephthalic acid whereby water is generated as a byproduct, as exemplified in Fig. 3.160.

In copolymers the polymer chain is composed of two or more types of monomers. The monomers can be arranged randomly, alternating, or as blocks (short molecule chains, consisting of the same monomer units). Another version is that blocks built from one type of monomer are fixed as side chains onto a backbone built from another monomer type. Common copolymers are polystyrene-butadiene-rubber (SBR) and acrylonitrile-butadiene-styrene (ABS).

The properties of polymeric materials can be further tailored by mixing or blending two or more polymers [3.160]. One goal of blending is to obtain materials with greater impact toughness than the pure polymers, whereby one component functions as a toughener for the other. In high-impact polystyrene, the high modulus of polystyrene is combined with the high impact strength of rubber particles (polybutadiene). Other examples for blends are PP-PC, PVC-ABS, and PE-PTFE.

The toughness of otherwise stiff polymers and the glass-transition temperature (see below) are increased by mixing low-molar-mass substances (plasticizers) into the polymers. The most common case is dioctyl phthalate as a plasticizer for PVC. A similar effect results if up to 8% water is incorporated into polyamide.

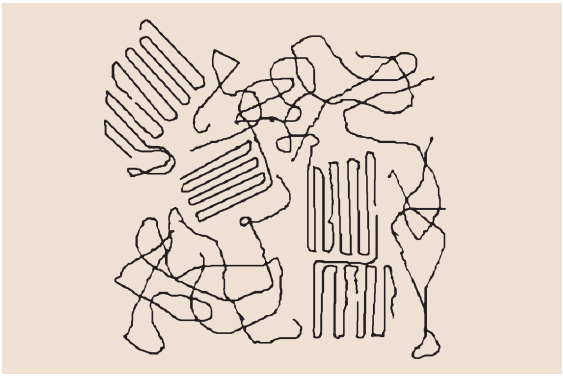

Fig. 3.161 Amorphous and crystalline regions in the morphology of a semicrystalline polymer

In a process known as cross-linking molecules are linked to one another to increase the temperature resistance, long-time creep strength, and insensitivity to stress cracks. Cross-linking can be achieved very precisely by irradiating plastics with high-energy electron beams or gamma rays. This optimization can be applied even to pure and widely used plastics, such as PE and PVC. Another approach is to add special compounds which are cross-linkable by irradiation, thus fixing two polymer chains to each other. The advantage of the cross-linking technique is that the properties are modified after the components have been formed into parts and that the process takes place at room temperature and at normal pressure.

Microstructure of Polymer Materials

Linear polymers can have a disordered state (amorphous) or a semicrystalline arrangement of the molecules (Fig. 3.161).

The amorphous state is characterized by a random tangle of molecules. In semicrystalline polymers some parts of the polymer molecules are ordered in the shape of folded-chain lamellae which are eventually arranged to form blocks. The degree of crystallinity can be estimated by density measurement, by thermal analysis/differential scanning calorimetry (DSC) or by

Table 3.46 Degree of crystallinity of common polymer materials

Polymer	Degrees of crystallinity (%)

XRD. It depends on the number and length of the side chains on the molecule backbone (degree of branching) and determines the density and the elastic moduli of a polymer material. For polyethylene the degree of crystallinity varies from 45% for low-density PE to 95% for high-density PE (Table 3.46).

In some semicrystalline polymers the folded-chain lamellae grow, starting at a nucleus, outwards, yielding spherulites [3.161]. The size of the spherulites can be modified by the addition of nucleants. Toughness and light transparency decrease with increasing spherulite size. Spherulites are visible by polarized-light microscopy of microtome sections (about 25 µm thick) (Fig. 3.162).

The polymer molecules can be strongly oriented parallel to the flow direction during production processes such as injection moulding due to the high viscosity of the melt. This occurs especially if metallic parts are used as inserts by which the melt flow is divided and then reunited after the flow around the insert [3.162, 163]. As a result one recognizes regions which show strong anisotropic mechanical properties within the normally isotropic polymer solid [3.164]. The aligned molecules can result in substantial residual stresses and give rise to crack initiation even when a low external load is applied. This molecular alignment can be lowered by relaxation at elevated temperatures, whereby changes of the shape can occur. This effect has to be taken into account if parts made from polymer materials are heated during further manufacturing or while in use. An application of the relaxation effect is the use of polymer films for shrink packaging, where an article is wrapped at room temperature and the film shrinks upon heating.

Thermal Properties

The strength of duroplastic materials does not change much with increasing temperature. They do not melt at all due to the three-dimensional molecule network but rather start to decompose. During heating of thermoplastic and elastomeric polymers temperature ranges with different polymer properties are observed: strong, hard, and brittle at low temperatures but ductile and deformable at increased temperatures, and finally changing from a solid to the state of a viscous melt. The transitions between the different states which are due to the arrangement and the mobility of the molecules can be investigated by DSC [3.165] whereby the exothermic and endothermic heat flux is registered (Fig. 3.163).

At a material-specific temperature an endothermic hump appears, extending over a certain temperature range. This is the transition into the glassy state due to the increased mobility of the molecule segments in the amorphous parts of the microstructure and is accompanied by an enormous decrease of viscosity and, thus, strength. The glass-transition temperature (T_g), which can be defined as the temperature at the first inflection point of the graph, is heating rate dependent and is specific to different materials (Table 3.47). The high level of heat flux is maintained, because the specific heat of the glassy polymer is greater than that of the solid polymer.

In very few cases and at very low temperature partial crystallization of the polymer can follow the transition into the glassy state, connected with an exothermic heat flow (dashed line in Fig. 3.163). With increasing temperature the crystalline regions of semicrystalline polymers will melt, which is indicated by another endothermic event, which represents the melting temperature (T_m) (Table 3.47). The large peak width, as compared with metals, is related to the nonuniformity of the polymer molecules and the high degree of imperfection of the polymer crystals. After that temperature range the polymer behaves like a high-viscosity melt.

Usually, technical applications of polymer materials are restricted to temperatures below the glass transition (polystyrene, PMMA, PET). In some cases polymers are also used above that temperature (polyisoprene, polybutadiene, polyethylene); then some polymers exhibit rubber-like properties.

Polymeric materials start to decompose or to be oxidized in air if heated over a certain temperature. In some cases they burn (PE, PP, PS) with a characteristic flame color. The decomposition is a process of thermal cracking of the material and/or an oxidation, whereby sometimes a characteristic smell of the fume occurs when the flame is blown out (PE: like burning candle or wax; PA: like burned hair or horn; PVC: stinging, acidic; PS: fruity). In some cases chemicals which are dangerous for humans or can alter other materials are set free. The burning of PUR generates toxic hydrocyanic acid. Overheating or burning of PVC yields hydrochloric acid vapor (HCl) which leads to the corrosion of parts made from Cu or other metals and is toxic to humans.

Mechanical Properties of Polymer Materials

As stated above the three basic types of polymers – thermoplastics, elastics, and duromers – show very different properties with different dependencies on temperature, which can be a reason for selecting a certain polymer. Choosing a polymeric material for a specific application [3.167] can be based on the difference in mechanical properties, such as tensile strength, impact, elastic behavior, but also often other properties have to be considered, such as density, corrosion resistance, or formability. The ratio of density and Young's modulus (Fig. 3.164) can be a potential criterion for selecting a certain polymer material for a certain application. Alternatively, the ratio of Young's modulus and impact

strength of a polymer material may be taken into account (Fig. 3.165).

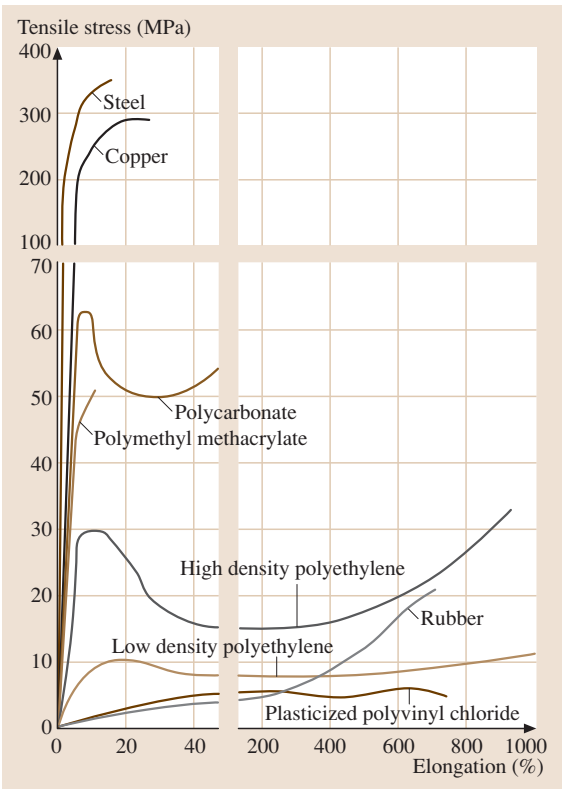

Fig. 3.166 Tensile stress–strain curves for polymers in comparison to copper and steel (after [3.166])

Standardized mechanical testing methods for polymer materials (Table 3.48) in most cases differ from those applied to other materials (Sect. 3.3). This is especially true for the size and shape of the specimens and the applied load [3.169].

Tensile stress–strain curves can be very different for polymer materials (Fig. 3.166) and they are strongly dependent on the testing temperature (Fig. 3.167). No linear region of the stress–strain curve of polymer materials exists from which the Young's modulus could be obtained. Therefore a *secant modulus* is calculated

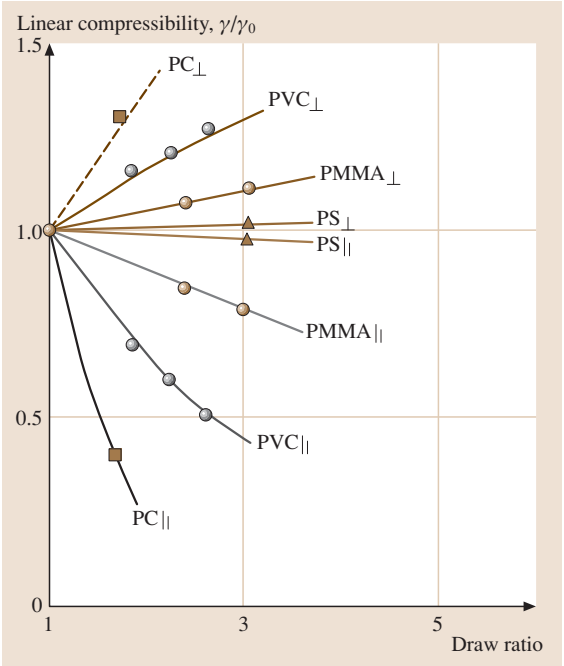

Fig. 3.168 Influence of the drawing ratio on the linear compressibility parallel and perpendicular to the drawing direction (after [3.166])

In general the values of the mechanical properties of polymer materials are inferior to those of metallic materials (Table 3.50).

The tensile strength generated by stretching the polymer chains during the manufacturing process can yield values of the ultimate tensile strength which are greater than those known for steel (for example, steel S355 ≈ 400 N/mm^2) (Table 3.51). An outstanding high tensile strength is exhibited by Aramid (poly-paraphenylene terephthalamide; Kevlar), which is used as a fiber.

has a significant influence on the mechanical properties (Fig. 3.168). For the determination of dynamic mechanical properties of polymers a torsion pendulum is used [3.171]. As a result the elastic shear modulus G and $\tan\delta$ are obtained. The shear modulus is strongly dependent on temperature (Fig. 3.169).

The mechanical properties of polymer materials can be further improved by fiber reinforcement [3.173, 174] (Sect. 3.7.10).

Polymer Interaction with Solvents

The dissolution of solid polymers in organic solvents or water starts with swelling, whereby the macromolecules are not degraded, which means that the chain length is not changed [3.175]. Only in some polymers are the chain molecules shortened by a chemical reaction with a chemical substance contained in a solvent. For example, the amid bondings in polyamides undergo hydrolysis under basic conditions (saponification), resulting in the generation of chain molecule fragments of different length. Swelling and subsequent dissolution are due to a competition of the intermolecular bonding forces between chains of the polymer, and the bonding forces between the macromolecules and the small solvent molecules, respectively. As a result, increasing numbers of solvent molecules penetrate the tangled polymer chain arrangement and lead to an increase of the volume of the polymer solid. This is accompanied by a lowering of the interaction forces between adjacent macromolecule segments and an increase of the mobility of the molecules with respect to each other and a loss of strength. The swelling and dissolution process may take up to several days or weeks at ambient temperature. Swelling often results in a sticky substance before the real dissolution happens. In some cases polymer solutions can be used as a glue which will have the strength of the starting polymer after the solvent has evaporated.

Benzene	18.8	Polystyrene	18.4

Some polymers can only incorporate a limited fraction of solvent into the solid. The interaction between a polymer and a selected solvent and therefore the solubility of the polymer can be predicted using the solubility parameter δ (Table 3.51), which is based on the cohesion forces, beside other factors [3.172]. As a rule, a substance can be regarded as a solvent if the difference of δ values is less than 2.

Aging and Corrosion

Aging of polymers is mainly due to chemical changes of the structure of the macromolecules accompanied by a shortening of the chain molecules, branching, cross-linking, and the generation of new chemical groups. A prerequisite for aging is the influence of light, especially UV light, and eventually oxygen from the air. As a result the polymer becomes brittle, cracks are generated, the quality of the surface is changed, and a loss of electrical insulation behavior will appear. Loss of plasticizer by diffusion also lowers the elasticity and the ductility, especially at lower temperatures. An especially dangerous situation is the interaction of a solvent or a solution and mechanical stress on a polymer part, leading to stress-corrosion failure.

3.7.9 Glass and Ceramics

Ceramic and glass materials are complex compounds and solid solutions containing metallic and nonmetallic elements, which are composed either by ionic or covalent bonds. Typical properties of glasses and ceramics include high hardness, high compressive strength, high brittleness, high melting point, and low electrical and thermal conductivity. There are several ways in which ceramics may be classified, such as by chemical composition, properties or applications. In Fig. 3.170 this

classification is made on the basis of chemical composition [3.1].

In the following, a closer look at some of the ceramic materials listed in Fig. 3.170 will be made. Detailed treatments of ceramics are given in [3.177, 178].

Glasses

Glasses are solid materials which have become rigid without crystallization (amorphous structure, Sect. 3.1). The microstructure is based on SiO_4 tetrahedral units which possess short-range order and are connected to each other by bridging oxygen, resulting in a three-dimensional framework of strong Si−O−Si bonds. The main assets of glasses are their optical transparency, pronounced chemical resistance, high mechanical strength, and relatively low fabrication costs. Glasses usually contain other oxides, notably CaO, Na_2O, K_2O, and Al_2O_3, which influence the glass properties. Beside about 70% SiO_2 soda-lime glasses, which are used for windows and containers, additionally consist of Na_2O (soda) and CaO (lime). Further applications of glasses are as lenses (optical glasses), fiberglass, industrial and laboratory ware, and as metal-to-glass sealing and soldering. The compositions of some commercial glass materials are described in Table 3.52 [3.176].

Glass Ceramics

Glass ceramics contain small amounts of nucleating agents (such as TiO_2 and ZrO_2) which induce crystallization of glasses when exposed to high temperatures. After melting and shaping of the glassy material, it is partly crystallized using a specific heat treatment at temperatures between 800 and 1200 °C. The residual glass phase occupies 5–50% of the volume and the crystalline phase has a grain size of 0.05–5 µm. In contrast to conventional ceramics, e.g., prepared by powder processing routes, glass ceramics are fully dense and pore-free, resulting in relatively high mechanical strength. Glass ceramics of the system $Li_2O-Al_2O_3-SiO_2$ show near-zero linear thermal expansion, such that the glass ceramic ware will not experience thermal shock. These materials also have a relatively high thermal conductivity and show exceptionally high dimensional and shape stability, even when subjected to considerable temperature variations. Glass ceramics are used in astronomical telescopes, as mirror spacers in lasers, as ovenware and tableware, as electrical insulators, and are utilized for architectural cladding, and for heat exchangers and regenerators.

Silicate Ceramics

Silicates are the most important constituents of the Earth's crust. Their structure, which is based on SiO_4 tetrahedrons (glasses are a derivative of silicates) depends on the actual composition. A three-dimensional network (quartz) is only stable when the ratio of O/Si is exactly 2. The addition of alkali or alkali-metal oxides to silica increases the overall O/Si ratio of the silicate and results in the progressive breakdown of the silicate structure into smaller units. In Table 3.53 the relationship of the O/Si ratio and the

	2.00	4.0	0.0	Three-dimensional network quartz, tridymite, cristabolite are all polymorphs of silica
 Repeat unit $(Si_4O_{10})^{4-}$	2.50	3.0	1.0	Infinite sheets $Na_2Si_2O_5$ clays (kaolinite)
 Repeat unit $(Si_4O_{11})^{6-}$	2.75	2.5	1.5	Double chains, e.g., asbestos
 Repeat unit $(SiO_3)^{2-}$	3.00	2.0	2.0	Chains $(SiO_3)_n^{2n-}$, Na_2SiO_3, $MgSiO_3$
 $(SiO_4)^{4-}$	4.00	0.0	4.0	Isolated SiO_4^{4-}, tetrahedra Mg_2SiO_4 olivine, Li_4SiO_4

The simplest way to determine the number of nonbridging oxygens per Si is to divide the charge on the repeat unit by the number of Si atoms in the repeat unit

silicate structure is demonstrated. Silicates are particularly useful for electrotechnical, electronic, and high-temperature applications as well as in the processing of materials.

Refractory Ceramics

Refractory ceramics are another important group of ceramics that are utilized in large tonnages. These materials must withstand high stresses at high tem-

peratures without melting or decomposing and must remain nonreactive and inert when exposed to severe environments. Refractory ceramics are composed of coarse oxide particles bonded by a finer refractory material. The finer material usually melts during firing and bonds the remaining material. Refractory ceramics generally contain 20–25% porosity as an important microstructural variable that must be well controlled during manufacturing. They are used for various applications ranging from low- to intermediate-temperature building bricks to high-temperature applications, where magnesite, silicon carbide, and stabilized zirconia (also used as thermal barrier coatings of nickel-based turbine components) are suitable. Typical applications include furnace linings for metal refining, glass manufacturing, metallurgical heat treatment, and power generation. Depending on their chemical composition and reaction oxide refractories can be classified into acidic, basic, and neutral refractories. Fireclays are acidic refractories and are formable with the addition of water (castable and cements). Very high melting points are provided by chromite and chromite–magnesite ceramics, which are neutral refractories. Examples of commercial refractories are given in Table 3.54.

Oxide Ceramics

Oxide ceramics are treated as a separate group of ceramics in [3.1] since they are the most common constituents

Table 3.56 Properties and applications of advanced ceramics

Property	Application (examples)
Thermal	
Insulation	High-temperature furnace linings for insulation (oxide fibers such as silica, alumina, and zirconia)
Refractoriness	High-temperature furnace linings for insulation and containment of molten metals and slags
Thermal conductivity	Heat sinks for electronic packages (AlN)
Electrical and dielectric	
Conductivity	Heat elements for furnaces (SiC, ZrO_2, $MoSi_2$)
Ferroelectricity	Capacitors (Ba-titanate-based materials)
Low-voltage insulators	Ceramic insulation (porcelain, steatite, forsterite)
Insulators in electronic applications	Substrate for electronic packaging and electical insulators in general (Al_2O_3, AlN)
Insulators in hostile environments	Spark plugs (Al_2O_3)
Ion-conducting	Sensors, fuel cells, and solid electrolytes (ZrO_2, β-alumina, etc.)
Semiconducting	Thermistors and heating elements (oxides of Fe, Co, Mn)
Nonlineal I–V characteristics	Current surge protectors (Bi-doped ZnO, SiC)
Gas-sensitive conductivity	Gas sensors (SnO_2, ZnO)
Magnetic and superconductive	
Hard magnets	Ferrite magnets [(Ba, Sr)O × $6Fe_2O_3$]
Soft magnets	Transformer cores [(Zn, M)Fe_2O_3, with M = Mn, Co, Mg]; magnetic tapes (rare-earth garnets)
Superconductivity	Wires and SQUID magnetometers ($YBa_2Cu_3O_7$)
Optical	
Transparency	Windows (soda-lime glasses), cables for opticalcommunication (ultrapure silica)
Translucency and chemical inertness	Heat- and corrosion-resistant materials, usually for Na lamps (Al_2O_3, MgO)
Nonlinearity	Switching devices for optical computing ($LiNbO_3$)
Infrared transparency	Infrared laser windows (CaF_2, SrF_2, NaCl)
Nuclear applications	
Fission	Nuclear fuel (UO_3, UC), fuel cladding (C, SiC), neutron moderators (C, BeO)
Fusion	Tritium breeder materials (zirconates and silicates of Li, Li_2O; fusion reactor lining (C, SiC, Si_3N_4, B_4C)
Chemical	
Catalysis	Filters (zeolites); purification of exhaust gases
Anticorrosion properties	Heat exchangers (SiC), chemical equipment in corrosive environment
Biocompatibility	Artificial joint prostheses (Al_2O_3)
Mechanical	
Hardness	Cutting tools (SiC whisker-reinforced Al_2O_3, Si_3N_4)
High-temperature strength retention	Stators and turbine blades, ceramic engines (Si_3N_4)
Wear resistance	Bearings (Si_3N_4)

of ceramics. The properties and applications of some important members are summarized in Table 3.55. For further reading the extensive treatment in [3.179] is recommended.

Nonoxide Ceramics

The *nonoxide ceramics* include essentially borides, carbides, nitrides, and silicides. A comprehensive overview of these materials is given in [3.1,177,178]. A few application examples will be given in the following. In recent years some effort has been made in the construction of ceramic automobile engine parts such as engine blocks, valves, cylinder liner, rotors for turbochargers, and so on. Ceramics under consideration for use in ceramic turbine engines include silicon nitride Si_3N_4, and silicon carbide SiC, which possess high thermal conductivity

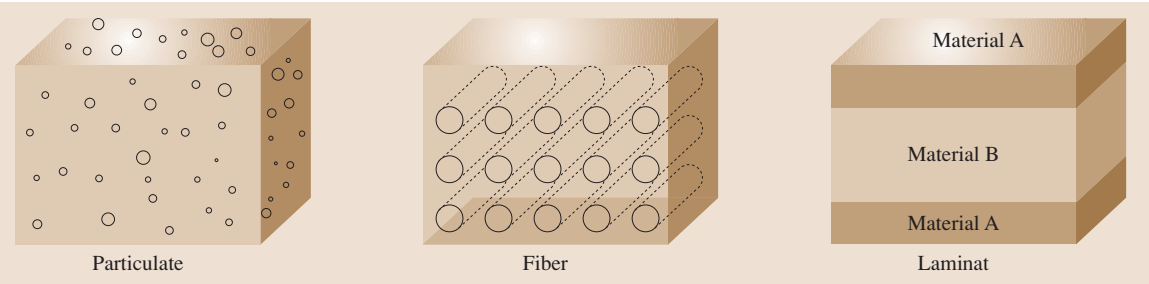

Fig. 3.171 Types of composites (schematic)

and thus excellent thermal-shock resistance. Boron carbide (B_4C), silicon carbide (SiC), and titanium diboride (TiB_2) are also being considered for armor systems to protect military personnel and vehicles from ballistic projectiles. The low density of ceramics makes them very attractive in this field. High-purity ceramics with simple crystal structures such as boron nitride (BN), silicon carbide (SiC), and aluminum nitride (AlN) may be used as substrate for integrated circuits (ICs), since they have better thermal conductivity and thermal expansion coefficients which are closer to the silicon IC chips than that of the presently used alumina. Further applications of nonoxide ceramics as well as advanced oxide ceramics are given in Table 3.56.

3.7.10 Composite Materials

Composite materials are formed when two materials which belong to different material classes are combined to attain properties which are not provided by the original materials. Possible combinations are:

- Metal–ceramics
- Metal–polymer
- Ceramic–polymer

The second phase could be introduced into the matrix material either in the form of homogeneously distributed particles, as fibers, or the materials form a laminate structure (Fig. 3.171).

In *dispersion-strengthened* alloys a small amount (usually $< 10\%$ volume fraction) of second-phase particles (metallic oxide or ceramic) are homogeneously distributed into the matrix material, commonly by mechanical alloying techniques [3.181]. These dispersoids are generally not coherent and, thus, effectively inhibit dislocation motion (Orowan circumvention at room temperature or by lowering dislocation line energy at higher temperatures [3.17]) when their distance is typically about 100 nm. The most important advantage over age-hardened alloys is the excellent elevated-temperature stability. Due to their insolubility within the metallic matrix no significant coarsening of the dispersoids is observed even after long-term exposure at temperatures close to the melting point of the matrix. Prominent examples are the oxide-dispersion-strengthened (ODS) nickel- and iron-based superalloys [3.182]. When the particles are large so that they do not significantly interact with moving dislocations, the rule of mixture can be applied for property determination, i. e., the properties can be directly determined by adding the percentage influence of each phase. Hence, the term *particulate-reinforced material* is more appropriate and the volume fraction of the reinforcement phase can exceed 50%. Applications are, e.g., cemented carbides as wear and cutting tools (Sect. 3.7.6), abrasives such as Al_2O_3, SiC, and BN, which are added to grinding and cutting wheels, and electrical contacts such as tungsten or oxide particle-reinforced silver.

The fibers in *fiber-reinforced* composites can be continuously (as in Fig. 3.171), orthogonal or randomly distributed. The properties of the fiber, i. e., strength, stiffness, etc., the aspect ratio l/d, where l is the fiber length and d is the diameter, and the volume fraction of

Table 3.57 Typical longitudinal and transverse tensile strengths for three unidirectionally fiber-reinforced composites. The fiber content in each is approximately 50 vol. % (after [3.180])

Material	Longitudinal tensile strength (MPa)	Transversale tensile strength (MPa)
Glass–polyester	700	20
Carbon (high modulus) –epoxy	1000	35
Kevlar–epoxy	1200	20

the fibers play a decisive role in the final performance of the reinforced composites. In the longitudinal direction (along the fiber axis) the strength is much higher than in the transverse direction (Table 3.57).

The matrix of fiber-reinforced materials should be tough enough to support the fibers and prevent cracks in broken fibers from propagating, and one has to be aware of chemical reactions when the matrix is a metallic material. If the fibers are exposed to high temperatures the coefficient of thermal expansion should not differ substantially from that of the matrix. Fiber composites may be used as fan blades in gas turbine engines and other aircraft and aerospace components, in lightweight automotive applications such as fiber-reinforced Al-matrix pistons, sporting goods (such as tennis rackets, golf club shafts, and fishing rods), and as corrosion-resistant components, to name some of the possible applications.

Laminar compositions could be very thin coatings such as thermal barrier coatings to protect Ni-based superalloys in high-temperature turbine applications (Sect. 3.7.5), thicker protective layers, or two-dimensional sheets or panels that have a preferred high-strength direction. The layers are stacked and joined by organic adhesives. Examples of laminar structures are adjacent wood sheets in plywood, capacitors composed of alternating layers of aluminum and mica, printed circuit boards, and insulation for motors, to mention a few.

4. Thermodynamics

Frank Dammel, Jay M. Ochterbeck, Peter Stephan

This chapter presents the basic definitions, laws and relationships concerning the thermodynamic states of substances and the thermodynamic processes. It closes with a section describing the heat transfer mechanisms.

4.1 Scope of Thermodynamics. Definitions

Thermodynamics is a subsection of physics that deals with energy and its relationship with properties of matter. It is concerned with the different forms of energy and their transformation between one another. It provides the general laws that are the basis for energy conversion, transfer, and storage.

4.1.1 Systems, System Boundaries, Surroundings

A thermodynamic system, or briefly a system, is a quantity of matter or a region in space chosen for a thermodynamic investigation. Some examples of systems are an amount of gas, a liquid and its vapor, a mixture of several liquids, a crystal or a power plant. The system is separated from the surroundings, the so-called environment, by a boundary (real or imaginary). The boundary is allowed to move during the process under investigation, e.g., during the expansion of a gas, and matter and energy may cross the boundary. Energy can cross a boundary with matter and in the form of heat transfer or work (Sect. 4.3.2). The system with its boundary serves as a region with a barrier in which computations of energy conversion processes take place. Using an energy balance relationship (the first law of thermodynamics) applied to a system, energies that cross the system boundary (in or out), the changes in stored energy, and the properties of the system are linked. A system is called closed when mass is not allowed to cross the boundary, and open when mass crosses the system boundary. While the mass of a closed system always remains constant, the mass inside an open system may also remain constant when the total mass flow in and the total mass flow out are equal. Changes of the mass stored in an open system will occur when the mass flow into the system over a certain time span is different from the mass flow out. Examples of closed systems are solid bodies, mass elements in mechanics, and a sealed container. Examples of open systems are turbines, turbojet engines, or a fluid (gases or liquids) flowing in channel. A system is called adiabatic when it is completely thermally isolated from its surrounding and no heat transfer can cross the boundary. A system that is secluded from all influences of its environment is called isolated. For an isolated system neither energy in the form of heat transfer or work nor matter are exchanged with the environment.

The distinction between a closed and an open system corresponds to the distinction between a Lagrangian and an Eulerian reference system in fluid mechanics. In the Lagrangian reference system, which corresponds to the closed system, the fluid motion is examined by dividing the flow into small elements of constant mass and deriving the corresponding equations of motion. In the Eulerian reference system, which corresponds to the open system, a fixed volume element in space is selected and the fluid flow through the volumetric element is examined. Both descriptions are equivalent, and it is often only a question of convenience whether one chooses a closed or an open system.

4.1.2 Description of States, Properties, and Thermodynamic Processes

A system is characterized by physical properties, which can be given at any instant, for example, pressure, temperature, density, electrical conductivity, and refraction index. The state of a system is determined by the values of these properties. The transition of a system from one equilibrium state to another is called a change of state.

Example 4.1: A balloon is filled with gas. The gas may then be the thermodynamic system. Measurements show that the mass of the gas is determined by volume, pressure, and temperature. The properties of the system are thus volume, pressure, and temperature, and the state of the system (the gas) is characterized through a fixed set of volume, pressure, and temperature. The transition to another fixed set, e.g., when a certain amount of gas effuses, is called a change of state.

The mathematical relationship between properties is called an equation of state.

Example 4.2: The volume of the gas in the balloon proves to be a function of pressure and temperature. The mathematical relationship between these properties is such an equation of state.

Properties are subdivided into three classes: *intensive properties* are independent of the size of a system and thus keep their values after a division of the system into subsystems.

Example 4.3: If a space filled with a gas of uniform temperature is subdivided into smaller spaces, the temperature remains the same in each subdivided space. Thus, temperature is an intensive property. Pressure would be another example of an intensive property.

Properties that are proportional to the mass of the system (i. e., the total is equal to the sum of the parts) are called *extensive properties*.

Example 4.4: The volume, the energy or the mass.

An extensive property X divided by the mass m of the system yields the *specific property* $x = X/m$.

Example 4.5: Take the extensive property volume of a given gas. The associate specific property is the specific volume $v = V/m$, where m is the mass of the gas. The SI unit for specific volume is m^3/kg. Specific properties all fall into the category of intensive properties.

Changes of state are caused by interactions of the system with the environment, for example, when energy is transferred to or from the system across the system boundary. In order to describe a change of state it is sufficient to specify the time history of the properties. The description of a process requires additional specifications of the extent and type of the interactions with the environment. Consequently, a process is a change of state caused by certain external influences. The term *process* is more comprehensive than the term *change of state*; for example, the same change between two states can be induced by different processes.

4.2 Temperatures. Equilibria

4.2.1 Thermal Equilibrium

We often talk about *hot* or *cold* bodies without quantifying such states exactly by a property. When a closed hot system A is exposed to a closed cold system B, energy is transported as heat transfer through the contact area. Thereby, the properties of both systems change until after a sufficient period of time new fixed values are reached and the energy transport stops. The two systems are in *thermal equilibrium* in this final state. The speed with which this equilibrium state is approached depends on the type of contact between the two systems and on the thermal properties. If, for example, the two systems are separated only by a thin metal wall, the equilibrium is reached faster than in the case of a thick polystyrene wall. A separating wall, which inhibits mass transfer and also mechanical, magnetic or electric interactions, but permits the transport of heat, is called diatherm. A diatherm wall is *thermally* conductive. A completely thermally insulated wall such that no thermal interactions occur with the surroundings is called adiabatic.

4.2.2 Zeroth Law and Empirical Temperature

In the case of thermal equilibrium between systems A and C and thermal equilibrium between systems B and C experience shows that the systems A and B must also be in thermal equilibrium. This empirical statement is called the *zeroth law of thermodynamics*. It reads: if two systems are both in thermal equilibrium with a third system, they are also in thermal equilibrium with each other. In order to find out if two systems A and B are in thermal equilibrium, they are exposed successively to a system C. The mass of system C may be small compared to those of systems A and B. If so, changes in state of systems A and B are negligible during equilibrium adjustment. When C is exposed to A, certain properties of C will change, for example, its electrical resistance. These properties then remain unchanged during the following exposure of C to B, if A and B were originally in thermal equilibrium. Using C in this way it is possible to verify if A and B are in thermal equilibrium. It is possible to assign any fixed values to the properties of C after equilibrium adjustment. These values are called *empirical temperatures*, where the measurement instrument is a thermometer.

4.2.3 Temperature Scales

A gas thermometer (Fig. 4.1), which measures the pressure p of a constant gas volume V, is used for the construction and definition of empirical temperature scales. The gas thermometer is brought into contact with systems of a constant state, e.g., a mixture of ice and water at a fixed pressure. After a sufficient period of time, the gas thermometer will be in thermal equilibrium with the system with which it is in contact. The gas volume is kept constant by changing the height Δz of the mercury column. The pressure exerted by the mercury column and environment is measured and the product pV is computed. The extrapolation of measurements at different, sufficiently low pressures leads to a threshold value A of the product pV for the pressure approaching zero. This value A, which is determined from the measurements, is assigned to an empirical temperature via the linear relationship

$$T = \text{const.}\, A\ . \tag{4.1}$$

After fixing the value *const* it is only necessary to determine the value of A from the measurements in order to compute the empirical temperature with (4.1). The specification of the empirical temperature scale requires

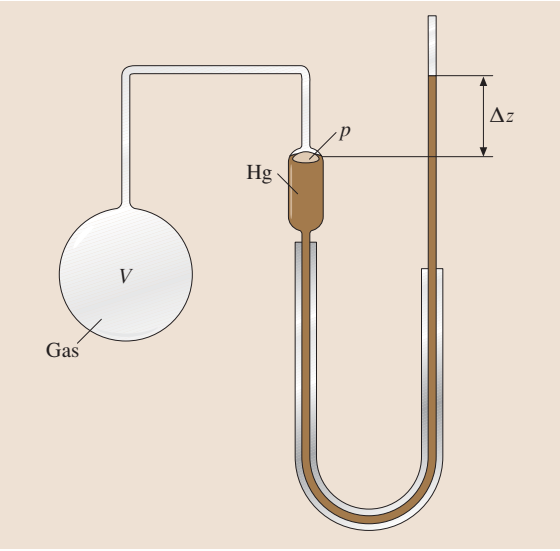

Fig. 4.1 Gas thermometer with gas volume in piston and mercury column

a fixed point. The 10th General Conference of Weights and Measures, held in Paris in 1954, assigned the triple point of water to a temperature $T_{tr} = 273.16$ Kelvin (designated by K). At the triple point of water vapor, liquid water, and ice coexist in equilibrium at a pressure of 611.657 ± 0.010 Pa. The temperature scale introduced in this way is named the *Kelvin scale*, and it is identical to the thermodynamic temperature scale. It holds that

$$T = T_{tr} A / A_{tr} , \tag{4.2}$$

if A_{tr} is the value of A measured with a gas thermometer at the triple point of water.

On the *Celsius scale*, where the unit of temperature t is designated by °C, the ice and steam points are assigned the values of $t_0 = 0\,°C$ and $t_1 = 100\,°C$, respectively, at a pressure of 0.101325 MPa. This corresponds quite accurately to absolute temperatures of $T_0 = 273.15\,K$ and $T_1 = 373.15\,K$. The temperature $T_{tr} = 273.16\,K$ at the triple point of water is roughly 0.01 K higher than the temperature at the ice point. The conversion of temperatures is carried out according to the equation

$$T = t + 273.15 , \tag{4.3}$$

where t is in °C and T is in K.

Additionally, the Fahrenheit scale is common in some countries, particularly the USA. The corresponding values on this scale are 32°F at the ice point and 212°F at the steam point of water (pressure in each case 0.101325 MPa). Conversion of a temperature t_F given in °F to a Celsius temperature t in °C is given by

$$t = \frac{5}{9}(t_F - 32) . \tag{4.4}$$

The degree increments of the Rankine scale (°R) are the same as Fahrenheit degrees, however, the reference 0 is set at absolute zero. It holds that

$$T_R = \frac{9}{5} T , \tag{4.5}$$

where T_R is in °R and T is in K. The ice point of water is thus given as 491.67 °R.

The International Practical Temperature Scale

Since it is difficult and time consuming to measure temperatures precisely with a gas thermometer, the international practical temperature scale was introduced by law. It is arranged by the International Committee for Weights and Measures so that its temperature approaches as close as possible the thermodynamic temperature of certain substances. The international practical temperature scale is fixed by the freezing and boiling points of these substances, which were determined as precisely as possible with a gas thermometer by the scientific national institutes of the different countries. Resistance thermometers, thermocouples, and radiation measuring devices are used to interpolate between the fixed points, whereas certain instructions are given for the relationships between the actually measured quantities and the temperature. The basic regulations of the international temperature scale are the same in all countries. They read:

1. In the international temperature scale of 1948 the symbol of the temperature is t and its unit is "°C" or "°C (Int. 1948)".
2. On the one hand the scale is based on a number of always reproducible equilibrium temperatures (fixed points), which are assigned to certain numerical values, and on the other hand on accurately defined formulas, which establish relationships between the temperature and the indications of the measuring instruments calibrated at the fixed points.
3. The fixed points and the assigned numerical values are summarized in tables (Table 4.1). With the exception of the triple points the assigned temperatures correspond to equilibrium states at the pressure 0.101325 MPa, which is the standard atmospheric pressure at sea level.

Table 4.1 Fixed points of the international temperature scale of 1990 (IPTS-90)

4. Formulas, which also are established by international agreements, are used for interpolation between fixed points. Thus, the indications of the standard instruments with which the temperatures have to be measured, are assigned to the numerical values of the international practical temperature.

In order to simplify temperature measurements other additional thermometric fixed points for substances, which can be easily produced in sufficiently pure form, were associated as accurately as possible to the lawful temperature scale. The most important ones are summarized in Table 4.2. The platinum resistance thermometer is used as the normal instrument between the triple point of equilibrium hydrogen at 13.8033 K (−259.3467 °C) and the melting point of silver at 1234.93 K (961.78 °C). Between the melting point of silver and the melting point of gold at 1337.33 K (1064.18 °C) a platinum–rhodium (10% rhodium)/platinum thermocouple is used as normal instrument. Above the melting point of gold, Planck's radiation law defines the international practical temperature

$$\frac{J_t}{J_{\mathrm{Au}}} = \frac{\exp\left(\frac{c_2}{\lambda(t_{\mathrm{Au}}+T_0)}\right)-1}{\exp\left(\frac{c_2}{\lambda(t+T_0)}\right)-1}\,, \qquad (4.6)$$

where J_t and J_{Au} are the radiation energies emitted by a black body at temperature t and at the gold point t_{Au}, respectively, at a wavelength of λ per unit area, time, and wavelength interval. The value of the constant c_2 is specified as 0.014388 Km (Kelvin meter), $T_0 = 273.15$ K is the numerical value of the melting temperature of ice, and λ is the numerical value in m of a wavelength in the visible spectrum. For practical temperature measurement [4.2, 3]

4.3 First Law of Thermodynamics

4.3.1 General Formulation

The first law is an empirical statement, which is valid because all conclusions drawn from it are consistent with experience. Generally, it states that energy can be neither destroyed nor created, thus energy is a conserved property. This means that the energy E of a system can be changed only by energy exchange into or out of the system. It is generally agreed that energy transferred to a system is positive and energy transferred from a system is negative. A fundamental formulation of the first law reads: every system possesses an extensive property energy, which is constant in an isolated system.

4.3.2 The Different Forms of Energy and Energy Transfer

In order to set up the first law mathematically it is necessary to distinguish and define the different forms of energy transfer.

Work

In thermodynamics the basic definition of the term *work* is adopted from mechanics: the work done on a system is equal to the product of the force acting on the system and the displacement from the point of application. The work done by a force F along the distance z between points 1 and 2 is given by

$$W_{12} = \int_1^2 \boldsymbol{F}\,\mathrm{d}z\,. \tag{4.7}$$

The mechanical work W_{m12} is the result of forces which accelerate a closed system of mass m from velocity w_1 to w_2 and raise it from level z_1 to level z_2 against gravity g. This associates a change in kinetic energy $mw^2/2$ and in potential energy mgz of the system

$$W_{m12} = m\left(\frac{w_2^2}{2} - \frac{w_1^2}{2}\right) + mg(z_2 - z_1)\,. \tag{4.8}$$

Equation (4.8) is known as the energy theorem of mechanics.

Moving boundary work, or simply boundary work, is the work that has to be done to change the volume of a system. In a system of volume V, which possesses the variable pressure p, a differential element $\mathrm{d}A$ of the boundary surface thereby moves the distance $\mathrm{d}z$. The work done is

$$\mathrm{d}W_v = -p\int_A \mathrm{d}\boldsymbol{A}\,\mathrm{d}z = -p\,\mathrm{d}V\,, \tag{4.9}$$

and thus

$$W_{v12} = -\int_1^2 p\,\mathrm{d}V\,. \tag{4.10}$$

The minus sign is due to the formal sign convention which states that work transferred to the system, which is connected to a volume reduction, is positive. Equation (4.10) is only valid if the pressure p of the system is in each instance of the change of state a continuous function of volume and equal to the pressure exerted by the environment. Then a small excess or negative pressure of the environment causes either a decrease or an increase of the system volume. Such changes between states, where even the slightest imbalance is sufficient to drive them in either direction, are called reversible. Accordingly, (4.10) is the moving boundary work for reversible changes of state. In real processes a finite excess pressure of the environment is necessary to overcome the internal friction of the system. Such changes in state are irreversible, where the added work is increased by the dissipated part W_{diss12}. The moving boundary work for an irreversible change of state is

$$W_{v12} = -\int_1^2 p\,\mathrm{d}V + W_{diss12}\,. \tag{4.11}$$

The dissipation work is always positive and increases the system energy and causes a different path $p(V)$

between the states than in the reversible case. The determination of the integral in (4.11) requires that p is a unique function of V. Equation (4.11) is, for example, not valid for a system area through which a sound wave travels.

Work can be derived as the product of a generalized force F_k and a generalized displacement dX_k. In real processes the dissipated work has to be added

$$dW = \sum F_k \, dX_k + dW_{diss} \, . \tag{4.12}$$

This equation shows that in irreversible processes ($W_{diss} > 0$) more work has to be done or less work is received than in reversible processes ($W_{diss} = 0$). Table 4.3 includes different forms of work.

Shaft work is work derived from a mass flow through a machine such as compressors, turbines, and jet engines. When a machine increases the pressure of a mass m along the path dz by dp, the shaft work is

$$dW_t = mv \, dp + dW_{diss} \, . \tag{4.13}$$

When kinetic energy and potential energy of the mass flow are also changed, mechanical work is done additionally. The shaft work done along path 1–2 is

$$W_{t12} = \int_1^2 V \, dp + W_{diss12} + W_{m12} \, , \tag{4.14}$$

with W_{m12} is given according to (4.8).

Internal Energy

In addition to any kinetic and potential energy, every system possesses energy stored internally as translational, rotational, and vibrational kinetic energy of the elementary particles. This is called the internal energy U of the system and is an extensive property. The total energy E a system of mass m possesses consists of internal energy, kinetic energy E_{kin}, and potential energy E_{pot}

$$E = U + E_{kin} + E_{pot} \, . \tag{4.15}$$

Heat Transfer

The internal energy of a system can be changed by doing work on it or by adding or removing matter. However, it can also be changed by exposing the system to its environment which has a different temperature. As a consequence, energy is transferred across the system boundary as the system will try to reach thermal equilibrium with the environment. This energy transfer is called heat transfer. Thus heat transfer can generally be defined as that energy a system exchanges with its environment which does not cross the system boundary as work or by accompanying mass transfer. The heat transfer from state 1 to 2 is denoted Q_{12}.

4.3.3 Application to Closed Systems

The heat transfer Q_{12} and work W_{12} to a closed system during the change of state from 1 to 2 cause a change of the system energy E

$$E_2 - E_1 = Q_{12} + W_{12} \, , \tag{4.16}$$

where W_{12} includes all forms of work done on the system. If no mechanical work is done, only the internal energy changes, and according to (4.15), $E = U$ holds. If it is additionally assumed that only moving boundary work is done on the system, (4.16) reads

$$U_2 - U_1 = Q_{12} - \int_1^2 p \, dV + W_{diss12} \, . \tag{4.17}$$

4.3.4 Application to Open Systems

Steady-State Processes

Very often work is done by a fluid flowing steadily through a device. If the work per unit time remains constant, such a process is called a *steady flow process*. Figure 4.2 shows a typical example: a flowing fluid (gas or liquid) of pressure p_1 and temperature T_1 may flow with velocity w_1 into system σ. If machine work is done as shaft work, W_{t12} is supplied at the shaft. Then the fluid flows through a heat exchanger, in which the heat transfer Q_{12} occurs with the environment, and the fluid eventually leaves the system σ with pressure p_2, temperature T_2, and velocity w_2. Tracking the path of a constant mass element Δm through the system σ means that a moving observer would consider the mass element Δm as a closed system, thus this corresponds to the Lagrangian description in fluid mechanics. Therefore, the first law for closed systems (4.16) is valid in this case. The work done on Δm consists of $\Delta m \, p_1 v_1$ to push Δm out of the environment across the system boundary, of the technical work W_{t12}, and of $-\Delta m \, p_2 v_2$ to bring Δm back into the environment. Thus, the work done on the closed system is

$$W_{12} = W_{t12} + \Delta m (p_1 v_1 - p_2 v_2) \, . \tag{4.18}$$

The term $\Delta m \, (p_1 v_1 - p_2 v_2)$ is referred to as the *flow work*. This flow work is the difference between

Table 4.3 Different forms of work. SI units are given in brackets

the shaft work W_{t12} and the work done on the closed system. With this relationship the first law for closed systems, (4.16), becomes

$$E_2 - E_1 = Q_{12} + W_{t12} + \Delta m(p_1 v_1 - p_2 v_2) \quad (4.19)$$

with E according to (4.15). The property enthalpy is defined as

$$H = U + pV \quad \text{or} \quad h = u + pv \quad (4.20)$$

and (4.19) then can be written as

$$0 = Q_{12} + W_{t12} + \Delta m\left(h_1 + \frac{w_1^2}{2} + gz_1\right) - \Delta m\left(h_2 + \frac{w_2^2}{2} + gz_2\right). \quad (4.21)$$

In this form the first law is used for steady flow processes in open systems. Equation (4.21) shows that the sum of all energies entering or leaving the system across the system boundary σ (Fig. 4.2) is zero, because a steady flow process is considered. These energies are in the form of the heat transfer Q_{12}, the shaft work W_{t12}, and the energies $\Delta m(h_1 + w_1^2/2 + gz_1)$ transferred to the system and $\Delta m(h_2 + w_2^2/2 + gz_2)$ transferred from the system with the mass Δm. The differential form of (4.21) reads

$$0 = \mathrm{d}Q + \mathrm{d}W_\mathrm{t} + \mathrm{d}m\left(h_1 + \frac{w_1^2}{2} + gz_1\right) - \mathrm{d}m\left(h_2 + \frac{w_2^2}{2} + gz_2\right).$$

When a continuous process is considered, it is better to use the following form of the balance equation instead of (4.21)

$$0 = \dot{Q} + P + \dot{m}\left(h_1 + \frac{w_1^2}{2} + gz_1\right) - \dot{m}\left(h_2 + \frac{w_2^2}{2} + gz_2\right).$$

In the above equation $\dot{Q} = \mathrm{d}Q/\mathrm{d}\tau$ is the heat transfer rate, $P = \mathrm{d}W_\mathrm{t}/\mathrm{d}\tau$ the shaft power, and $\dot{m}$ the mass flow rate. Changes of kinetic and potential energy in these cases are often negligible, such that (4.21) is simplified to

$$0 = Q_{12} + W_{t12} + H_1 - H_2. \quad (4.22)$$

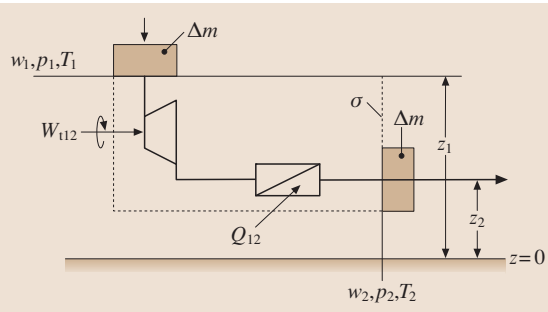

Fig. 4.2 Work for an open system

Special cases of this equation are:

a) Adiabatic changes of state, which typically appear in devices such as compressors, turbines, and jet engines

$$0 = W_{t12} + H_1 - H_2 \,. \tag{4.23}$$

b) Throttling of a flow in an adiabatic tube through a restriction (Fig. 4.3) which causes a pressure reduction. It holds that

$$H_1 = H_2 \tag{4.24}$$

before and after the throttling valve. Thus, the enthalpy remains constant during the throttling, assuming that changes of kinetic and potential energies are negligible.

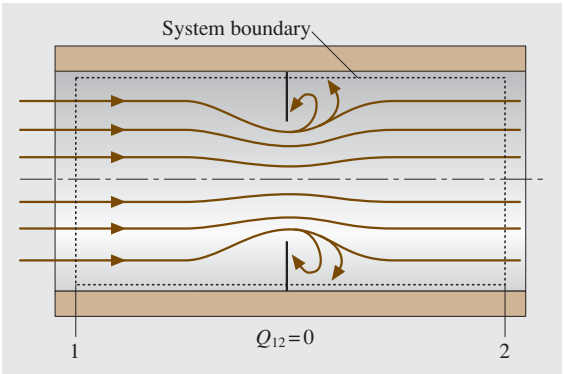

Fig. 4.3 Adiabatic throttling

Transient Processes

Referring to Fig. 4.2, when the mass Δm_1 transferred to the system over a period of time differs from the mass Δm_2 transferred from the system during the same period, the result is mass stored (or loss) in the system. This results in a time-variable internal energy of the system and possibly also time-variable kinetic and potential energies. The energy change of a system during a change of state 1–2 is $E_2 - E_1$. Therefore, (4.21) has to be replaced by the following form of the first law

$$E_2 - E_1 = Q_{12} + W_{t12} + \Delta m_1\left(h_1 + \frac{w_1^2}{2} + g z_1\right) - \Delta m_2\left(h_2 + \frac{w_2^2}{2} + g z_2\right) . \tag{4.25}$$

If the fluid states 1 at the inlet and 2 at the outlet vary in time, it is appropriate to use the differential notation:

$$\mathrm{d}E = \mathrm{d}Q + \mathrm{d}W_t + \mathrm{d}m_1\left(h_1 + \frac{w_1^2}{2} + g z_1\right) - \mathrm{d}m_2\left(h_2 + \frac{w_2^2}{2} + g z_2\right) . \tag{4.26}$$

When investigating the filling and emptying of containers it is usually possible to neglect changes in kinetic and potential energies. Furthermore, often no shaft work is done, thus, (4.26) is reduced to

$$\mathrm{d}U = \mathrm{d}Q + h_1\,\mathrm{d}m_1 - h_2\,\mathrm{d}m_2 \tag{4.27}$$

with the (time-variable) internal energy $U = um$ of the mass stored in the container. It is agreed that $\mathrm{d}m_1$ is mass transferred to and $\mathrm{d}m_2$ mass transferred from the system. If mass is only supplied, $\mathrm{d}m_2$ is equal to zero; if mass is only discharged, $\mathrm{d}m_1$ is equal to zero. For a continuously running process the following form of the balance equation is more suitable than (4.25)

$$\mathrm{d}E/\mathrm{d}\tau = \dot{Q} + P + \dot{m}_1\left(h_1 + \frac{w_1^2}{2} + g z_1\right) - \dot{m}_2\left(h_2 + \frac{w_2^2}{2} + g z_2\right) . \tag{4.28}$$

4.4 Second Law of Thermodynamics

4.4.1 The Principle of Irreversibility

When two systems A and B are exposed to each other, energy exchange processes take place and a new equilibrium state is reached after a sufficient period of time. As an example, a system A may be in contact with a system B that has a different temperature. In the final state both systems will have the same temperature and equilibrium will have been reached. Until equilibrium has been reached a continuous series of nonequilibrium states will be passed. It is from common experience that this process has a natural direction (e.g., heat transfer from hot to cold) and does not proceed in the reverse direction independently, i. e., without exchange with the environment. Such processes are referred to as being irreversible. Exchange processes, which pass through nonequilibrium states, are in principle irreversible. On the other hand, a process that consists of a continu-

ous series of equilibrium states is reversible. This may be exemplified by the frictionless, adiabatic compression of a gas. It is possible to transfer moving boundary work to the system *gas* by exerting a force, for example, an excess pressure of the environment, on the system boundary. If this force is increased very slowly, the volume of the gas decreases and the temperature increases, whereas the gas is at any time in an equilibrium state. If the force is slowly reduced to zero, the gas returns to its initial state; thus, this process is reversible. Reversible processes are idealized borderline cases of real processes and do not occur in nature. All natural processes are irreversible, because a finite force is necessary to initiate a process, e.g., a finite force to move a body against friction or a finite temperature difference for heat transfer. These facts known from experience lead to the following formulations of the second law:

- All natural processes are irreversible.
- All processes including friction are irreversible.
- Heat transfer does not independently occur from a body of lower to a body of higher temperature.

Independently in this connection means that it is not possible to carry out the mentioned process without causing effects on nature. Beside these examples, further formulations valid for other special processes exist.

4.4.2 General Formulation

The mathematical formulation of the second law is realized by introducing the term *entropy* as another property of a system. The practicality of this property can be shown by using the example of heat transfer between a system and its environment. According to the first law, a system can exchange energy by work and by heat transfer with its environment. The supply of work causes a change of the internal energy such that, for example, the system's volume is changed at the expense of the environment's volume. Consequently, $U = U(V, \ldots)$. The volume is an exchange variable. It is an extensive property, which is *exchanged* between the system and environment. It is also possible to look upon the heat transfer between a system and its environment as an exchange of an extensive property. In this way, only the existence of such a property is postulated. Its introduction is solely justified by the fact that all statements derived from it correspond with experience. This new extensive property is called entropy and denoted with S. Consequently, $U = U(V, S, \ldots)$. If only moving boundary work occurs and heat transfer occurs, $U = U(V, S)$. Differentiation leads to the *Gibbs equation*

$$\mathrm{d}U = T\,\mathrm{d}S - p\,\mathrm{d}V \tag{4.29}$$

with the thermodynamic temperature

$$T = (\partial U/\partial S)_\mathrm{V} \tag{4.30}$$

and the pressure

$$p = -(\partial U/\partial V)_\mathrm{S}\,. \tag{4.31}$$

A relationship equivalent to (4.29) is derived by eliminating U and replacing it by enthalpy $H = U + pV$ such that

$$\mathrm{d}H = T\,\mathrm{d}S + V\,\mathrm{d}p\,. \tag{4.32}$$

It can be shown that the thermodynamic temperature is identical to the temperature measured by a gas thermometer (Sect. 4.2.3). From examination of the characteristics of entropy it follows that in an isolated system, which is initially in nonequilibrium (for example, because of a nonuniform temperature distribution) and then approaches equilibrium, the entropy always increases. In the borderline case of equilibrium a maximum of entropy is reached. The internal entropy increase is denoted by $\mathrm{d}S_\mathrm{gen}$. For the considered case of an isolated system it holds that

$$\mathrm{d}S = \mathrm{d}S_\mathrm{gen}$$

with $\mathrm{d}S_\mathrm{gen} > 0$. If a system is not isolated, entropy is also changed by $\mathrm{d}S_\mathrm{Q}$ due to heat transfer (with the environment) and by $\mathrm{d}S_\mathrm{m}$ because of mass transfer with the environment. However, energy transfer by work with the environment does not change the system entropy. Thus, it holds generally that

$$\mathrm{d}S = \mathrm{d}S_\mathrm{Q} + \mathrm{d}S_\mathrm{m} + \mathrm{d}S_\mathrm{gen}\,. \tag{4.33}$$

The formulation for the time-variable system entropy $\dot{S} = \mathrm{d}S/\mathrm{d}\tau$ reads

$$\dot{S} = \dot{S}_\mathrm{Q} + \dot{S}_m + \dot{S}_\mathrm{gen} \tag{4.34}$$

with $\dot{S}_\mathrm{gen}$ being the entropy generation rate caused by internal irreversibilities, and $\dot{S}_\mathrm{Q} + \dot{S}_\mathrm{m}$ is called the entropy flow. These values, which are exchanged across the system boundary, are combined to

$$\dot{S}_\mathrm{fl} = \dot{S}_\mathrm{Q} + \dot{S}_\mathrm{m}\,. \tag{4.35}$$

The rate of change of the system entropy S consists, thus, of the entropy flow $\dot{S}_\mathrm{fl}$ and entropy generation $\dot{S}_\mathrm{gen}$

$$\dot{S} = \dot{S}_\mathrm{fl} + \dot{S}_\mathrm{gen}\,. \tag{4.36}$$

For the entropy generation it holds that

$$\begin{aligned} \dot{S}_{\mathrm{gen}} &= 0 \quad \text{for reversible processes,} \\ \dot{S}_{\mathrm{gen}} &> 0 \quad \text{for irreversible processes,} \\ \dot{S}_{\mathrm{gen}} &< 0 \quad \text{for impossible processes.} \end{aligned} \tag{4.37}$$

4.4.3 Special Formulations

Adiabatic, Closed Systems

Since $\dot{S}_{\mathrm{Q}} = 0$ for adiabatic systems and $\dot{S}_{\mathrm{m}} = 0$ for closed systems, it follows that $\dot{S} = \dot{S}_{\mathrm{gen}}$. Thus, the entropy of an adiabatic, closed system can never decrease. It can only increase during an irreversible process or remain constant during a reversible process. If an adiabatic, closed system consists of α subsystems, then it holds for the sum of entropy changes ΔS^{α} of the subsystems that

$$\sum_{\alpha} \Delta S^{\alpha} \geq 0 \,. \tag{4.38}$$

With $\mathrm{d}S = \mathrm{d}S_{\mathrm{gen}}$, (4.29) reads for an adiabatic, closed system

$$\mathrm{d}U = T\,\mathrm{d}S_{\mathrm{gen}} - p\,\mathrm{d}V \,.$$

On the other hand it follows from the first law according to (4.17)

$$\mathrm{d}W_{\mathrm{diss}} = T\,\mathrm{d}S_{\mathrm{gen}} = \mathrm{d}\Psi \tag{4.39}$$

or

$$W_{\mathrm{diss}12} = TS_{\mathrm{gen}12} = \Psi_{12} \,, \tag{4.40}$$

where Ψ_{12} is called the dissipated energy during the change in state 1–2. The dissipated energy is always positive. This statement is not only true for adiabatic systems but also for all general cases, because, according to definition, the entropy generation is the fraction of entropy change, which arises when the system is adiabatic and closed and therefore $\dot{S}_{\mathrm{fl}} = 0$ holds.

Systems with Heat Transfer

For closed systems with heat transfer (4.29) becomes

$$\begin{aligned} \mathrm{d}U &= T\,\mathrm{d}S_{\mathrm{Q}} + T\,\mathrm{d}S_{\mathrm{gen}} - p\,\mathrm{d}V \\ &= T\,\mathrm{d}S_{\mathrm{Q}} + \mathrm{d}W_{\mathrm{diss}} - p\,\mathrm{d}V \,. \end{aligned} \tag{4.41}$$

A comparison with the first law, (4.17), results in

$$\mathrm{d}Q = T\,\mathrm{d}S_{\mathrm{Q}} \,. \tag{4.42}$$

Thus, heat transfer is energy transfer, which together with entropy crosses the system boundary, whereas work is exchanged without entropy exchange. Adding the always positive term $T\,\mathrm{d}S_{\mathrm{gen}}$ to the right-hand side of (4.42) leads to the *Clausius inequality*

$$\mathrm{d}Q \leq T\,\mathrm{d}S \quad \text{or} \quad \Delta S \geq \int_1^2 \frac{\mathrm{d}Q}{T} \,. \tag{4.43}$$

In irreversible processes the entropy change is larger than the integral over all $\mathrm{d}Q/T$; the equals sign is only valid for the reversible case. For open systems with heat addition, $\mathrm{d}S_{\mathrm{Q}}$ in (4.41) has to be replaced by $\mathrm{d}S_{\mathrm{fl}} = \mathrm{d}S_{\mathrm{Q}} + \mathrm{d}S_{\mathrm{m}}$.

4.5 Exergy and Anergy

According to the first law, the energy of an isolated system is constant. As it is possible to transform every nonisolated system into an isolated one by adding the environment, it is always possible to define a system in which the energy remains constant during a thermodynamic process. Thus, a loss of energy is not possible, and energy is only converted in a thermodynamic process. How much of the energy stored in a system is converted depends on the state of the environment. If it is in equilibrium with the system, no energy is converted. The larger the difference from equilibrium, the more energy of the system can be converted and thus the greater the potential to perform work.

Many thermodynamic processes take place in the Earth's atmosphere, which is the environment of most thermodynamic systems. In comparison to the much smaller thermodynamic systems, the Earth's atmosphere can be considered as an infinitely large system, in which the intensive properties pressure, temperature, and composition do not change during a process (as long as daily and seasonal variations of the intensive properties are neglected). In many engineering processes work is obtained by bringing a system with a given initial state into equilibrium with the environment. The maximum work is obtained when all changes of state are reversible.

The maximum work that could be obtained by establishing equilibrium with the environment is called the exergy W_{ex}.

4.5.1 Exergy of a Closed System

In order to calculate the exergy of a system at state 1, a process is considered that brings the system reversibly into thermal and mechanical equilibrium with its environment. Equilibrium exists if the temperature of the system at the final state 2 is equal to the temperature of the environment, i. e., $T_2 = T_{env}$, and if the pressure of the system in state 2 is equal to the pressure of the environment, i. e., $p_2 = p_{env}$. Neglecting the kinetic and potential energy of the system, the first law according to (4.16) reads

$$U_2 - U_1 = Q_{12} + W_{12} \,. \tag{4.44}$$

To execute the entire process reversibly, it is necessary to bring the system to the environment temperature through a reversible, adiabatic change of state. Then heat transfer has to occur reversibly at the constant temperature T_{env}.

From the second law, (4.42), it follows for the heat transfer that

$$Q_{12} = T_{env}(S_2 - S_1) \,. \tag{4.45}$$

The work W_{12} done on the system consists of the maximum useful work and the moving boundary work $-p_{env}(V_2 - V_1)$, which is necessary to overcome the pressure of the environment. The maximum useful work is the exergy W_{ex}, thus it follows that

$$W_{12} = W_{ex} - p_{env}(V_2 - V_1) \,. \tag{4.46}$$

Inserting (4.45) and (4.46) into (4.44) gives

$$U_2 - U_1 = T_{env}(S_2 - S_1) + W_{ex} - p_{env}(V_2 - V_1) \,. \tag{4.47}$$

In state 2 the system is in equilibrium with the environment, denoted by the index 'env'. Thus, the exergy of the closed system is

$$-W_{ex} = U_1 - U_{env} - T_{env}(S_1 - S_{env}) + p_{env}(V_1 - V_{env}) \,. \tag{4.48}$$

For a constant-volume system it holds that $V_1 = V_{env}$ and the last term is cancelled. If the initial state of the system already is in equilibrium with the environment (state 1 = state env), according to (4.48) no work can be obtained.

Thus it holds that the internal energy of the environment cannot be transformed into exergy. Consequently, the enormous energies stored in the atmosphere surrounding us cannot be used to power vehicles.

4.5.2 Exergy of an Open System

The maximum shaft work, or the exergy from a mass flow, is obtained when the mass flow is brought reversibly into equilibrium with the environment by performing work and heat transfer with the environment. Neglecting changes of kinetic and potential energies, the first law for steady flow processes in open systems, (4.22), reads

$$-W_{ex} = H_1 - H_{env} - T_{env}(S_1 - S_{env}) \,. \tag{4.49}$$

This means that only a part of the enthalpy, H_1 reduced by $H_{env} + T_{env}(S_1 - S_{env})$, is transformed into shaft work. If the heat transfer from the environment to the mass flow, $T_{env}(S_1 - S_{env})$, is negative then the exergy exceeds the change in enthalpy by the fraction of this added heat.

4.5.3 Exergy and Heat Transfer

Figure 4.4 shows a device which is used to transform the heat transfer Q_{12} from an energy storage of temperature T into work W_{12}. The heat transfer Q_{env12}, which cannot be transformed into work, is rejected to the environment. The maximum shaft work is obtained if all changes in state are reversible. This maximum shaft work is equal to the exergy of the heat transfer. All changes in state are reversible if

$$\int_1^2 \frac{\mathrm{d}Q}{T} + \int_1^2 \frac{\mathrm{d}Q_{env}}{T_{env}} = 0$$

with $\mathrm{d}Q + \mathrm{d}Q_{env} + \mathrm{d}W_{ex} = 0$ according to the first law. The resulting exergy of the heat transfer to machines and apparatuses is

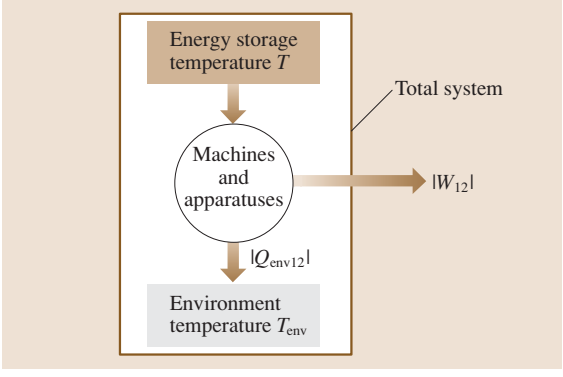

Fig. 4.4 Conversion of heat into work

$$-W_{ex} = \int_1^2 \left(1 - \frac{T_{env}}{T}\right) dQ \tag{4.50}$$

or in differential notation

$$-dW_{ex} = \left(1 - \frac{T_{env}}{T}\right) dQ\,. \tag{4.51}$$

In a reversible process only the fraction of the supplied heat transfer multiplied with the so-called Carnot factor $1-(T_{env}/T)$ can be transformed into work. The fraction $dQ_{env} = -T_{env}(dQ/T)$ has to be transferred to the environment and it is impossible to obtain it as work. This shows additionally that the heat transfer, which is available at ambient temperature, can not be transformed into exergy.

4.5.4 Anergy

Energy that cannot be converted into exergy W_{ex} is called anergy B. Each amount of energy consists of exergy W_{ex} and anergy B, i. e.,

$$E = W_{ex} + B\,. \tag{4.52}$$

Thus it holds that:

- For a closed system according to (4.48) with $E = U_1$

$$B = U_{env} + T_{env}(S_1 - S_{env}) - p_{env}(V_1 - V_{env}) \tag{4.53}$$

- For an open system according to (4.49) with $E = H_1$

$$B = H_{env} + T_{env}(S_1 - S_{env}) \tag{4.54}$$

- For heat transfer according to (4.51) with $dE = dQ$

$$B = \int_1^2 \frac{T_{env}}{T}\, dQ \tag{4.55}$$

4.5.5 Exergy Losses

The energy dissipated in a process is not lost completely. It increases the entropy, and because of $U(S, V)$, also the internal energy of a system. It is possible to think of the dissipated energy as heat transfer in a substitutional process, which is transferred from the outside ($d\Psi = dQ$) and causes the same entropy increase as in the irreversible process. Since the heat transfer dQ, (4.51), is partly transformable into work, the fraction

$$-dW_{ex} = \left(1 - \frac{T_{env}}{T}\right) d\Psi \tag{4.56}$$

of the dissipated energy $d\Psi$ can also be obtained as work (exergy). The remaining fraction $T_{env}\, d\Psi/T$ of the dissipated energy has to be transferred to the environment as heat transfer and is not transformable into work. This exergy loss is equal to the anergy of the dissipated energy and is, according to (4.55), given by

$$W_{loss12} = \int_1^2 \frac{T_{env}}{T}\, d\Psi = \int_1^2 T_{env}\, dS_i\,. \tag{4.57}$$

For a process in a closed, adiabatic system it holds that $dS_i = dS$ and thus

$$W_{loss12} = \int_1^2 T_{env}\, dS = T_{env}(S_2 - S_1)\,. \tag{4.58}$$

In contrast to energy, exergy does not follow a conservation equation. The exergy transferred to a system at steady state is equal to the sum of the exergy transferred from the system plus exergy losses. The thermodynamic effect of losses caused by irreversibilities is more unfavorable for lower temperatures T at which the process takes place; see (4.57).

4.6 Thermodynamics of Substances

In order to utilize the primary laws of thermodynamics, which are generally set up for any arbitrary substance, and to calculate exergies and anergies, it is necessary to determine actual numerical values for the properties U, H, S, p, V, and T. From these U, H, and S typically are called caloric, where p, V, and T are thermal properties. The relationships between properties depend on the corresponding substance. Equations that specify the relationships between the properties p, V, and T are called *equations of state*.

4.6.1 Thermal Properties of Gases and Vapors

An equation of state for pure substances is of the form

$$F(p, v, T) = 0 \tag{4.59}$$

or $p = p(v, T)$, $v = v(p, T)$, and $T = T(p, v)$. For calculations equations of state of the form $v = v(p, T)$ are preferred, as the pressure and temperature are usually the independent variables used to describe a system.

Ideal Gases

A particularly simple equation of state is that for ideal gases

$$pV = mRT \quad \text{or} \quad pv = RT, \tag{4.60}$$

which relates the absolute pressure p, the volume V, the specific volume v, the individual gas constant R, and the thermodynamic temperature T. A gas is assumed to behave as an ideal gas only when the pressure is sufficiently low compared to the critical pressure p_{cr} of the substance, i. e., $p/p_{cr} \to 0$.

Gas Constant and Avogadro's Law

As a measure of the amount of a given system, the *mole* is defined with the unit symbol mol. The amount of a substance is 1 mol when it contains as many identical elementary entities (i. e., molecules, atoms, elementary particles) as there are atoms in exactly 12 g of pure carbon-12.

The number of particles of the same type contained in a mole is called Avogadro's number (in German literature the number is sometimes referred to as Loschmidt's number). It has the numerical value

$$N_A = (6.02214199 \pm 4.7 \times 10^{-7}) \times 10^{26} \text{ /kmol} . \tag{4.61}$$

The mass of a mole (N_A particles of the same type) is a specific quantity for each substance and is referred to as the molar mass (see tab003-9 for values), which is given by

$$M = m/n \tag{4.62}$$

(SI unit kg/kmol, m mass in kg, n molar amount in kmol). According to Avogadro (1811), ideal gases contain an equal number of molecules at the same pressure and at the same temperature occupying equal spaces.

After introducing the molar mass into the equation of state for ideal gases, (4.60), it follows that $pV/nT = MR$ has a fixed value for all gases

$$MR = R_u, \tag{4.63}$$

where R_u is called the universal gas constant, and is a fundamental constant with the numerical value

$$R_u = 8.314472 \pm 1.5 \times 10^{-5}\ \text{kJ/kmol K}\,. \tag{4.64}$$

Incorporating R_u, the equation of state for ideal gases reads

$$pV = nR_uT\,. \tag{4.65}$$

Example 4.6: A gas bottle of volume $V_1 = 200\,\text{l}$ contains hydrogen at $p_1 = 120\,\text{bar}$ and $t_1 = 10\,°\text{C}$. What space is occupied by the hydrogen at $p_2 = 1\,\text{bar}$ and $t_2 = 0\,°\text{C}$, if the hydrogen is assumed to behave as an ideal gas? According to (4.65), $p_1V_1 = nRT_1$ and $p_2V_2 = nRT_2$; thus

$$V_2 = \frac{p_1T_2}{p_2T_1}V_1 = \frac{120\,\text{bar} \times 273.15\,\text{K}}{1\,\text{bar} \times 283.15\,\text{K}} 0.2\,\text{m}^3 = 23.15\,\text{m}^3\,. \tag{4.66}$$

Real Gases

The ideal gas equation of state is valid for real gases and vapors only as a limiting law at sufficiently low pressures. The deviation of the behavior of gaseous water from the ideal gas equation of state is shown in Fig. 4.5, in which pv/RT is displayed against t for different pressures. The real gas factor Z, where $Z = pv/RT$, is equal to 1 for ideal gases, but deviates from this value for real gases. For air between 0 °C and 200 °C, and for hydrogen between −15 °C and 200 °C, the deviations of Z from ideal gas behavior are approximately 1% at a pressure of 20 bar. At atmospheric pressure the deviations from the ideal gas law are negligible for nearly all gases. For cases where significant deviation is found from ideal gas behavior, different equations of state are established to describe the behavior of real gases. In one of the simplest forms, the real gas factor Z, a series of additive correction terms are used to modify its value from unity for the ideal gas case

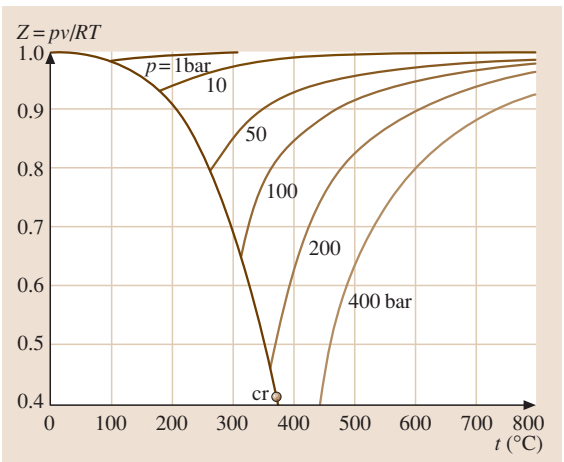

Fig. 4.5 The real gas factor of water vapor

$$Z = \frac{pv}{RT} = 1 + \frac{B(T)}{v} + \frac{C(T)}{v^2} + \frac{D(T)}{v^3}\,, \tag{4.67}$$

where B is called the second, C the third, and D the fourth virial coefficients. A compilation of second virial coefficients for many gases is provided by reference charts [4.7, 8]. The virial equation with two or three virial coefficients is only valid at moderate pressures. A balanced compromise between computational effort and achievable accuracy is given by the equation of state by Benedict–Webb–Rubin [4.9] for denser gases, which reads

$$Z = 1 + \frac{B(T)}{v} + \frac{C(T)}{v^2} + \frac{a\alpha}{v^5RT} + \frac{c}{v^3RT^2}\left(1 + \frac{\gamma}{v^2}\right)\exp\left(-\frac{\gamma}{v^2}\right)\,, \tag{4.68}$$

with

$$B(T) = B_0 - \frac{A_0}{RT} - \frac{C_0}{RT^3} \quad \text{and} \quad C(T) = b - \frac{a}{RT}\,.$$

The equation contains the eight constants A_0, B_0, C_0, a, b, c, α, and γ, which are available for many substances [4.9]. Highly exact equations of state are needed for the working substances water [4.10], air [4.11], and refrigerants [4.12] used in heat engines and refrigerators. The equations for these substances are more elaborate, contain more constants, and computer software is typically needed to utilize them.

Vapors

Vapors are gases which are close to saturation conditions and to condensation. A vapor is called *saturated* if the slightest temperature reduction leads to condensation, and *superheated* if a finite temperature reduction is necessary to obtain condensation. If heat is transferred to a liquid at constant pressure, the temperature of the liquid rises. When a certain temperature is reached,

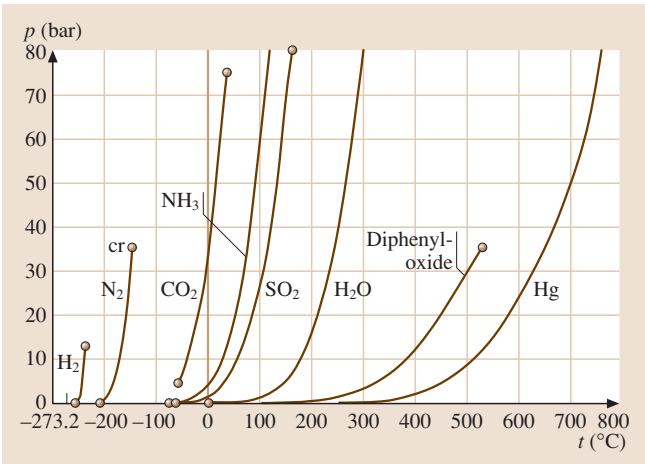

Fig. 4.6 Liquid–vapor saturation curves of some substances

vapor at the same temperature begins to be generated, where the vapor and liquid are in equilibrium. This state is called the saturation state. It is characterized by corresponding values for *saturation temperature* and *saturation pressure*. Their interdependence is described by the *liquid–vapor saturation curve* in Fig. 4.6. It starts at the triple point and ends at the critical point (cr) of a substance. Above the critical state p_{cr}, T_{cr}, vapor and liquid are no longer separated by a clear boundary but merge continuously (see Table 4.4). As with the triple point, at which vapor, liquid and solid phases of a substance are in equilibrium, every substance also has a characteristic critical point.

The vapor pressure of many substances is well approximated between the triple point and the boiling

point at atmospheric pressure by the Antoine equation

$$\ln p = A - \frac{B}{C+T}\,, \tag{4.69}$$

in which A, B, and C are the *Antoine coefficients* that vary from substance to substance (see Table 4.5). If superheated vapor is compressed at constant temperature by reducing the volume, the pressure increases similar to an ideal gas almost like a hyperbola, e.g., see the 300 °C isotherm in Fig. 4.7. Condensation starts as soon as the saturation pressure is reached, and the

volume is reduced without a pressure increase until all vapor is condensed. Any further volume reduction causes a considerable pressure increase. The band of curves in Fig. 4.7 is, as a graphical description of an equation of state, characteristic for many substances. Connecting the specific volumes of the liquid at saturation temperature before evaporation and of the saturated vapor, v' and v'', results in two curves a and b, called the *saturated liquid line* and the *saturated vapor line*, which meet at the critical point. With the steam quality x, defined as the mass of the saturated vapor m'' related to the total mass of saturated vapor m'' and saturated liquid m', and the specific volumes v' of the saturated liquid and v'' of the saturated vapor, it holds for wet steam that

$$v = xv'' + (1-x)v' \,. \tag{4.70}$$

Lines of constant x are shown in Fig. 4.7.

Example 4.7: 1000 kg saturated wet steam at 121 bar is in a vessel of 2 m^3 volume. How is the total mass distributed between liquid and vapor? An interpolation of the values in the saturated water table (Table 4.6) leads to the specific volumes $v' = 0.001530\,m^3/kg$ of saturated liquid and $v'' = 0.01410\,m^3/kg$ of saturated vapor at 121 bar. The average specific volume $v = V/m$ is $v = 2\,m^3/1000\,kg = 0.002\,m^3/kg$. Equation (4.70) gives

$$\begin{aligned} x &= (v-v')/(v''-v') \\ &= (0.002-0.001530)/(0.01410-0.001530) \\ &= 0.03739 \\ &= m''/m \,, \end{aligned}$$

and thus

$$\begin{aligned} m'' &= 1000 \times 0.03739\,kg = 37.39\,kg \,, \\ m' &= (1000-37.39)\,kg = 962.61\,kg \,. \end{aligned}$$

It also is possible to display the equation of state as a surface in space with coordinates p, v, and t (Fig. 4.8).

The two-dimensional diagrams in Figs. 4.6 and 4.7 are projections of this three-dimensional surface onto the respective planes.

4.6.2 Caloric Properties of Gases and Vapors

Ideal Gases

The internal energy of ideal gases depends only on temperature, $u = u(T)$, and thus also the enthalpy $h = u + pv = u + RT$ is solely a function of temperature, $h = h(T)$. The derivatives of u and h with respect to temperature are called *specific heats*. The specific heats are also functions of temperature and increase with temperature (see Table 4.8 for values of air).

$$du/dT = c_v \tag{4.71}$$

is the specific heat at constant volume and

$$dh/dT = c_p \tag{4.72}$$

the specific heat at constant pressure. The derivative of $h - u = RT$ is

$$c_p - c_v = R \,. \tag{4.73}$$

The difference of the molar specific heats $\overline{C}_p = Mc_p$ and $\overline{C}_v = Mc_v$ is equal to the universal gas constant

$$\overline{C}_p - \overline{C}_v = R_u \,.$$

The specific heat ratio $\varkappa = c_p/c_v$ plays an important role in reversible, adiabatic changes of state and is hence also called an *adiabatic exponent*.

For monatomic gases the specific heat ratio is fairly accurately $\varkappa = 1.66$, for diatomic gases $\varkappa = 1.40$, and

for triatomic gases $\varkappa = 1.30$. The average specific heat is the integral mean value defined by

$$[c_p]_{t_1}^{t_2} = \frac{1}{t_2 - t_1} \int_{t_1}^{t_2} c_p \, dt \,,$$

$$[c_v]_{t_1}^{t_2} = \frac{1}{t_2 - t_1} \int_{t_1}^{t_2} c_v \, dt \,. \qquad (4.74)$$

From (4.71) and (4.72) it follows for the change of internal energy and enthalpy that

$$u_2 - u_1 = [c_v]_{t_1}^{t_2}(t_2 - t_1) = [c_v]_0^{t_2} t_2 - [c_v]_0^{t_1} t_1 \qquad (4.75)$$

and

$$h_2 - h_1 = [c_p]_{t_1}^{t_2}(t_2 - t_1) = [c_p]_0^{t_2} t_2 - [c_p]_0^{t_1} t_1 \,. \qquad (4.76)$$

Numerical values for $[c_p]_0^t$ and $[c_v]_0^t$ can be determined from the average molar specific heats given in Table 4.8.

Taking into account (4.71) and (4.60), the specific entropy arises from (4.29) as

$$ds = \frac{du + p\,dv}{T} = c_v \frac{dT}{T} + R \frac{dv}{v} \,, \qquad (4.77)$$

or after integration with $c_v = \text{const.}$ as

$$s_2 - s_1 = c_v \ln \frac{T_2}{T_1} + R \ln \frac{v_2}{v_1} \,. \qquad (4.78)$$

The integration of (4.32) with constant c_p leads to the equivalent equation

$$s_2 - s_1 = c_p \ln \frac{T_2}{T_1} + R \ln \frac{p_2}{p_1} \,. \qquad (4.79)$$

Real Gases and Vapors

The caloric properties of real gases and vapors are usually determined by measurements, but it is also possible to derive them, apart from an initial value, from equation of states. They are displayed in tables and diagrams as $u = u(v, T)$, $h = h(p, T)$, $s = s(p, T)$, $c_v = c_v(v, T)$,

Table 4.8 Mean molar specific heats $[\bar{C}_p]_0^t$ of ideal gases in kJ/(kmolK) between 0 °C and t °C. The mean molar specific heat $[\bar{C}_v]_0^t$ is determined by subtracting the value of the universal gas constant 8.3143 kJ/(kmolK) from the numerical values given in the table. For the conversion to 1 kg the numerical values have to be divided by the molar weights given in the last line

and $c_p = c_p(p, T)$. Often computer software is necessary to analyze equations of state.

For vapors it holds that the enthalpy h'' of the saturated vapor differs from the enthalpy h' of the saturated boiling liquid at p, $T = \text{const.}$ by the enthalpy of vaporization

$$\Delta h_v = h'' - h' \,, \tag{4.80}$$

which decreases with increasing temperature and reaches zero at the critical point, where $h'' = h'$. The enthalpy of wet vapor is

$$h = (1-x)h' + xh'' = h' + x\Delta h_v \,. \tag{4.81}$$

Accordingly, the internal energy is

$$u = (1-x)u' + xu'' = u' + x(u'' - u') \tag{4.82}$$

and the entropy

$$s = (1-x)s' + xs'' = s' + x\Delta h_v/T \,, \tag{4.83}$$

because enthalpy of vaporization and entropy of vaporization $s'' - s'$ are related through

$$\Delta h_v = T(s'' - s') \,. \tag{4.84}$$

According to the Clausius–Clapeyron relation, the enthalpy of vaporization with gradient $\mathrm{d}p/\mathrm{d}T$ is connected to the liquid–vapor saturation curve $p(T)$ via

$$\Delta h_v = T(v'' - v')\frac{\mathrm{d}p}{\mathrm{d}T} \,, \tag{4.85}$$

with T being the saturation temperature at pressure p. This relationship can be used to calculate the remaining quantity when two out of the three quantities Δh_v, $v'' - v'$, and $\mathrm{d}p/\mathrm{d}T$ are known.

If properties do not have to be calculated continuously or if powerful computers are not available,

At the reference state $t = 0\,°C$ saturated liquid possesses the enthalpy $h' = 200.0\,kJ/kg$ and the specific entropy $s' = 1.0\,kJ/(kgK)$

saturated water tables, in which the results of theoretical and experimental investigations are collected, are used for practical calculations. Such tables are collected in Tables 4.6–4.13, for working fluids important in engineering. Diagrams are advantageous to determine reference values and to display changes of state, e.g., a t–s diagram as shown in Fig. 4.9. Most commonly used in practice are Mollier diagrams, which include the enthalpy as one of the coordinates, see Fig. 4.10.

The specific heat $c_p = (\partial h/\partial T)_p$ of vapor depends, as well as on temperature, also considerably on pressure. In the same way, $c_v = (\partial u/\partial T)_v$ depends, besides on temperature, also on the specific volume. Approaching the saturated vapor line, c_p of the superheated vapor increases considerably with decreasing temperature and tends toward infinity at the critical point. While $c_p - c_v$ is a constant for ideal gases, this is not true for vapors.

4.6.3 Incompressible Fluids

An incompressible fluid is a fluid whose specific volume depends neither on temperature nor on pressure, such that the equation of state is given by $v = \text{const}$. As a good approximation, liquids and solids can generally be considered as incompressible. The specific heats c_p and c_v do not differ for incompressible fluids, $c_p = c_v = c$. Thus the caloric equations of state are

$$\mathrm{d}u = c\,\mathrm{d}T \tag{4.86}$$

and

$$\mathrm{d}h = c\,\mathrm{d}T + v\,\mathrm{d}p\,, \tag{4.87}$$

as well as

$$\mathrm{d}s = c\frac{\mathrm{d}T}{T}\,. \tag{4.88}$$

4.6.4 Solid Materials

Thermal Expansion

Similar to liquids, the influence of pressure on volume in equations of state $V = V(p, T)$ for solids is mostly negligibly small. Nearly all solids expand like liquids with increasing temperature and shrink with decreasing temperature. An exception is water, which has its highest density at 4 °C and expands both at higher and lower temperatures than 4 °C. A Taylor-series expansion with respect to temperature of the equation of state, truncated after the linear term, leads to the volumetric expansion with the cubic volumetric expansion coefficient γ_V (SI unit 1/K)

$$V = V_0 \left[1 + \gamma_V (t - t_0)\right] .$$

Accordingly, the area expansion is

$$A = A_0 \left[1 + \gamma_A (t - t_0)\right]$$

and the length expansion

$$l = l_0 \left[1 + \gamma_L (t - t_0)\right] ,$$

where $\gamma_A = (2/3)\gamma_V$ and $\gamma_L = (1/3)\gamma_V$. Average values for γ_L in the temperature interval between 0 °C and t °C can be derived for some solids from the values in Table 4.14 by dividing the given length change $(l - l_0)/l_0$ by the temperature interval $t - 0\,°C$.

Melting and Sublimation Curve

Within certain limits, each pressure of a liquid corresponds to a temperature at which the liquid is in equilibrium with its solid. This relationship $p(T)$ is determined by the melting curve (Fig. 4.11), whereas the sublimation curve displays the equilibrium between gas and solid. Figure 4.11 includes additionally the liquid–vapor saturation curve. All three curves meet at the triple point at which the solid, the liquid, and the gaseous phase of a substance are in equilibrium with

Caloric Properties

During the freezing of a liquid the latent heat of fusion Δh_f is released (Table 4.15). At the same time the liquid entropy is reduced by $\Delta s_f = \Delta h_f / T_f$ with T_f being the melting or freezing temperature. According to the Dulong–Petit law the molar specific heat divided by the number of atoms in the molecule is, above ambient temperature, about 25.9 kJ/kmol K. If absolute zero is approached, this approximation rule is no longer valid. Therefore, the molar specific heat at constant volume is for all solids

$$\overline{C} = a(T/\Theta)^3, \quad \text{for} \quad T/\Theta < 0.1$$

with $a = 4782.5$ J/mol K and where Θ is the Debye temperature (Table 4.16).

4.6.5 Mixing Temperature. Measurement of Specific Heats

If several substances with different masses m_i, temperatures t_i, and specific heats c_{pi} ($i = 1, 2, \ldots$) are mixed at constant pressure without external heat supply, a mixing temperature t_m arises after a sufficient period of time. It is

$$t_m = \left(\sum m_i c_{pi} t_i\right) / \left(\sum m_i c_{pi}\right)$$

with c_{pi} being the mean specific heats between 0 °C and t °C. It is possible to calculate an unknown specific heat from the measured temperature t_m, if all other specific heats are known.

Example 4.8: A mass of $m_a = 0.2\,\mathrm{kg}$ aluminium at $t_a = 100\,^\circ\mathrm{C}$ is inserted into a thermally perfectly isolated calorimeter, which is filled with 0.8 kg water ($c_p = 4.186\,\mathrm{kJ/kg\,K}$) at 15 °C and which consists of 0.25 kg silver ($c_{ps} = 0.234\,\mathrm{kJ/kg\,K}$). After reaching equilibrium a mixing temperature of 19.24°*C* is measured. What is the specific heat of aluminium? Therefore,

$$t_m = \frac{(mc_p + m_s c_{ps})t + m_a c_{pa} t_a}{mc_p + m_s c_{ps} + m_a c_{pa}} ,$$

which resolves to

$$c_{pa} = \frac{(mc_p + m_s c_{ps})(t - t_m)}{m_a (t_m - t_a)} ,$$

$$c_{pa} = \left(0.8\,\mathrm{kg} \times 4.186 \frac{\mathrm{kJ}}{\mathrm{kgK}} + 0.25\,\mathrm{kg} \times 0.234 \frac{\mathrm{kJ}}{\mathrm{kgK}}\right) \times \frac{15\,^\circ\mathrm{C} - 19.24\,^\circ\mathrm{C}}{0.2\,\mathrm{kg}(19.24\,^\circ\mathrm{C} - 100\,^\circ\mathrm{C})} .$$

$$c_{pa} = 0.894\,\mathrm{kJ/kg\,K} .$$

4.7 Changes of State of Gases and Vapors

4.7.1 Change of State of Gases and Vapors in Closed Systems

A closed thermodynamic system has a fixed mass Δm. The following changes of state (constant volume, constant pressure, and constant temperature) are idealized limiting cases of real changes of state. The gas volume remains unchanged during changes of state at *constant volume* or *isochoric* changes of state, e.g., when a gas volume is in a container with solid, rigid walls. No work is done, and the supplied heat transfer causes only a change of internal energy. During a change of state at *constant pressure* or an *isobaric* change of state the gas volume has to increase if heat transfer is supplied. The supplied heat transfer increases the enthalpy during reversible changes of state. Changes of state at constant temperature are also called isothermal changes of state. Apart from a very few exceptions, heat has to be transferred to the gas during expansion and transferred from the gas during compression in order for the temperature to remain constant. For an ideal gas at constant temperature, the internal energy does not change, as $U(T) = \text{const.}$, thus the supplied heat transfer is equal to the work done by the system. The isotherm of an ideal gas ($pV = mRT = \text{const.}$) is a hyperbola in the *p–V* diagram.

During adiabatic changes of state there is no heat exchange between the system and its environment. The cases are approximately realized in compressors and expansion machines, because there the compression or expansion takes place in a very short period of time such that little heat transfer is exchanged with the environment during the change of state. According to the second law (see Sect. 4.4.3) the entire entropy change is caused by internal irreversibilities of the system, $\dot{S} = \dot{S}_{gen}$. A reversible adiabatic process proceeds at constant entropy $\dot{S} = 0$, where such a change of state is called isentropic. Thus, a reversible adiabatic process is at the same time also an isentropic process. However, an isentropic process is not necessarily also an adiabatic process, because from $\dot{S} = \dot{S}_Q + \dot{S}_{gen} = 0$ it does not always follow that $\dot{S}_Q = 0$.

Figure 4.13 shows the different changes of state in *p–V* and *T–S* diagrams. Additionally, the most important relationships for the properties of ideal gases are given.

An isothermal change of state requires perfect heat exchange, whereas no heat exchange at all with the environment must take place during an adiabatic change of state. Both cannot be achieved completely in reality. Therefore, a *polytropic* change of state is introduced via

$$pV^n = \text{const.} , \qquad (4.89)$$

and reversible adiabate ($n = \varkappa$). It holds further that

$$
\begin{aligned}
v_2/v_1 &= (p_1/p_2)^{1/n} = (T_1/T_2)^{1/(n-1)} \,, \\
W_{12} &= mR(T_2 - T_1)/(n-1) \\
&= (p_2V_2 - p_1V_1)/(n-1) \\

\end{aligned}
$$

and

$$
W_{t12} = nW_{12} \,. \qquad (4.91)
$$

The heat exchanged is

$$
Q_{12} = mc_v(n - \varkappa)(T_2 - T_1)/(n-1) \,. \qquad (4.92)
$$

Example 4.9: A compressed air system should deliver 1000 m^3_n compressed air of 15 bar per hour (note: 1 m^3_n = 1 standard cubic meter for a gas volume at 0 °C and 1.01325 bar). The air inlet is at a pressure of $p_1 = 1$ bar and a temperature $t_1 = 20$ °C. The adiabatic exponent of air is $\varkappa = 1.4$. How much power is required, if the compression is polytropic with $n = 1.3$? What heat transfer rate has to be exchanged for this process?

The inlet air volume flow is, as given in the requirements, 1000 m^3 at 0 °C and 1.01325 bar,

$$
\begin{aligned}
\dot{V}_1 &= \frac{p_0T_1}{p_1T_0}\dot{V}_0 \\
&= \frac{1.01325 \times 293.15}{1 \times 273.15} 1000 \, \frac{\mathrm{m}^3}{\mathrm{h}} \\
&= 1087.44 \, \frac{\mathrm{m}^3}{\mathrm{h}} \,.
\end{aligned}
$$

For polytropic changes of state, Eqs. (4.91) and (4.90) yield

$$P = \dot{W}_t = \frac{n p_1 \dot{V}_1}{n-1}\left[\left(\frac{p_2}{p_1}\right)^{\frac{n-1}{n}} - 1\right]$$
$$= \frac{1.3 \times 10^5 \frac{\mathrm{N}}{\mathrm{m}^2} 1087.44 \frac{\mathrm{m}^3}{\mathrm{h}}}{1.3-1}\left(15^{\frac{1.3-1}{1.3}} - 1\right)$$
$$= 113.6\,\mathrm{kW}\,.$$

According to (4.91) and (4.92),

$$\frac{Q_{12}}{W_{t12}} = \frac{\dot{Q}}{P} = c_v \frac{n-\varkappa}{nR}$$

or, since $R = c_p - c_v$ and $\varkappa = c_p/c_v$

$$\frac{\dot{Q}}{P} = \frac{1}{n}\frac{n-\varkappa}{\varkappa-1}\,.$$

Thus, $\dot{Q} = \frac{1}{1.3}\frac{1.3-1.4}{1.4-1} 113.6\,\mathrm{kW} = -21.85\,\mathrm{kW}$.

4.7.2 Changes of State of Flowing Gases and Vapors

In order to describe the flow of a fluid mass Δm, in addition to the thermodynamic properties, the size and direction of the velocity everywhere in the field are also required. The following discussion is limited to steady flows in channels with constant, diverging, or converging cross sections.

In addition to the first and the second law the conservation of mass law holds

$$\dot{m} = A w \varrho = \text{const.} \qquad (4.93)$$

For a flow that does no work on the environment the first law, (4.21), is reduced to

$$\Delta m(h_2 - h_1) + \Delta m\left(\frac{w_2^2}{2} - \frac{w_1^2}{2}\right) + \Delta m g(z_2 - z_1)$$
$$= Q_{12}\,, \qquad (4.94)$$

regardless of whether the flow is reversible or irreversible. Neglecting changes in potential energy, it holds that for an adiabatic flow

$$h_2 - h_1 + \frac{w_2^2}{2} - \frac{w_1^2}{2} = 0\,. \qquad (4.95)$$

Thus, the increase in kinetic energy is equal to the decrease in enthalpy of the fluid. For an adiabatic throttle process, it follows from (4.93), provided A, $\varrho = \text{const.}$, that $w = \text{const.}$ and thus from (4.95) that $h_1 = h_2 = \text{const}$. The pressure reduction in an adiabatic throttle process is accompanied by an entropy increase, since the process is irreversible. According to (4.32), the enthalpy change in a reversible adiabatic flow is caused by a change in pressure, $\mathrm{d}h = v\,\mathrm{d}p$.

Flow of Ideal Gases

Applying (4.95) to an ideal gas exiting a vessel (Fig. 4.14), in which the gas in the vessel possesses

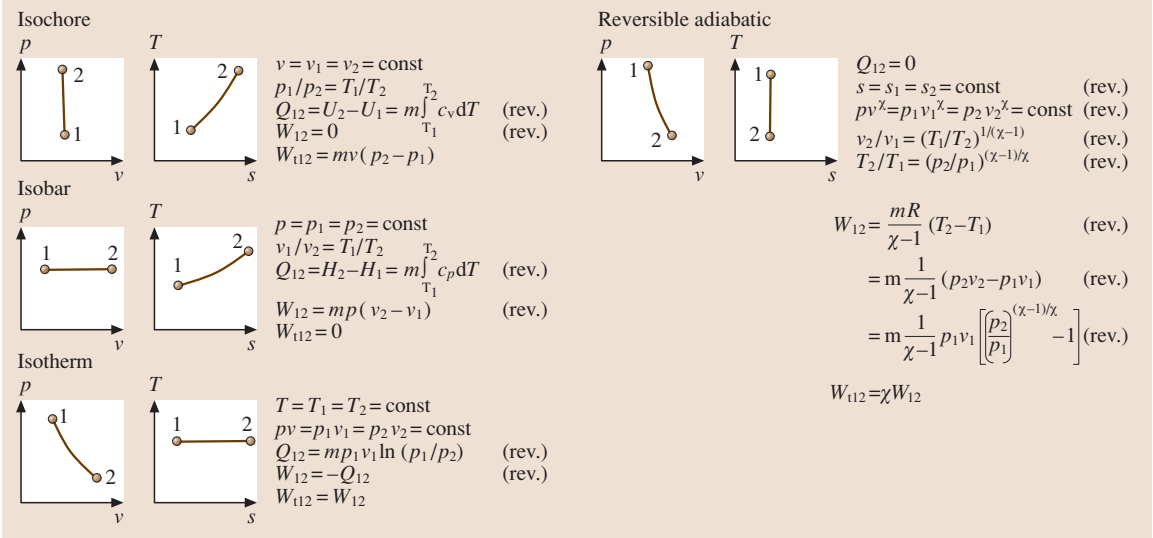

Fig. 4.13 Changes of state of ideal gases. The (rev.) denotes that the change of state is reversible.

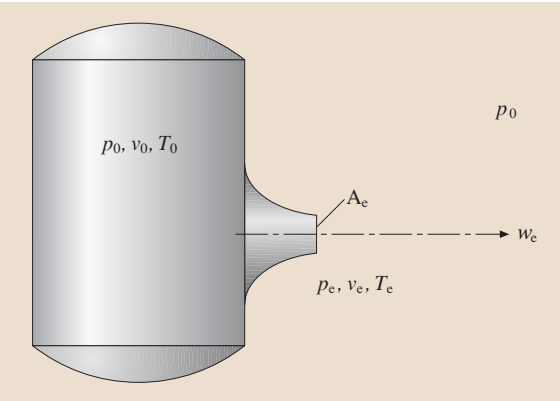

Fig. 4.14 Flow out of a pressure vessel

the constant state p_0, v_0, T_0 with $w_0 = 0$, and where $h_e - h_0 = c_p(T_e - T_0)$, $w_0 = 0$, leads to

$$\frac{w_e^2}{2} = c_p(T_0 - T_e) = c_p T_0\left(1 - \frac{T_e}{T_0}\right).$$

For a reversible adiabatic change of state, according to (4.90), $T_e/T_0 = (p_e/p_0)^{(\varkappa-1)/\varkappa}$. Additionally, it holds that $T_0 = p_0 v_0/R$ according to (4.60) and $c_p/R = \varkappa/(\varkappa - 1)$ according to (4.73). Thus, the exit velocity is given by

$$w_e = \sqrt{2\frac{\varkappa}{\varkappa - 1} p_0 v_0 \left[1 - \left(\frac{p_e}{p_0}\right)^{\frac{\varkappa-1}{\varkappa}}\right]}. \qquad (4.96)$$

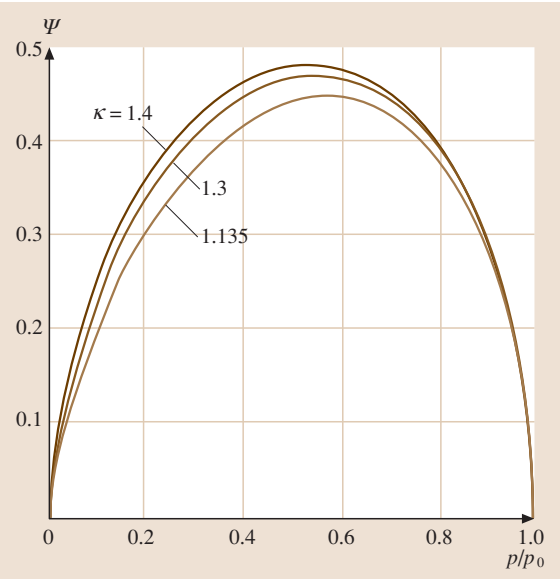

Fig. 4.15 Outlet function Ψ

Taking into account $p_0 v_0^* = p_e v_e^*$, the out-flowing mass $\dot{m} = A_e w_e / v_e$ is

$$\dot{m} = A\Psi\sqrt{2p_0/v_0} \qquad (4.97)$$

with the outlet function

$$\Psi = \sqrt{\frac{\varkappa}{\varkappa - 1}}\sqrt{\left(\frac{p}{p_0}\right)^{\frac{2}{\varkappa}} - \left(\frac{p}{p_0}\right)^{\frac{\varkappa+1}{\varkappa}}}. \qquad (4.98)$$

The result is a function of the adiabatic exponent $\varkappa$ and of the pressure ratio p/p_0 (Fig. 4.15) and has a maximum Ψ_{max}, which can be determined from evaluating $d\Psi/d(p/p_0) = 0$. This maximum corresponds to a specific pressure ratio that is called the *Laval pressure ratio*

$$\frac{p_s}{p_0} = \left(\frac{2}{\varkappa + 1}\right)^{\frac{\varkappa}{\varkappa-1}}. \qquad (4.99)$$

At this pressure ratio

$$\Psi_{max} = \left(\frac{2}{\varkappa + 1}\right)^{\frac{1}{\varkappa-1}}\sqrt{\frac{\varkappa}{\varkappa + 1}}. \qquad (4.100)$$

Corresponding to this pressure ratio, according to (4.96) with $p_e/p_0 = p_s/p_0$ and a velocity $w_e = w_s$, is the relation

$$w_s = \sqrt{2\frac{\varkappa}{\varkappa + 1} p_0 v_0} = \sqrt{\varkappa p_s v_s} = \sqrt{\varkappa R T_s}. \qquad (4.101)$$

This is equal to the sonic velocity in state p_s, v_s. Generally, the sonic velocity is the velocity at which pressure and density fluctuations are transmitted. For reversible adiabatic changes of state it is given by

$$w_s = \sqrt{(\partial p/\partial \varrho)_s}.$$

Thus, for ideal gases it takes on the value $w_s = \sqrt{\varkappa RT}$, where the sonic velocity is a property.

Example 4.10: A steam boiler produces 10 t of saturated vapor at $p_0 = 15$ bar. The vapor may be treated as an ideal gas ($\varkappa = 1.3$). How large must the cross section of the safety relief valve be in order to be able to discharge the entire vapor mass flow?

Since the out-flowing mass $\dot{m}$ is constant in every cross section, it follows from (4.97) that $A\Psi = \text{const.}$ as well. As the discharge flow area is decreased, A decreases, and Ψ increases, reaching at most the value Ψ_{max}. Then the back pressure is less than or equal to the Laval pressure. In the present case the back pressure of the atmosphere, $p = 1$ bar, is less than the Laval pressure, which is

calculated with (4.99) to be 8.186 bar. With this result the required cross section follows from (4.97), if $\Psi = \Psi_{max} = 0.472$ according to (4.100) is inserted. With $\dot{m} = 10 \times 10^3 \times (1/3600)\,kg/s = 2.7778\,kg/s$ and $v_0 = v'' = 0.1317\,m^3/kg$ (according to Table 4.9 at $p_0 = 15$ bar) it follows from (4.97) that $A = 12.33\,cm^2$. Because of the jet's contraction, where the size depends on the design of the valve, an increase should be added.

Jet and Diffusion Flow

As shown in Fig. 4.16, for a given adiabatic exponent $\varkappa$ a certain pressure ratio p/p_0 corresponds to a specific value of the outlet function Ψ. Since the mass flow $\dot{m}$ is constant in each cross section, it follows from (4.97) that also $A\Psi = \text{const}$. Thus, it is possible to assign to each pressure ratio a certain cross section A; see Fig. 4.16. Two cases have to be distinguished:

a) The pressure decreases in the flow direction. The curves Ψ, A, and w in Fig. 4.16 are passed through from right to left. At first the cross section A decreases, then it increases again. The velocity increases and goes from subsonic to supersonic. The kinetic energy of the flow increases. Such an apparatus is called a nozzle. In a nozzle that operates only in the subsonic regime the cross section decreases continuously, whereas it increases in the supersonic regime. In a nozzle narrowing in the flow direction the pressure at the outlet cross section cannot decrease below the Laval pressure, even if the outside pressure is arbitrarily small. This follows from $A\Psi = \text{const}$. Since A decreases in the flow direction, Ψ can only increase, reaching at most the value Ψ_{max} to which the Laval pressure ratio corresponds.
If the pressure at the outlet cross section of a nozzle is reduced below the pressure value corresponding to the outlet cross section, the jet expands after leaving the nozzle. If the back pressure is increased above the correct value, the pressure increase moves upstream where in this case the gas exits with subsonic velocity. If the gas exits with sonic, or in a diverging nozzle with supersonic velocity, a shock occurs at the nozzle outlet and the pressure increases to the pressure of the environment.

b) The pressure increases in the flow direction. The curves Ψ, A, and w in Fig. 4.16 are passed through from left to right. At first the cross section decreases, then increases again. The velocity decreases from supersonic to subsonic, and the kinetic energy decreases while the pressure increases. Such an apparatus is called a diffuser. In a diffuser that works only in the subsonic regime the cross section increases continuously, whereas it decreases in the supersonic regime.

4.8 Thermodynamic Processes

4.8.1 Combustion Processes

Heat transfer for technical processes is still mostly obtained through combustion. Combustion is a chemical reaction during which a substance, e.g., carbon, hydrogen, or hydrocarbons, is oxidized and which is strongly exothermic, i. e., a large quantity of heat is released. Fuels can be solid, liquid, or gaseous. The required oxygen is mostly provided by atmospheric air. To start a combustion process the fuel must be brought above its ignition temperature, which, in turn, varies according to the type of fuel being used. The main components of all important technical fuels are carbon C, and hydrogen H. In addition, oxygen O, and, with the exception of natural gas, a certain amount of sulfur are also present. Sulfur reacts during a combustion process to produce the unwanted compound sulfur dioxide SO_2.

Equations of Reactions

The elements H, C, and S, which are contained in fuels as mentioned above, are burned to CO_2, H_2O, and SO_2, if complete combustion takes place. The equation of reaction leads to the required amount of oxygen and to the resulting amount of each product in the exhaust gas. For the combustion of carbon C it holds that

$$\begin{aligned} \mathrm{C} + \mathrm{O_2} &= \mathrm{CO_2}\,, \\ 1\,\mathrm{kmol\ C} + 1\,\mathrm{kmol\ O_2} &= 1\,\mathrm{kmol\ CO_2}\,, \\ 12\,\mathrm{kg\ C} + 32\,\mathrm{kg\ O_2} &= 44\,\mathrm{kg\ CO_2}\,. \end{aligned}$$

From this it follows that the minimum oxygen demand for complete combustion is

$$o_{\min} = 1/12\,\mathrm{kmol/kg\ C}$$

or

$$O_{\min} = 1\,\mathrm{kmol/kmol\ C}.$$

The minimum air demand for complete combustion is called the *theoretical air* and results from the oxygen fraction of 21 mol% in air

$$l_{\min} = (o_{\min}/0.21)\ \mathrm{kmol\ air\,/\,kg\ C}$$

or

$$L_{\min} = (O_{\min}/0.21)\ \mathrm{kmol\ air\,/\,kmol\ C}\,.$$

The amount of CO_2 in the exhaust gas is $(1/12)$ kmol/kg C. Similarly, the equations of reaction for the combustion of hydrogen H_2 and sulfur S are

$$\begin{aligned} \mathrm{H_2} + 1/2\,\mathrm{O_2} &= \mathrm{H_2O}\,, \\ 1\,\mathrm{kmol\ H_2} + 1/2\,\mathrm{kmol\ O_2} &= 1\,\mathrm{kmol\ H_2O}\,, \\ 2\,\mathrm{kg\ H_2} + 16\,\mathrm{kg\ O_2} &= 18\,\mathrm{kg\ H_2O}\,, \end{aligned}$$

$$\begin{aligned} \mathrm{S} + \mathrm{O_2} &= \mathrm{SO_2}\,, \\ 1\,\mathrm{kmol\ S} + 1\,\mathrm{kmol\ O_2} &= 1\,\mathrm{kmol\ SO_2}\,, \\ 32\,\mathrm{kg\ S} + 32\,\mathrm{kg\ O_2} &= 64\,\mathrm{kg\ SO_2}\,. \end{aligned}$$

Denoting the carbon, hydrogen, sulfur, and oxygen fractions by c, h, s, and o in kg per kg fuel, according to the above calculations, the minimum oxygen demand becomes

$$o_{\min} = \left(\frac{c}{12} + \frac{h}{4} + \frac{s}{32} - \frac{o}{32}\right)\mathrm{kmol/kg}\,, \qquad (4.102)$$

or for short

$$o_{\min}\frac{1}{12}c\sigma\ \mathrm{kmol/kg}\,, \qquad (4.103)$$

where σ is a characteristic of the fuel (O_2 demand in kmol related to the kmol C in the fuel). The actual air demand (related to 1 kg fuel) is

$$l = \lambda l_{\min} = (\lambda o_{\min}/0.21)\ \mathrm{kmol\ air/kg}\,, \qquad (4.104)$$

where λ is the excess air number. In addition to the combustion products CO_2, H_2O, and SO_2, exhaust gases also ordinarily contain water with a content of $w/18$ (SI units of kmol per kg fuel), and the supplied combustion air l less the spent oxygen $o_{\min}$. The supplied combustion air is therefore assumed to be dry or it is assumed that the water vapor content is negligibly small. The following exhaust amounts, related to 1 kg of fuel, are given by

$$\begin{aligned} n_{\mathrm{CO_2}} &= c/12\,, \\ n_{\mathrm{H_2O}} &= h/2 + w/18\,, \\ n_{\mathrm{SO_2}} &= s/32\,, \\ n_{\mathrm{O_2}} &= (\lambda - 1)o_{\min}\,, \\ n_{\mathrm{N_2}} &= 0.791\,. \end{aligned}$$

The sum is the total exhaust amount

$$n_{\mathrm{exh}} = \left[c/12 + h/2 + w/18 + s/32 + (\lambda - 1)o_{\min} + 0.791\right]\mathrm{kmol/kg}.$$

Table 4.18 Net calorific values of the simplest fuels at 25 °C and 1.01325 bar

	C	CO	H_2 (gross calorific value)	H_2 (net calorific value)	S
kJ/kmol	393 510	282 989	285 840	241 840	296 900
kJ/kg	32 762	10 103	141 800	119 972	9260

This can be simplified by using (4.102) and (4.104) to yield

$$n_{exh} = \left[l + \frac{1}{12}\left(3h + \frac{3}{8}o + \frac{2}{3}w\right)\right] \text{ kmol/kg} . \tag{4.105}$$

Example 4.11: 500 kg coal with the composition $c = 0.78$, $h = 0.05$, $o = 0.08$, $s = 0.01$, and $w = 0.02$ and an ash content $a = 0.06$ are completely burned per hour in a furnace with excess air number $\lambda = 1.4$. How much air is necessary, how much exhaust arises, and what is its composition?

The minimum oxygen demand is determined according to (4.102)

$$o_{min} = \left(\frac{0.78}{12} + \frac{0.05}{4} + \frac{0.01}{32} - \frac{0.08}{32}\right) \text{kmol/kg}$$
$$= 0.0753 \text{ kmol/kg} .$$

The minimum air demand is

$$l_{min} = o_{min}/0.21 = 0.3586 \text{ kmol/kg} .$$

The amount of air that has to be supplied is

$$l = \lambda l_{min} = 1.4 \times 0.3586 = 0.502 \text{ kmol/kg} .$$

Thus $0.502 \text{ kmol/kg} \times 500 \text{ kg/h} = 251 \text{ kmol/h}$. With the molar mass of air $M = 28.953$ kg/kmol, the air demand becomes $0.502 \times 28.953 \text{ kg/kg} = 14.54 \text{ kg/kg}$. Thus, $14.54 \text{ kg/kg} \times 500 \text{ kg/h} = 7270 \text{ kg/h}$. The exhaust amount is determined according to (4.105)

$$n_{exh} = (0.502 + 1/12(3 \times 0.05 + 3/8 \times 0.08$$
$$+ 2/3 \times 0.02)) \text{ kmol/kg}$$
$$= 0.518 \text{ kmol/kg} .$$

Thus $0.581 \text{ kmol/kg} \times 500 \text{ kg/h} = 259 \text{ kmol/h}$ with 0.065 kmol CO_2/kg, 0.0261 kmol H_2O/kg, 0.0003 kmol SO_2/kg, 0.3966 kmol N_2/kg and 0.0301 kmol O_2/kg.

Net Calorific Value and Gross Calorific Value

The net calorific value is the energy released during combustion, if the exhaust gases are cooled down to the temperature at which the fuel and air are supplied. Water is included in the exhaust gases as vapor. If the water vapor is condensed, the released heat is called the gross calorific value. Net and gross calorific values are specified, according to DIN 51900, for combustion at atmospheric pressure, if all involved substances possess a temperature of 25 °C before and after combustion. Net and gross calorific values (Tables 4.18–4.20) are independent of the amount of excess air and are only a characteristic of the fuel. The gross calorific value Δh_{gcv} exceeds the net calorific value Δh_{ncv} by the enthalpy of vaporization Δh_v of the water included in the exhaust gas

$$\Delta h_{gcv} = \Delta h_{ncv} + (8.937h + w)\, \Delta h_v .$$

Because the water leaves technical furnaces mostly as vapor, often only the net calorific value can be utilized. The net calorific value of heating oil can be expressed quite well, as experience shows [4.19], by the equation

$$\Delta h_{ncv} = (54.04 - 13.29\varrho - 29.31s) \text{ MJ/kg} , \tag{4.106}$$

where the density ϱ of the heating oil in kg/dm^3 is at 15 °C and the sulfur content s is in kg/kg.

Example 4.12: What is the net calorific value of a light heating oil with a density of $\varrho = 0.86$ kg/dm^3 and a sulfur content of $s = 0.8$ mass%? According to (4.106)

$$\Delta h_{ncv} = (54.04 - 13.29 \times 0.86$$
$$- 29.31 \times 0.8 \times 10^{-2}) \text{ MJ/kg}$$
$$= 42.38 \text{ MJ/kg} .$$

Combustion Temperature

The theoretical combustion temperature is the temperature of the exhaust gas at complete isobar-adiabatic combustion if no dissociation takes place. The heat released during combustion increases the internal energy and thus the temperature of the gas, which provides the basis for doing flow work. The theoretical combustion temperature is calculated under the condition that the enthalpy of all substances transferred to the combustion

$$\Delta h_{\mathrm{ncv}}\left[c_{\mathrm{fuel}}\right]_{25\,^\circ\mathrm{C}}^{t_{\mathrm{fuel}}}(t_{\mathrm{fuel}}-25\,^\circ\mathrm{C}) + l\left[\overline{C}_{p\,\mathrm{air}}\right]_{25\,^\circ\mathrm{C}}^{t_{\mathrm{air}}}(t_{\mathrm{air}}-25^\circ\mathrm{C}) = n_{\mathrm{exh}}\left[\overline{C}_{p\,\mathrm{exh}}\right]_{25\,^\circ\mathrm{C}}^{t}(t-25\,^\circ\mathrm{C})\,. \quad (4.107)$$

This equation includes the temperatures t_{fuel} of the fuel and t_{air} of the air, the theoretical combustion temperature t, the mean specific heat $\left[c\right]_{25\,^\circ\mathrm{C}}^{t_{\mathrm{fuel}}}$ of the fuel, and the mean specific heats $\left[\overline{C}_{p\,\mathrm{air}}\right]_{25\,^\circ\mathrm{C}}^{t_{\mathrm{air}}}$ of air and $\left[\overline{C}_{p\,\mathrm{exh}}\right]_{25\,^\circ\mathrm{C}}^{t}$ of the exhaust gas. The latter consists of the mean molar specific heats of the single

components

$$n_{\text{exh}}\left[\overline{C}_{p\,\text{exh}}\right]_{25\,^\circ\text{C}}^{t} = \frac{c}{12}\left[\overline{C}_{p\text{CO}_2}\right]_{25\,^\circ\text{C}}^{t} + \left(\frac{h}{2}+\frac{w}{18}\right)\left[\overline{C}_{p\text{H}_2\text{O}}\right]_{25\,^\circ\text{C}}^{t} + \frac{s}{32}\left[\overline{C}_{p\text{SO}_2}\right]_{25\,^\circ\text{C}}^{t} + (\lambda-1)\,o_{\min}\left[\overline{C}_{p\text{O}_2}\right]_{25\,^\circ\text{C}}^{t} + 0.79l\left[\overline{C}_{p\text{N}_2}\right]_{25\,^\circ\text{C}}^{t}\,. \quad (4.108)$$

The theoretical combustion temperature must be determined iteratively from (4.107) and (4.108). The actual combustion temperature is, even with complete combustion of the fuel, lower than the theoretical combustion temperature due to heat transfer to the environment, mainly by radiation. Also lowering the combustion temperature is the break-up of molecules (dissociation) starting above 1500 °C and the considerable dissociation above 2000 °C. The dissociation heat is released again when the temperature decreases below the dissociation temperature.

4.8.2 Internal Combustion Cycles

In internal combustion cycles, the combustion gas serves as a working fluid. It does not operate through a closed process but is discharged as exhaust gas to the environment after performing work in a turbine or a piston engine. Open gas turbine cycles and internal combustion engines (Otto and Diesel), as well as fuel cells, are internal combustion cycles. The quality of the energy transformation is assessed by the total energy efficiency

$$\eta = -P/(\dot{m}_{\text{fuel}}\Delta h_{\text{ncv}})\,,$$

where P is the power output of the cycle, $\dot{m}$ is the mass flow rate of the supplied fuel, and Δh_{ncv} is its net calorific value. The total exergetic efficiency $\xi = -P/(\dot{m}_{\text{fuel}} w_{\text{ex,fuel}})$ specifies what fraction of the exergy flow coming with the fuel is transformed into power output. Generally, w_{ex} is only slightly larger than the net calorific value, and η and ξ thus hardly differ in their numerical values. The typical total efficiency is approximately 42% for large engines (Diesel), 25% for automotive engines, and 20–30% for open gas turbine cycles.

Open Gas Turbine Cycle

In an open gas turbine plant, the inlet air is brought to a high pressure through a compressor, then preheated and heated in a combustion chamber via the combustion of the injected fuel. The combustion gases pass through a turbine, in which they do work (against the blades). The gas exiting the turbine is used to preheat the combustion air in a heat exchanger, and is then discharged into the environment. The compressor and turbine are placed on the same shaft. The power output is transformed into electric energy by a generator, which is connected to the shaft.

Otto Engine

Figure 4.17 shows the cycle of an Otto engine in p–V and T–S diagrams. At the end of the intake stroke, the cylinder is filled with a combustible fresh air–fuel

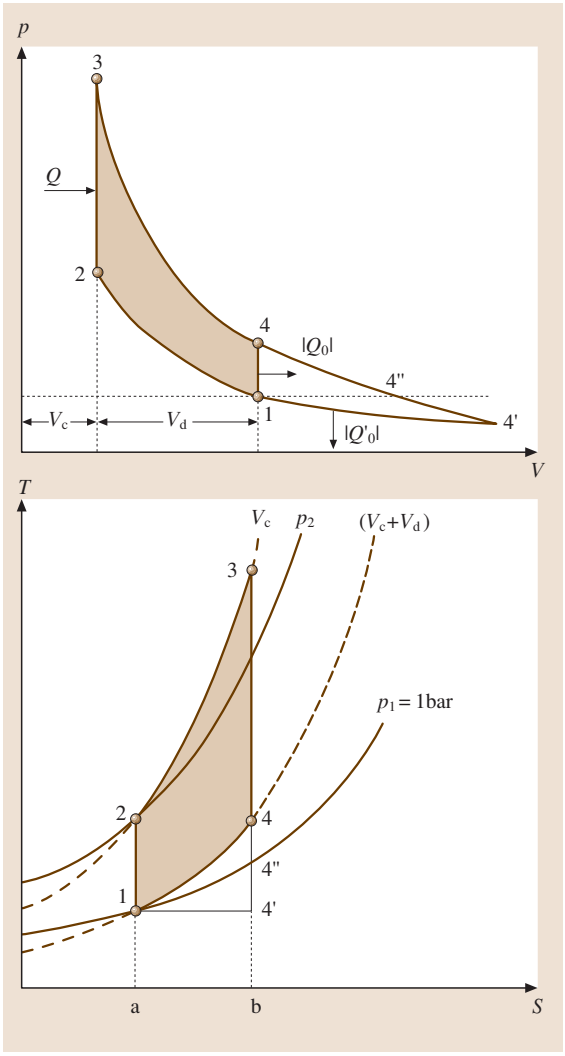

Fig. 4.17 Theoretical process of the Otto engine on p–V and the T–S diagrams

mixture of state 1 at the environment temperature and atmospheric pressure. The mixture is compressed along the adiabate 1–2 from the initial volume $V_c + V_d$ to the compression volume V_c where V_d is the displacement volume. At the top dead center 2, combustion is initiated by electric spark ignition, whereby the pressure rises from state 2 to state 3. This change of state takes place so quickly that it can be assumed to be isochoric. In Fig. 4.17 (simplifying) it is assumed that the gas is not changed and that the heat released during combustion $Q_{23} = Q$ is supplied from the outside. The gas expands along the adiabatic 3–4–4"–4' and forces the piston to return. The exhaust beginning in state 4 is substituted by the removal of energy by heat transfer $|Q_0|$ at constant volume, whereas the pressure decreases from state 4 to state 1. In state 1, the combustion gases have to be replaced by a new mixture. In order to do so, twin stroke (not shown) is necessary in a four-stroke Otto engine.

The heat transfer to the gas is

$$Q = Q_{23} = mc_v(T_3 - T_2) \tag{4.109}$$

and from the gas is

$$|Q_0| = |Q_{41}| = mc_v(T_4 - T_1)\,. \tag{4.110}$$

The work is

$$|W_t| = Q - |Q_0|\ , \tag{4.111}$$

and the thermal efficiency is given by

$$\eta = \frac{|W_t|}{Q} = 1 - \frac{T_4 - T_1}{T_3 - T_2} = 1 - \frac{T_1}{T_2}$$
$$= 1 - \left(\frac{p_1}{p_2}\right)^{\frac{\varkappa-1}{\varkappa}} = 1 - \frac{1}{\varepsilon^{\varkappa-1}}\,. \tag{4.112}$$

The compression ratio $\varepsilon = V_1/V_2 = (V_c + V_d)/V_c$ specifies the degree of adiabatic compression of the mixture. Thus, the thermal efficiency depends, except for the adiabatic exponent, only on the pressure ratio p_2/p_1 or the compression ratio ε and not on the amount of energy supplied by heat transfer. The compression ratio is limited by the self-ignition temperature of the fuel–air mixture.

Diesel Engine

The limitation to moderate compression ratios and pressures does not exist for the Diesel engine, in which the high compression heats the combustion air above the self-ignition temperature of the fuel that is injected into the hot air. Figure 4.18 shows the simplified process of the Diesel engine. It consists of the adiabatic compression 1–2 of the combustion air, isobaric combustion 2–3' after the injection of the fuel into the hot, compressed combustion air, adiabatic relaxation 3'–4, and ejection 4–1 of the exhaust gases, which is replaced in Fig. 4.18 by an isochore with heat removal. The supplied heat transfer is

$$Q_{23'} = Q = mc_p(T_{3'} - T_2) \tag{4.113}$$

and the removed heat transfer is

$$|Q_{41}| = |Q_0| = mc_v(T_4 - T_1) \tag{4.114}$$

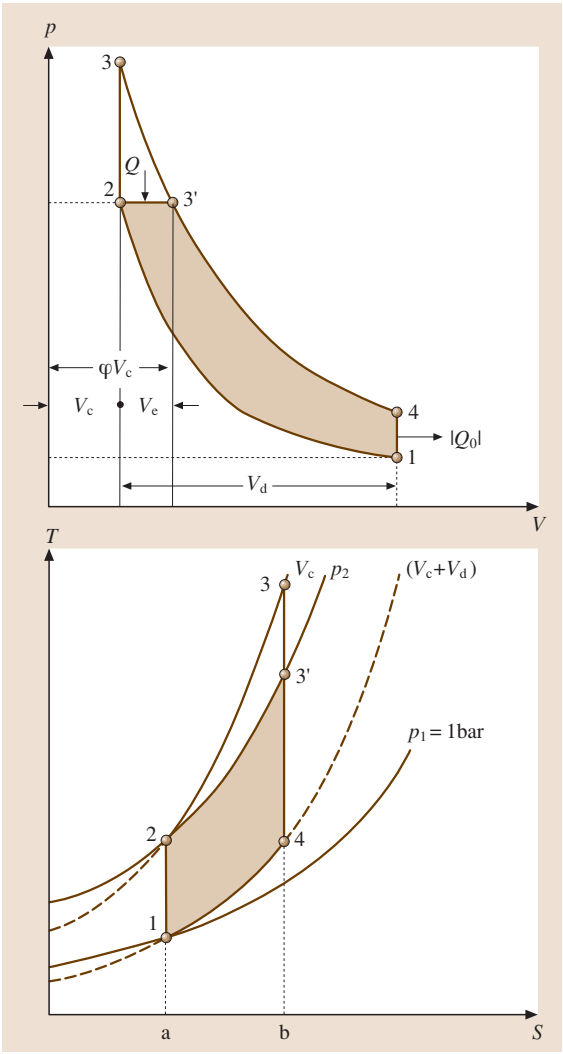

Fig. 4.18 Theoretical process of the Diesel engine on p–V and T–S diagrams

during the imaginary isochore 4–1. The work is given by

$$|W_t| = Q - |Q_0|$$

and the thermal efficiency by

$$\eta = \frac{|W_t|}{Q} = 1 - \frac{1}{\varkappa}\frac{T_4 - T_1}{T_{3'} - T_2} = 1 - \frac{1}{\varkappa}\frac{\frac{T_4}{T_3}\frac{T_3}{T_2} - \frac{T_1}{T_2}}{\frac{T_{3'}}{T_2} - 1} . \tag{4.115}$$

With the compression ratio $\varepsilon = V_1/V_2 = (V_c + V_d)/V_c$ and the cutoff ratio $\varphi = (V_c + V_e)/V_c$, the following equation for the thermal efficiency results

$$\eta = 1 - \frac{1}{\varkappa\,\varepsilon^{\varkappa-1}}\frac{\varphi^{\varkappa} - 1}{\varphi - 1} . \tag{4.116}$$

The thermal efficiency of the Diesel cycle depends, except for the adiabatic exponent, only on the compression ratio ε and on the cutoff ratio φ, which increases with increasing load.

Fuel Cells

In a fuel cell, hydrogen reacts electrochemically with oxygen to produce water

$$H_2 + \frac{1}{2}O_2 \rightarrow H_2O .$$

In this so-called cold combustion, the chemical bond energy is transformed directly into electrical energy. Figure 4.19 shows, as an example, a fuel cell with a proton conductive electrolyte, where hydrogen is supplied at the side of the anode. With the help of a catalyst, it is decomposed into two protons (H^+) and two electrons (e^-). The electrons move through a load, e.g., a motor, to the cathode. The protons move through the electrolyte to the cathode, where they, supported by a catalyst, react with the supplied oxygen, O_2, and the electrons to produce water, H_2O. There is a voltage U between the anode and cathode, and the electric current $I = F\dot{n}_{el}$ with $\dot{n}_{el} = 2\dot{n}_{H_2}$ flows. F is the Faraday constant $F = 96\,485.3$ As/mol, and $\dot{n}_{el}$ is the flow rate of electrons (SI unit mol/s). The actual terminal voltage is smaller than the reversible one because of losses due to energy dissipation in the cell. The electric power of the cell is calculated from

$$\dot{Q} + P = \dot{n}_{H_2}\Delta H^R_{H_2}$$

with the flow rate $\dot{n}_{H_2}$ of the supplied hydrogen and its molar reaction enthalpy $\Delta H^R_{H_2}$ (SI unit J/mol), which is equal to the negative molar net calorific value $\Delta H_{m\,ncv} = M_{H_2}\Delta h_{ncv}$ (Sect. 4.8.1). Analogous to the efficiency of other combustion plants, the efficiency of a fuel cell is defined as

$$\eta_{fc} = \frac{-P}{\dot{n}_{H_2}\,\Delta H_{m\,ncv}} ,$$

where the fuel cell is generally about 50% efficient.

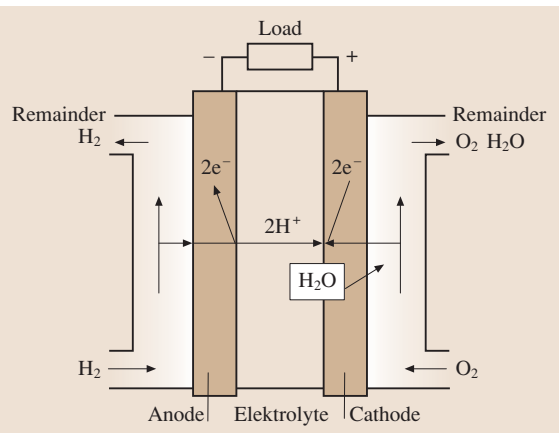

Fig. 4.19 Scheme of a fuel cell with a proton conductive electrolyte

4.8.3 Cyclic Processes, Principles

A process that brings a system back to its initial state is called a cyclic process. After the system has passed through such a cycle, all the properties of the system such as pressure, temperature, volume, internal energy, and enthalpy return to their initial values and thus produce

$$\sum Q_{ik} + \sum W_{ik} = 0 . \tag{4.117}$$

The total work done is $-W = -\sum W_{ik} = \sum Q_{ik}$.

Machines in which a fluid is undergoing a cycling process serve to transform heat transfer into work or to transfer thermal energy from a low- to a high-temperature level while work is supplied. According to the second law of thermodynamics, it is not possible to transform all the supplied heat transfer into work. If the amount of heat supplied is larger than the amount of heat discharged, the process works as a power cycle or a thermal power plant whose purpose is to deliver work. If the amount of heat discharged is smaller than the amount of heat supplied, work must be supplied. Such a process can be used for heat transfer from a medium at a lower temperature to a medium at a higher temperature, e.g., ambient temperature. The required work is

also discharged as heat at the higher temperature. Such a process works as a refrigeration cycle. In a heat pump process, heat is absorbed from the environment and is discharged together with the supplied work at a higher temperature.

Carnot Cycle

The cycle process introduced in 1824 by Carnot is shown in Figs. 4.20 and 4.21. Even though not very important in practice, the Carnot cycle played a decisive roll in the historical development of heat transfer theory. It consists of the following changes of state (here, the clockwise process of a power cycle):

1 – 2 Isothermal expansion at temperature T with heat addition Q
2 – 3 Reversible adiabatic expansion from pressure p_2 to pressure p_3
3 – 4 Isothermal compression at temperature T_0 with heat removal $|Q_0|$
4 – 1 Reversible adiabatic compression from pressure p_4 to pressure p_1

The heat supplied is

$$Q = mRT \ln V_2/V_1 = T(S_2 - S_1) \qquad (4.118)$$

and the heat removed is

$$|Q_0| = mRT_0 \ln V_3/V_4 = T_0(S_3 - S_4) = T_0(S_2 - S_1)\,. \qquad (4.119)$$

The technical work done is $-W_t = Q - |Q_0|$, and the thermal efficiency is

$$\eta = |W_t|/Q = 1 - (T_0/T)\ . \qquad (4.120)$$

With the inverse sequence 4 – 3 – 2 – 1 of changes of state, the heat absorbed Q_0 is from a body at a lower temperature and, with the supply of the technical work W_t, the heat discharged Q is at the higher temperature T. Such a counterclockwise Carnot cycle results in heat removal Q_0 from a chilled system at the low temperature T_0, thus working as a refrigerator, and can discharge the heat $|Q| = W_t + Q_0$ at the higher temperature T to the environment. If the purpose of the process is the heat release $|Q|$ at the higher temperature T for heating, the process works as a heat pump. The heat transfer Q_0 is then removed from the environment at the lower temperature T_0. Carnot cycles gained no practical importance, however, because their power related to the volume of a corresponding machine is very small. However, as an ideal, i. e., reversible, process the Carnot cycle is often used for comparison in order to assess other cyclic processes.

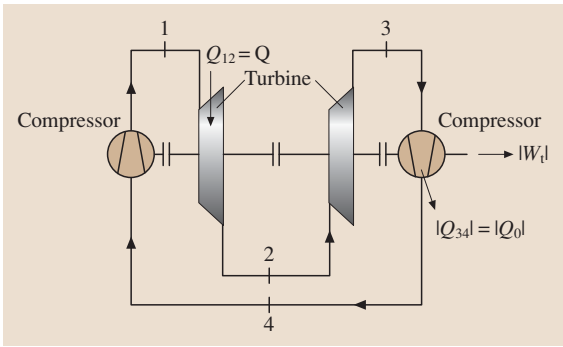

Fig. 4.20 Scheme of a Carnot power cycle

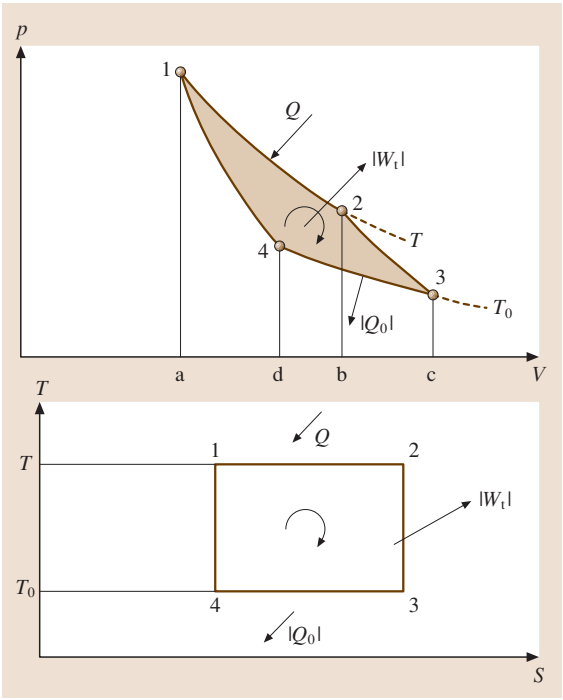

Fig. 4.21 The Carnot cycle on p–V and T–S diagrams

4.8.4 Thermal Power Cycles

In thermal power plants, energy in the form of heat transfer is transformed from the combustion gases in the working fluid, which undergoes a cyclic process. The Ackeret–Keller process consists of the following changes of state as shown in Fig. 4.22 in a p–V and T–S diagram:

1 – 2 Isothermal compression from pressure p_0 to pressure p at temperature T_0
2 – 3 Isobaric heat supply at pressure p
3 – 4 Isothermal expansion from pressure p to pressure p_0 at temperature T
4 – 1 Isobaric heat removal at pressure p_0

Because this process can be traced back to a proposal by the Swedish engineer J. Ericson (1803–1899), it is also called the Ericson cycle. It was first used in 1941, however, by Ackeret and Keller as a comparison process for gas turbine plants. The heat transfer required for the isobaric heating 2 – 3 of the compressed working fluid is provided by the isobaric cooling 4 – 1 of the expanded working fluid, $Q_{23} = |Q_{41}|$.

The thermal efficiency is equal to the efficiency of the Carnot cycle, because

$$-W_t = Q_{34} - |Q_{21}| \tag{4.121}$$

and

$$\eta = 1 - \frac{|Q_{21}|}{Q_{34}} = 1 - \frac{T_0}{T} \,. \tag{4.122}$$

However, the technical realization of this process is difficult because isothermal compression and relaxation

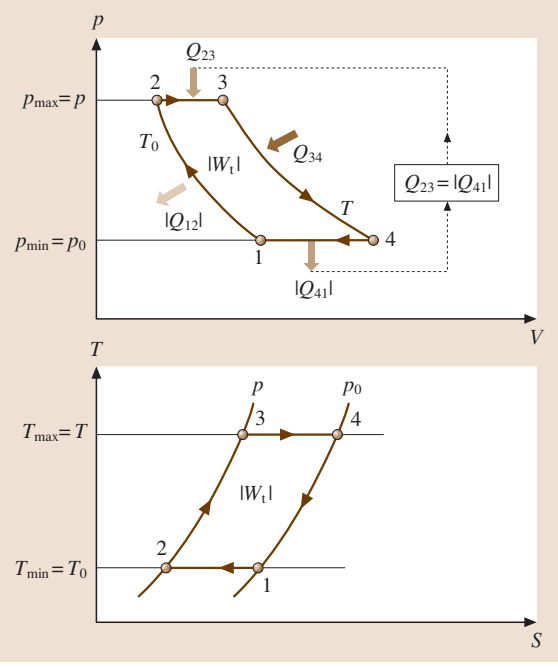

Fig. 4.22 The Ackeret–Keller process on p–V and T–S diagrams

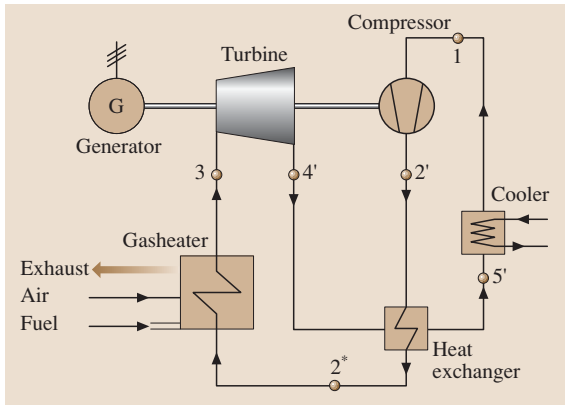

Fig. 4.23 Gas turbine process with a closed cycle

are hardly achievable due to the fact that they only can be approximated by multistage adiabatic compression with intermediate cooling. The Ackeret–Keller process serves mainly as a comparison process for the gas turbine process with multistage compression and relaxation. In a closed gas turbine plant (Fig. 4.23), a gas is compressed in the compressor, heated to a high temperature in the heat exchanger and the gas heater, then expanded in a turbine, where work is done, and cooled again to the initial temperature in the heat exchanger and in the adjacent cooler. Then the gas is drawn in by the compressor once again. Often air is used as the working fluid, but other gases such as helium or nitrogen are also sometimes used. The closed gas turbine plant is easily adjustable, and fouling of the turbine blades can be prevented by using suitable gases. A drawback in comparison to open plants is the higher energy costs, because a cooler is required and high-quality steels are needed for the heater. Figure 4.24 shows the process in the p–V and T–S diagram.

The reversible cyclic process consisting of two isobars and two isentropes is called the Joule process (states 1, 2, 3, 4). The supplied heat transfer is

$$\dot{Q} = \dot{m} c_p \, (T_3 - T_2) \,, \tag{4.123}$$

and the discharged heat transfer is

$$\left|\dot{Q}_0\right| = \dot{m} \, c_p \, (T_4 - T_1) \,. \tag{4.124}$$

The power is

$$\begin{aligned} -P &= -\dot{m} w_t = \dot{Q} - \left|\dot{Q}_0\right| \\ &= \dot{m} \, c_p (T_3 - T_2) \left(1 - \frac{T_4 - T_1}{T_3 - T_2}\right) \end{aligned} \tag{4.125}$$

and the thermal efficiency is

$$\eta = \frac{|P|}{\dot{Q}} = \left(1 - \frac{T_4 - T_1}{T_3 - T_2}\right) . \tag{4.126}$$

Because of the isentropic equation,

$$\left(\frac{p_0}{p}\right)^{\frac{\varkappa-1}{\varkappa}} = \frac{T_1}{T_2} = \frac{T_4}{T_3} \tag{4.127}$$

so

$$\frac{T_4 - T_1}{T_3 - T_2} = \frac{T_1}{T_2} = \left(\frac{p_0}{p}\right)^{\frac{\varkappa-1}{\varkappa}} \tag{4.128}$$

and the thermal efficiency is

$$\eta = \frac{|P|}{\dot{Q}} = 1 - \left(\frac{p_0}{p}\right)^{\frac{\varkappa-1}{\varkappa}} , \tag{4.129}$$

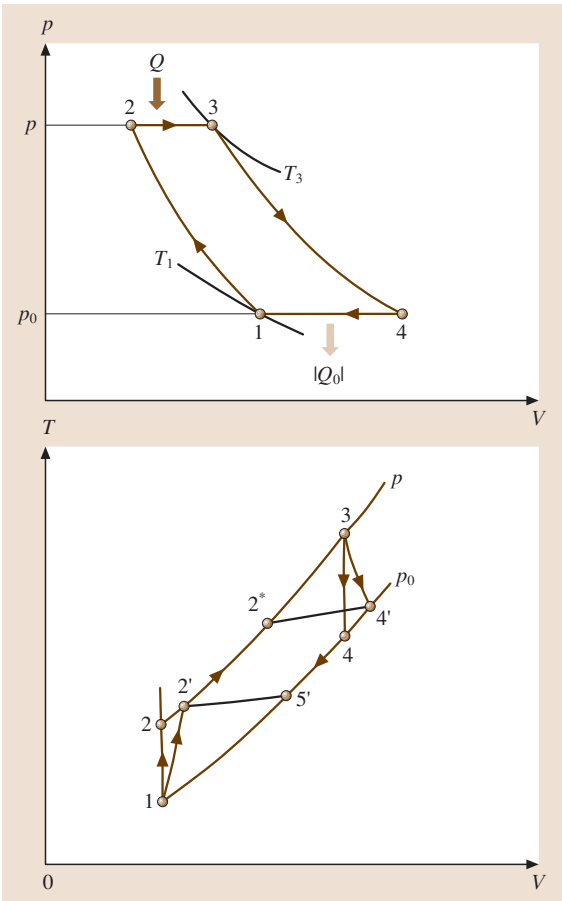

Fig. 4.24 The gas turbine process on p–V and T–S diagram. The p–V diagram shows only the reversible process (Joule process) 1, 2, 3, 4

which depends only on the pressure ratio p/p_0 or on the temperature ratio T_2/T_1 of the compression. The compressor power increases faster with the pressure ratio than does the turbine power so that the received power output according to (4.125), taking into account (4.128) becomes

$$-P = \dot{m} c_p T_1 \left[\frac{T_3}{T_1} - \left(\frac{p}{p_0}\right)^{\frac{\varkappa-1}{\varkappa}}\right]\left[1 - \left(\frac{p_0}{p}\right)^{\frac{\varkappa-1}{\varkappa}}\right] \tag{4.130}$$

which has a maximum at a certain pressure ratio for given values of the highest temperature T_3 and the lowest temperature T_1. This optimal pressure ratio follows from (4.130) through differentiation as

$$\left(\frac{p}{p_0}\right)^{\frac{\varkappa-1}{\varkappa}}_{\text{opt}} = \sqrt{\frac{T_3}{T_1}} , \tag{4.131}$$

which is, because of (4.128), equivalent to $T_4 = T_2$. Considering the efficiencies η_T of the turbine and η_C of the compressor, and the mechanical efficiency η_m for the energy transformation between turbine and compressor, the optimal pressure ratio results to

$$\left(\frac{p}{p_0}\right)^{\frac{\varkappa-1}{\varkappa}}_{\text{opt}} = \sqrt{\eta_m \eta_T \eta_C (T_3/T_1)} . \tag{4.132}$$

More than half of the turbine power of a gas turbine plant is required to drive the compressor. The completely installed power is thus four to six times the power output.

The working fluid of vapor power plants, usually water, evaporates and condenses during the process. Most electric energy is generated with such plants. The simplest form of the cyclic process (Fig. 4.25) is as follows.

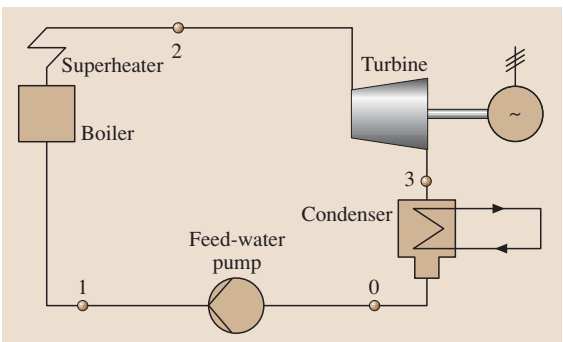

Fig. 4.25 Vapor power plant

In the boiler the working fluid is heated isobarically at a high pressure to the boiling point, evaporated, then superheated in the superheater. The vapor is then expanded adiabatically in the turbine where work is done, and condensed with heat removal in the condenser. The liquid is pressurized in the feed-water pump to the pressure of the boiler and again discharged into the boiler. The reversible cyclic process $0-1'-2-3'-0$ (Fig. 4.26), consisting of two isobars and two isentropes, is called the Clausius–Rankine process. The real cycle consists of the changes of state $0-1-2-3-0$ in Fig. 4.26. The heat absorption in the steam generator is

$$\dot{Q}_{\text{in}} = \dot{m}(h_2 - h_1) \tag{4.133}$$

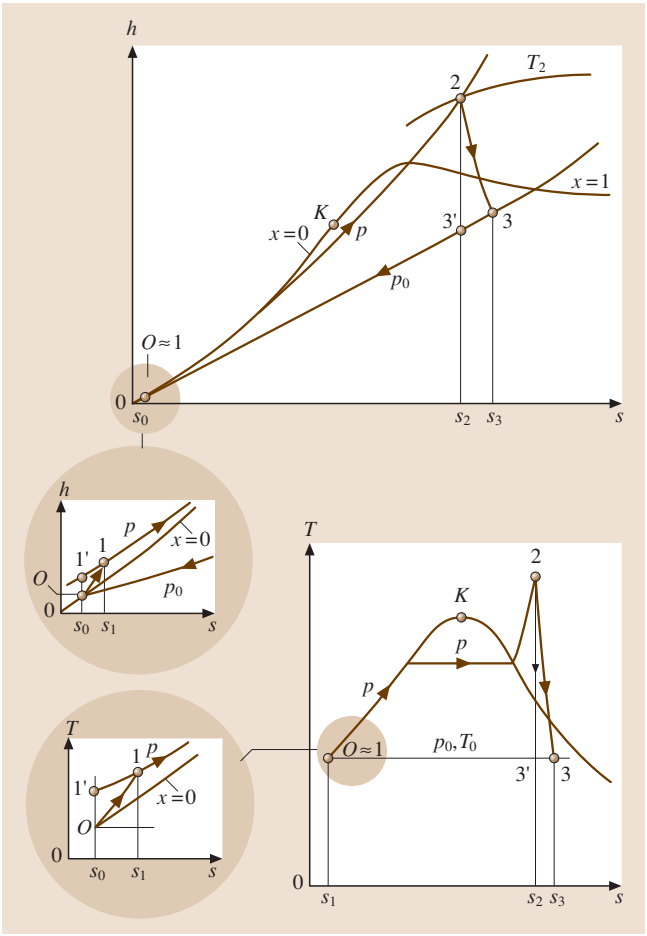

Fig. 4.26 Changes of state of the water in the cycle of a basic vapor power plant on T–S and h–s diagrams

and the power of the adiabatic turbine is

$$|P_{\text{T}}| = |\dot{m} w_{\text{t23}}| = \dot{m}(h_2 - h_3) = \dot{m}\eta_{\text{T}}(h_2 - h_3') \tag{4.134}$$

with the isentropic turbine efficiency η_{T}. The heat transfer discharged in the condenser is

$$-\dot{Q}_{\text{out}} = \dot{m}(h_3 - h_0)\,. \tag{4.135}$$

The power output of the cyclic process is

$$-P = -\dot{m} w_{\text{t}} = -P_{\text{T}} - P_{\text{P}} \tag{4.136}$$

with the pump power

$$P_{\text{P}} = \dot{m}(h_1 - h_0) = \dot{m}\frac{1}{\eta_{\text{C}}}(h_{1'} - h_0)\,, \tag{4.137}$$

where η_{C} is the efficiency of the feed-water pump. The power output differs only slightly from the power output of the turbine. The thermal efficiency is

$$\eta = -\frac{\dot{m} w_{\text{t}}}{\dot{Q}_{\text{in}}} = \frac{(h_2 - h_3) - (h_1 - h_0)}{h_2 - h_1}\,. \tag{4.138}$$

At a counter-pressure of $p_0 = 0.05$ bar, a main steam pressure of 150 bar, and a vapor temperature of 500 °C, the thermal efficiency achieves values of $\eta \approx 0.42$. Considerably higher thermal efficiencies of (presently) up to $\eta \approx 0.58$ can be achieved in combined gas–vapor power plants, in which the combustion gas at first does work in a gas turbine, where it is expanded, then is supplied to a vapor power plant in order to generate steam.

4.8.5 Refrigeration Cycles and Heat Pumps

Compression Refrigeration Cycle

In refrigerating machines, as well as in power plants, gases or vapors are used as working fluids. These gases/vapors are called refrigerants. A refrigeration machine is used to remove heat from a chilled system. For this purpose, it is necessary to do work, which is then transferred as heat together with the heat removed from the chilled system to the environment. For cooling with temperatures to about $-100\,^{\circ}\mathrm{C}$, compression refrigeration machines are primarily used.

Figure 4.27 shows a schematic diagram of a compression refrigeration machine. The compressor which is usually a piston compressor for small powers and a turbo compressor for large powers, draws in vapor from the evaporator at the pressure p_0 and the corresponding saturation temperature T_0 and compresses it along adiabate $1-2$ (Fig. 4.28) to pressure p. The vapor is then liquefied at pressure p in the condenser. The liquid refrigerant is expanded in the throttle valve and returns to the evaporator, where it is supplied with heat. The refrigeration machine removes from the chilled system the heat transfer q_0, which is transferred to the evaporator. In the condenser, the heat transfer $|q| = q_0 + w_t$ is transferred to the environment.

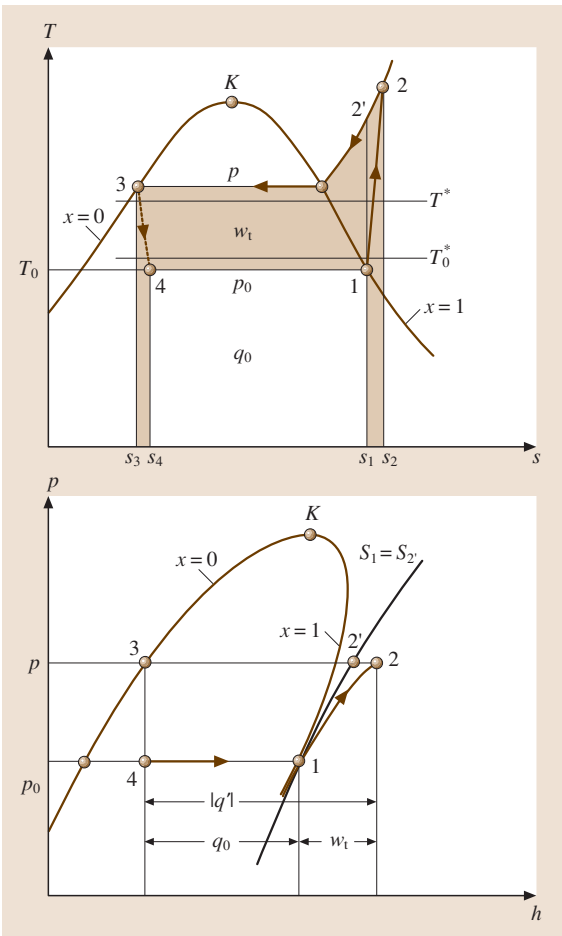

Fig. 4.28 Cycle of the refrigerant in a vapor refrigeration plant in the T–S and the p–h (Mollier) diagram

Since water freezes at $0\,^{\circ}\mathrm{C}$, and water vapor has an inconveniently large specific volume, other fluids such as ammonia NH_3, carbon dioxide CO_2, propane C_3H_8, butane C_4H_{10}, tetrafluoroethane $C_2H_2F_4$, and difluorochlormethane CHF_2Cl are used as refrigerants. Saturated refrigerant properties are given in Tables 4.10–4.13. For mass flow $\dot{m}$ of the circulating refrigerant, the refrigeration capacity is

$$\dot{q}_0 = \dot{m} q_0 = \dot{m}(h_1 - h_4) = \dot{m}\left[h''(p_0) - h'(p)\right] , \tag{4.139}$$

since $h_4 = h_3 = h'(p)$. The required power for the compressor is

$$\begin{aligned} P_C &= \dot{m} w_{t12} = \dot{m}(h_2 - h_1) \\ &= \dot{m}\frac{1}{\eta_C}\left[h_{2'} - h''(p_0)\right] , \end{aligned} \tag{4.140}$$

where η_C is the isentropic efficiency of the compressor. The heat transfer from the condenser is given by

$$|\dot{q}| = \dot{m}\,|q| = \dot{m}(h_2 - h_3) = \dot{m}\left[h_2 - h'(p)\right] . \tag{4.141}$$

The coefficient of performance of a refrigeration machine is defined as the ratio of the refrigeration capacity $\dot{q}_0$ to the required power P of the compressor

$$\varepsilon_R = \frac{\dot{q}_0}{P_C} = \frac{q_0}{w_{t12}} = \eta_C \frac{h''(p_0) - h'(p)}{h_{2'} - h''(p_0)} , \tag{4.142}$$

which depends, besides on the isentropic compressor efficiency, only on the two pressures p and p_0.

Compression Heat Pump

A compression heat pump works according to the same process as the compression refrigeration system shown in Figs. 4.27 and 4.28, where its purpose, however, is for heating. In order to provide heating, then, the heat transfer q_0 (anergy) is from the environment and is, together with the done work, w_t (the exergy), supplied as

a heat transfer $|q| = q_0 + w_t$ to the heated system. The coefficient of performance of a heat pump is defined as the ratio of the heating output $|\dot{q}|$ to the required power P of the compressor

$$\varepsilon_{hp} = \frac{|\dot{q}|}{P} = \frac{|q|}{w_t} = \eta_V \frac{h_2 - h'(p)}{h_{2'} - h''(p_0)} \,. \qquad (4.143)$$

As shown in the T–S diagram in Fig. 4.28, the area representing w_t becomes smaller at a high ambient temperature T_0^* and at a low heating temperature T^* because less power is required for the compressor and the coefficient of performance increases. In order to run heat pumps economically for the heating of housing spaces, the heating temperature must be kept low, e.g., with a floor heating at $t^* \lessapprox 29\,°C$. Additionally, heat pumps become uneconomic when the environment temperature is too low. If the coefficient of performance decreases below about 2.3, no primary energy is saved when compared to conventional heating, because the mean efficiencies for the transformation of primary energy P_{Pr} into electrical energy P in a power plant in order to run the heat pump $\eta_{el} = P/P_{Pr}$ are typically about 0.4. In that case, the heating coefficient $\xi = |\dot{q}|/P_{Pr}$ of 0.92 corresponds to the efficiency of conventional heating. Today's electrically driven heat pumps rarely achieve heating coefficients of 2.3 in the annual mean, unless the heat pump is switched off at ambient temperatures lower than approximately 3 °C and the housing space is heated conventionally. Motor-driven heat pumps with waste heat recovery and sorption heat pumps exploit the primary energy better than electrically driven heat pumps.

4.8.6 Combined Power and Heat Generation (Co-Generation)

The generation of thermal energy and electrical energy in heating power plants is called combined power and heat generation. A large amount of a power plant's waste heat, which arises in the process, is used for heating. Since the heat required for heating consists mainly – more than 90% – of anergy, less primary energy, which consists mainly of exergy, is transformed into thermal energy than in conventional heating. Low-pressure vapor is discharged from the vapor turbine; it contains, in addition to the anergy, so much exergy that the heating energy and the exergy losses in the heat distribution – normally in a long-distance heating network – are covered. Even though, compared with a simple power plant, operation work is lost due to the vapor withdrawal, the primary energy consumption for the simultaneous generation of work and thermal energy is smaller than the separate generation of work in a power plant and of thermal energy in a conventional heating system. A simplified circuit is shown in Fig. 4.29. Depending on the kind of circuit used, heating coefficients, $\xi = |\dot{q}|/P_{Pr}$, up to about 2.2 are accessible [4.20], whereas P_{Pr} is only the fraction of the primary energy that accounts for the heating. The heating coefficients are considerably above those of most heating pump systems.

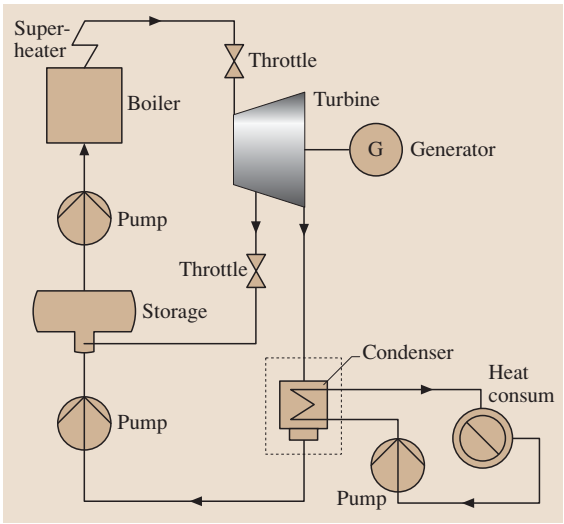

Fig. 4.29 Scheme of combined power and heat generation in extraction back-pressure operation

4.9 Ideal Gas Mixtures

A mixture of ideal gases that do not react chemically with each other also behaves as an ideal gas. The following equation of state holds

$$pV = nR_u T \,. \tag{4.144}$$

Each single gas, called a component, spreads over the entire space V as though the other gases were not present. Thus, the following equation holds for each component

$$p_i V = n_i R_u T \,, \tag{4.145}$$

where p_i is the pressure exerted by each gas individually, which is referred to as the partial pressure. The sum of all the *partial pressures* leads to $\sum p_i V = \sum n_i R_u T$ or $V \sum p_i = R_u T \sum n_i$. Comparison with (4.144) shows that

$$p = \sum p_i \tag{4.146}$$

holds. In other words, the total pressure p of the gas mixture is equal to the sum of the partial pressures of the single gases, if each gas occupies the volume V of the mixture at temperature T (Dalton's law). The thermal equation of state of an ideal gas mixture can also be written as

$$pV = mRT \,, \tag{4.147}$$

with the gas constant R of the mixture

$$R = \sum R_i m_i / m \,. \tag{4.148}$$

Specific (related to the mass in kg) caloric properties of a mixture at pressure p and temperature T result from adding the caloric properties at the same values p, T of the single gases according to their mass fractions, or

$$c_v = \frac{1}{m}\sum m_i c_{vi} \,, \qquad c_p = \frac{1}{m}\sum m_i c_{pi} \,,$$
$$u = \frac{1}{m}\sum m_i u_i \,, \qquad h = \frac{1}{m}\sum m_i h_i \,. \tag{4.149}$$

An exception to this general rule is entropy. During the mixing of single gases of state p, T to a mixture of the same state, an entropy increase takes place. This process is described by the following relation

$$s = \frac{1}{m}\left(\sum m_i s_i - \sum m_i R_i \ln \frac{n_i}{n}\right) \,, \tag{4.150}$$

where n_i is the number of moles of the single gases and n is the number of moles of the mixture. Consequently, $n_i = m_i/M_i$ and $n = \sum n_i$ with the mass m_i and the molar mass M_i of the single gases. Mixtures of real gases and liquids deviate from the above relations, in particular at higher pressures.

4.9.1 Mixtures of Gas and Vapor. Humid Air

Mixtures of gases and easily condensable vapors occur often in physics and in technology. Atmospheric air consists mostly of dry air and water vapor. Drying and climatization processes are governed by the laws of vapor–air mixtures. This holds true in the same way for the formation of fuel and vapor–air mixtures in a combustion engine. The following is limited to the examination of atmospheric air. Dry air consists of 78.04 mol% nitrogen, 21.00 mol% oxygen, 0.93 mol% argon, and 0.03 mol% carbon dioxide. Atmospheric air can be considered as a binary mixture of dry air and water, which can be present as vapor, liquid, or solid. This mixture is also called humid air. Dry air is considered a uniform substance. Since the total pressure during changes of state is almost always close to atmospheric pressure, it is possible to consider humid air, consisting of dry air and water vapor, as a mixture of ideal gases. The following relation then holds for dry air and water vapor

$$p_{air} V = m_{air} R_{air} T \quad \text{and} \quad p_v V = m_v R_v T \,. \tag{4.151}$$

These equations, together with $p = p_{air} + p_v$, allows for the determination of the mass of water vapor which is added to 1 kg dry air.

$$x_v = \frac{m_v}{m_{air}} = \frac{R_{air} p_v}{R_v (p - p_v)} \,. \tag{4.152}$$

The quantity $x_v = m_v/m_{air}$ is called the absolute or specific humidity. This quantity must not be confused with the quality x for mixtures of vapors and liquid. If water in the air is not only present as vapor, but also as liquid or solid, the water content x must be distinguished from the specific humidity x_v. The water content is defined as

$$x = \frac{m_w}{m_{air}} = \frac{m_v + m_\ell + m_{ice}}{m_{air}} = s_v + x_\ell + x_{ice} \,, \tag{4.153}$$

where m_v denotes the vapor mass, m_ℓ, the liquid mass, and m_{ice}, the ice mass in the dry air of mass m_{air}. The value x_v is the specific humidity (vapor content), x_ℓ, the liquid content, and x_{ice}, the ice content. The water content can lie between 0 (dry air) and ∞ (pure water). If

humid air of temperature T is saturated with water vapor, the partial pressure of the water vapor is equal to the saturation pressure $p = p_{vs}$ at temperature T, and the specific humidity becomes

$$x_s = \frac{R_{air} p_{vs}}{R_v (p - p_{vs})} . \qquad (4.154)$$

Example 4.13: What is the specific humidity of saturated humid air at a temperature of 20 °C and a total pressure of 1000 mbar?

The gas constants are $R_{air} = 0.2872\,\mathrm{kJ/kg\,K}$ and $R_v = 0.4615\,\mathrm{kJ/kg\,K}$. The saturated water temperature (Table 4.6) includes the vapor pressure, which is $p_{vs}(20\,°C) = 23.39\,\mathrm{mbar}$. It follows, then

$$x_s = \frac{0.2872 \times 23.39}{0.4615\,(1000 - 23.39)} \times 10^3\,\frac{\mathrm{g}}{\mathrm{kg}} = 14.905\,\frac{\mathrm{g}}{\mathrm{kg}}\,.$$

Other values of x_s are given in Table 4.21.

Degree of Saturation and Relative Humidity.

The degree of saturation is defined as $\Psi = x_v/x_s$, which is a relative measure of the vapor content. In meteorology, however, the relative humidity $\varphi = p_v(t)/p_{vs}(t)$ is often used. Close to saturation, the two values differ only slightly because

$$\frac{x_v}{x_s} = \frac{p_v(p - p_{vs})}{p_{vs}(p - p_v)} \quad \text{or} \quad \Psi = \varphi\frac{(p - p_{vs})}{(p - p_v)}\,.$$

At saturation, $\Psi = \varphi = 1$. If the pressure of saturated humid air is increased or if the temperature is decreased, the excess water vapor condenses. The condensed vapor drops out as fog or precipitation (rain); at temperatures below 0 °C, ice crystals (snow) arise. In this case, the water content is larger than the vapor content: $x > x_v = x_s$. The relative humidity can be determined with directly displaying instruments (e.g., a hair hygrometer) or with the help of an aspiration psychrometer.

Enthalpy of Humid Air

Since the amount of dry air remains constant during changes of state of humid air, and only the added amount of water varies as a result of thawing or evaporation, all properties are related to 1 kg dry air. The dry air contains $x = m_w/m_{air}$ kg water from which $x_v = m_v/m_{air}$ is vaporous. For the enthalpy h_{1+x} of the unsaturated ($x = x_v < x_s$) mixture of 1 kg dry air and x kg vapor it holds that

$$h_{1+x} = c_{p\,air}t + x_v(c_{p\,v}t + \Delta h_v)\,, \qquad (4.155)$$

with the constant-pressure specific heats $c_{p\,air} = 1.005\,\mathrm{kJ/kgK}$ of air and $c_{p\,v} = 1.86\,\mathrm{kJ/kgK}$ of water vapor, and the enthalpy of vaporization $\Delta h_v = 2500.5\,\mathrm{kJ/kg}$ of water at 0 °C. In the temperature range of interest between −60 °C and 100 °C, constant values of c_p can be assumed. At saturation, $x_v = x_s$ and $h_{1+x} = (h_{1+x})_s$. If the water content x is larger than the saturation content x_s at temperatures $t > 0°C$, the water

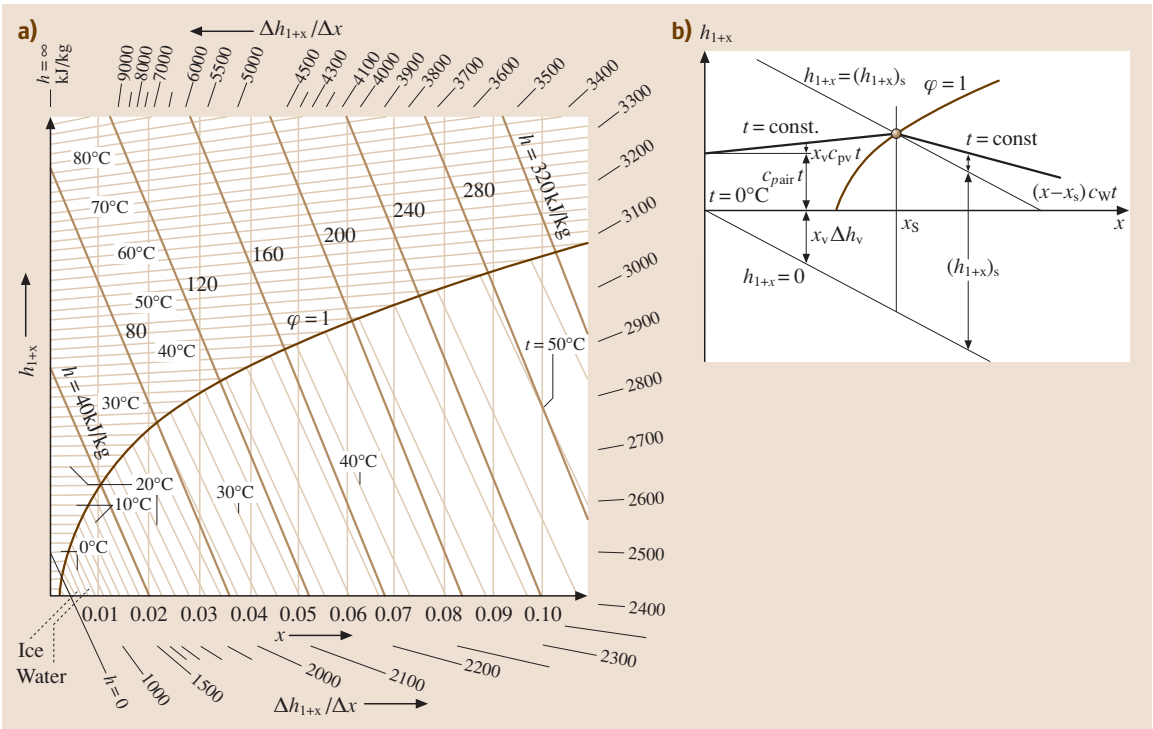

Fig. 4.30 h_{1+x}–x diagram of humid air according to Mollier

fraction $x - x_s = x_\ell$ drops out of the mixture as fog or as precipitate, and it holds that

$$h_{1+x} = (h_{1+x})_s + (x - x_s) c_w t \,. \qquad (4.156)$$

At temperatures $t < 0\,°C$, the water fraction $x - x_s = x_{ice}$ drops out as snow or ice, then

$$h_{1+x} = (h_{1+x})_s - (x - x_s)(\Delta h_f - c_{ice} t) \,. \qquad (4.157)$$

The specific heat of water is $c_w = 4.19\,kJ/kg\,K$; the specific heat of ice is $c_{ice} = 2.04\,kJ/kg\,K$; and the latent heat of fusion of ice is $\Delta h_f = 333.5\,kJ/kg$. Saturation pressures, specific humidities, and enthalpies of saturated humid air at temperatures between $-20\,°C$ and $+100\,°C$ for a total pressure of 1000 mbar are given in Table 4.21. At $t = 0\,°C$, water can be present simultaneously in all three states of aggregation. The following relation then holds for the enthalpy h_{1+x} of the mixture

$$h_{1+x} = x_s \Delta h_v - x_{ice} \Delta h_f \,. \qquad (4.158)$$

Mollier Diagram of Humid Air

Figure 4.30a shows the h_{1+x}–x diagram introduced by Mollier for the graphical depiction of changes of state of humid air. The enthalpy h_{1+x} of $(1 + x)$ kg humid air is plotted in an oblique coordinate system against the water content. The axis $h = 0$ corresponding to humid air at 0 °C is inclined right downward in such a way that the 0 °C isotherm of unsaturated humid air is horizontal. Figure 4.30b shows the construction of isotherms according to (4.155) and (4.156). Lines of constant x are vertical, while lines of constant h are straight lines parallel to the axis $h_{1+x} = 0$. Figure 4.30a includes the saturation curve $\varphi = 1$ for a total pressure of 1000 mbar. It divides the region of unsaturated mixtures (top) from the fog region (bottom), in which the humidity is contained in the mixture partly as vapor, partly as liquid (fog, precipitate) or solid (ice, fog, snow). Isotherms in the unsaturated region are, according to (4.155), towards the right, slightly ascending straight lines, which deviate at the saturation curve downward and in the fog region are nearly parallel to the straight lines of constant enthalpy, as according to (4.156). The vapor content of a state in the fog region with temperature t and water content x is determined by following isotherm t until it intersects with the saturation curve $\varphi = 1$. The fraction x_s read off in the intersection point is as vapor and thus the fraction $x - x_s$ as liquid and / or ice contained in the

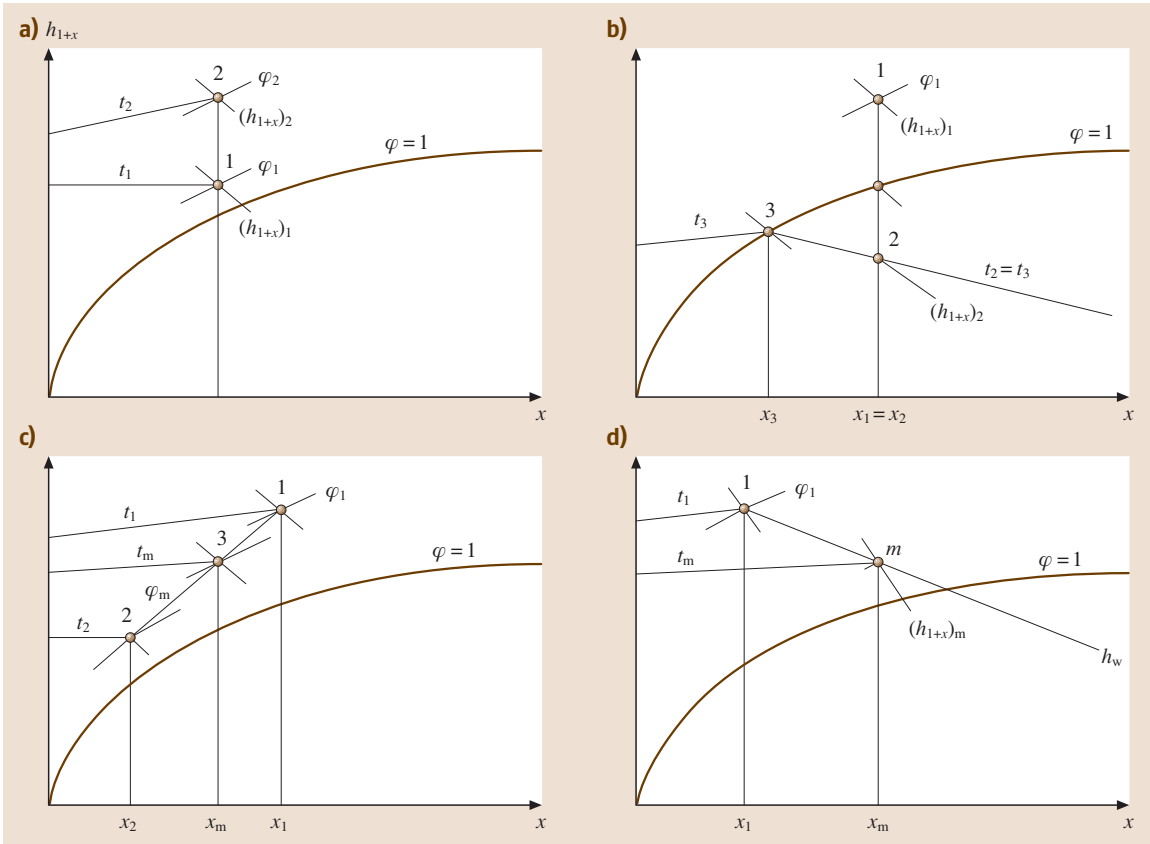

Fig. 4.31a–d Changes of state of humid air. **(a)** heating and cooling **(b)** cooling below dew point **(c)** mixture **(d)** addition of water or vapor

mixture. The inclined, beam-like pieces of straight lines $\Delta h_{1+x}/\Delta x$ determine, together with the zero-point, the direction of a change of state starting from an arbitrary state in the diagram, when water or vapor with an enthalpy in kJ/kg corresponding to the values at the boundary beams is added to the mixture. In order to find the direction of the change of state, a straight line parallel to the line determined by the origin ($h = 0,\ x = 0$) and the boundary beam must be drawn through the point of the initial state.

Changes of State of Humid Air

Heating or Cooling. If a given mixture is heated, the change of state is vertically upwards (1–2 in Fig. 4.31a). If a given mixture is cooled, the change of state is vertically downwards (2–1). As long as states 1 and 2 are in the unsaturated region, the exchanged heat related to 1 kg dry air corresponds to the vertical distance of two points of state measured in the enthalpy scale:

$$Q_{12} = m_{\text{air}}(c_{\text{p air}} + c_{\text{p v}}x)(t_2 - t_1)\,, \tag{4.159}$$

where $c_{\text{p air}} = 1.005\,\text{kJ/kg K}$ and $c_{\text{p v}} = 1.852\,\text{kJ/kg K}$. When humid air is cooled below the dew point of water (1–2 in Fig. 4.31b), precipitation drops out. The discharged heat is

$$Q_{12} = m_{\text{air}}\left[(h_{1+x})_2 - (h_{1+x})_1\right]\,, \tag{4.160}$$

where $(h_{1+x})_1$ is given by (4.155) and $(h_{1+x})_2$ by (4.156). An amount of water specified by

$$m_{\text{w}} = m_{\text{air}}(x_1 - x_3) \tag{4.161}$$

is removed.

Example 4.14: 1000 kg of humid air at $t_1 = 30\,^\circ\text{C}$, $\varphi_1 = 0.6$, and $p = 1000\,\text{mbar}$ is cooled to 15 °C. How much precipitation falls out?

The specific humidity results from (4.152) with $p_{\text{v}} = \varphi_1 p_{\text{vs}}$. According to Table 4.21, $p_{\text{vs}}\,(30\,^\circ\text{C}) =$

42.46 mbar, thus,

$$x_1 = \frac{R_{air}\,(\varphi_1\,p_{vs})}{R_v\,(p-\varphi_1\,p_{vs})} = \frac{0.2872\times0.6\times42.46}{0.4615\,(1000-0.6\times42.46)} = 16.25\times10^{-3}\,\text{kg/kg} = 16.25\,\text{g/kg}\,.$$

The 1000 kg of humid air consists of $1000/(1+x_1) = 1000/1.01625\,\text{kg} = 984.01\,\text{kg}$ dry air and $(1000-984.01)\,\text{kg} = 15.99\,\text{kg}$ water vapor. The water content at point 3, $x_3 = x_s$, follows from Table 4.21 at $t_3 = 15\,°\text{C}$ to $x_3 = 10.79\,\text{g/kg}$, thus, $m_\ell = 984.01\times(16.25-10.80)\times10^{-3}\,\text{kg} = 5.36\,\text{kg}$.

Mixture of Two Amounts of Air. If two amounts of humid air at states 1 and 2 are mixed adiabatically (i. e., without heat exchange with the environment), state m after the mixture (point 3 in Fig. 4.31c) is located on the straight line connecting states 1 and 2. Point m is determined by subdividing the straight connecting line 1–2 equivalent to the ratio of the dry air masses m_{air2}/m_{air1}. It is then

$$x_m = \frac{m_{air1}x_1 + m_{air2}x_2}{m_{air1}+m_{air2}}\,. \qquad (4.162)$$

Mixing two saturated air amounts of different temperatures always leads to the formation of fog, as the water amount $x_m - x_s$ drops out, where x_s is the specific humidity at saturation on the isotherm passing through the mixture point in the fog region.

Example 4.15: 1000 kg of humid air at $t_1 = 30\,°\text{C}$ and $\varphi_1 = 0.6$ are mixed at 1000 mbar with 1500 kg of saturated humid air at $t_2 = 10\,°\text{C}$. What is the temperature after the mixture?

As calculated in the previous example, $x_1 = 16.25\,\text{g/kg}$. The specific humidity at saturation for $t_2 = 10\,°\text{C}$ given in Table 4.21 is $x_{2s} = 7.7377\,\text{g/kg}$. The dry air masses are

$$m_{air1} = 1000/(1+x_1)\,\text{kg} = 1000/(1+16.25\times10^{-3})\,\text{kg} = 984.01\,\text{kg}\,,$$

and

$$m_{air2} = 1500/(1+x_{2s})\,\text{kg} = 1500/(1+7.7377\times10^{-3})\,\text{kg} = 1488.5\,\text{kg}\,.$$

The water content after the mixture therefore becomes

$$x_m = \frac{984.01\times16.25+1488.5\times7.7377}{984.01+1488.5}\,\text{g/kg} = 11.12\,\text{g/kg}\,.$$

The enthalpies, calculated according to (4.155), are

$$(h_{1+x})_1 = \left[1.005\times30+16.25\times10^{-3}\times(1.86\times30+2500.5)\right]\text{kJ/kg} = 71.69\,\text{kJ/kg}\,,$$

$$(h_{1+x})_2 = \left[1.005\times10+7.7377\times10^{-3}\times(1.86\times10+2500.5)\right]\text{kJ/kg} = 29.54\,\text{kJ/kg}\,.$$

The enthalpy of the mixture is

$$(h_{1+x})_m = \frac{m_{air1}(h_{1+x})_1 + m_{air2}\,(h_{1+x})_2}{m_{air1}+m_{air2}} = \frac{984.01\times71.69+1488.5\times29.54}{984.01+1488.5}\,\text{kJ/kg} = 46.31\,\text{kJ/kg}.$$

On the other hand, according to (4.155), the following also holds

$$(h_{1+x})_m = \left(1.005\,t_m + 11.12\times10^{-3}\times(1.86\,t_m+2500.5)\right)\text{kJ/kg}.$$

From this it follows that $t_m = 18\,°\text{C}$.

Addition of Water or Vapor. If humid air is mixed with m_w kg of water or water vapor, the water content after the mixture is $x_m = (m_{air1}x_1 + m_w)/m_{air1}$. The enthalpy is

$$(h_{1+x})_m = \left[m_{air\,1}(h_{1+x})_1 + m_w h_w\right]/m_{air1}\,. \qquad (4.163)$$

The final state after the mixture is located in the Mollier diagram for humid air (Fig. 4.31d) on a straight line passing through the origin with the gradient h_w, where $h_w = \Delta h_{1+x}/\Delta x$ is given by the pieces of straight lines on the boundary scale.

Wet-Bulb Temperature. When unsaturated humid air of state t_1, x_1 passes over a water or ice surface, water evaporates or ice sublimates, causing the specific humidity of the humid air to increase. During this increase in specific humidity, the temperature of the water or of the ice decreases and adopts, after a sufficiently long time, a final value, which is called the wet-bulb temperature. The wet-bulb temperature t_{wb} can be determined in the Mollier diagram by looking for the isotherm t_{wb} in the fog region whose extension passes through state 1.

4.10 Heat Transfer

If temperature differences exist between bodies that are not isolated from each other or within different areas of the same body, energy flows from the region of higher temperature to the region of lower temperature. This process is called heat transfer and will continue until the temperatures are balanced. Three modes of heat transfer are distinguished.

- Heat transfer by conduction in solids, motionless liquids, or motionless gases. Kinetic energy is hereby transferred from a molecule or an elementary particle to its neighbor.
- Heat transfer by convection in liquids or gases with bulk fluid motion.
- Heat transfer by radiation takes place in the form of electromagnetic waves and without the presence of an intervening medium.

In engineering, all three modes of heat transfer are often present at the same time.

4.10.1 Steady-State Heat Conduction

Steady-State Heat Conduction Through a Plane Wall

If different temperatures are prescribed on two surfaces of a plane wall with thickness δ, according to Fourier's law, the heat transfer

$$Q = \lambda A \frac{T_1 - T_2}{\delta} \tau$$

flows through the area A over time τ. Here, λ is a material property (SI unit W/(Km)) that is called the thermal conductivity (Table 4.22). The rate of heat transfer is given by $Q/\tau = \dot{Q}$ (SI unit W), and $Q/(\tau A) = \dot{q}$ is referred to as the heat flux (SI unit W/m^2). It holds, then

$$\dot{Q} = \lambda A \frac{T_1 - T_2}{\delta} \quad \text{and} \quad \dot{q} = \lambda \frac{T_1 - T_2}{\delta} . \tag{4.164}$$

Similar to electric conduction, where a current I flows only when a voltage U exists to overcome the resistance R ($I = U/R$), heat transfer occurs only when a temperature difference $\Delta T = T_2 - T_1$ exists

$$\dot{Q} = \frac{\lambda A}{s} \Delta T .$$

Analogous to Ohm's law, $R_{\text{th}} = \delta/(\lambda A)$ is called the thermal resistance (SI unit K/W).

Fourier's Law

Considering a layer perpendicular to the heat transfer of thickness dx instead of the wall with the finite thickness δ leads to Fourier's law in the differential form

$$\dot{Q} = -\lambda A \frac{\mathrm{d}T}{\mathrm{d}x} \quad \text{and} \quad \dot{q} = -\lambda \frac{\mathrm{d}T}{\mathrm{d}x} , \tag{4.165}$$

where the minus sign results from the fact that heat transfer occurs in the direction of decreasing temperature. Here, $\dot{Q}$ is the heat transfer in the direction of the x-axis, as is the same for $\dot{q}$. The heat flux in the direction of the three coordinates x, y, and z is given in vector form by

$$\dot{q} = -\lambda \left(\frac{\partial T}{\partial x} \boldsymbol{e}_x + \frac{\partial T}{\partial y} \boldsymbol{e}_y + \frac{\partial T}{\partial z} \boldsymbol{e}_z \right) \tag{4.166}$$

with the unit vectors $\boldsymbol{e}_x, \boldsymbol{e}_y, \boldsymbol{e}_z$. At the same time, (4.166) is the general form of Fourier's law. In this form, Fourier's law holds for isotropic materials, i. e., materials with equal thermal conductivities in the direction of the three coordinate axes.

Steady-State Heat Conduction Through a Tube Wall

According to Fourier's law, the heat transfer rate through a cylindrical area of radius r and length l is $\dot{Q} = -\lambda\, 2\pi r l (\mathrm{d}T/\mathrm{d}r)$. Under steady-state conditions, the heat transfer rate is the same for all radii and thus $\dot{Q} = \text{const}$. It is therefore possible to separate the variables T and r and to integrate from the inner surface of the cylinder, $r = r_{\text{i}}$ with $T = T_{\text{i}}$, to an arbitrary location r with temperature T. The temperature profile in a tube wall of thickness $r - r_{\text{i}}$ becomes

$$T_{\text{i}} - T = \frac{\dot{Q}}{\lambda\, 2\pi l} \ln \frac{r}{r_{\text{i}}} .$$

With temperature T_{o} at the outer surface at radius r_{o}, the heat transfer rate through a tube of thickness $r_{\text{o}} - r_{\text{i}}$ and length l becomes

$$\dot{Q} = \lambda\, 2\pi l \frac{T_{\text{i}} - T_{\text{o}}}{\ln r_{\text{o}}/r_{\text{i}}} . \tag{4.167}$$

In order to obtain formal agreement with (4.164), it is also possible to write

$$\dot{Q} = \lambda A_{\text{m}} \frac{T_{\text{i}} - T_{\text{o}}}{\delta} \tag{4.168}$$

where $\delta = r_{\text{o}} - r_{\text{i}}$ and $A_{\text{m}} = \frac{A_{\text{o}} - A_{\text{i}}}{\ln(A_{\text{o}}/A_{\text{i}})}$, if $A_{\text{o}} = 2\pi r_{\text{o}} l$ is the outer and $A_{\text{i}} = 2\pi r_{\text{i}} l$ is the inner surface of the tube.

A_m is the logarithmic mean between the outer and inner tube surfaces. The thermal resistance of the tube $R_{th} = \delta/(\lambda A_m)$ (SI unit K/W) must be overcome by the temperature difference so that heat transfer occurs.

4.10.2 Heat Transfer and Heat Transmission

If heat is transferred from a fluid to a wall, conducted through the wall and, on the other side, transferred to a second fluid, this process is called heat transmission. In this case, two heat transfer processes and a heat conduction process are connected in series. There exists a steep temperature drop in a layer directly at the wall (Fig. 4.32), where the temperature changes only slightly farther away from the wall. Due to the no-slip condition

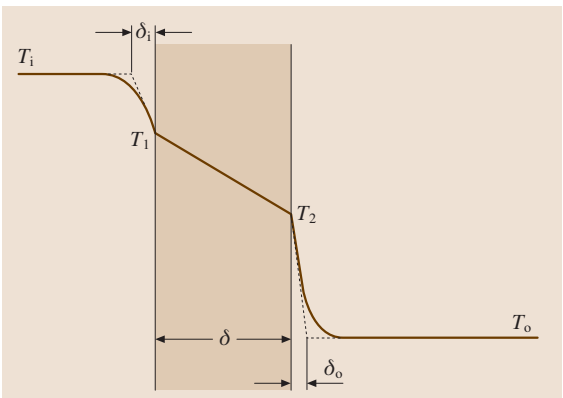

Fig. 4.32 Heat transmission through a flat wall

for the fluid at the wall surface, it can simplistically be assumed that a thin fluid boundary layer at rest, of thickness δ_i and δ_o, respectively, adheres to the wall while the fluid outside balances the temperature differences. In the thin fluid layer, heat transfer is by conduction and, according to Fourier's law, the heat flow transfer rate at the left wall side is given by

$$\dot{Q} = \lambda A \frac{T_i - T_1}{\delta_i} ,$$

where λ is the thermal conductivity of the fluid. The film thickness depends on many parameters such as the velocity of the fluid along the wall and the form and surface conditions of the wall. It has been proven suitable to use the quotient $\lambda/\delta_i = \alpha$ instead of the film thickness δ_i. This leads to the Newtonian formulation for the heat transfer rate from a fluid to a solid surface

$$\dot{Q} = \alpha A (T_f - T_0) , \qquad (4.169)$$

where T_f is the fluid temperature and T_0 is the surface temperature. The quantity α is defined as the heat transfer coefficient (SI unit $W/(m^2K)$). Orders of magnitude for heat transfer coefficients are given in Table 4.23. The basics needed for the calculation of α are contained in section Sect. 4.10.4. Following Ohm's law $I = (1/R) \times U$, the quantity $1/(\alpha A) = R_{th}$ is also called the convective heat transfer resistance (SI unit K/W). It must be overcome by the temperature difference $\Delta T = T_f - T_0$ to enable the heat transfer $\dot{Q}$. In Fig. 4.32, the heat transfer must overcome three single resistances in series, which sum up to the total resistance.

Heat Transmission Through a Plane Wall.

The heat transfer passing through a plane wall (Fig. 4.32) is given by

$$\dot{Q} = kA(T_i - T_o) , \qquad (4.170)$$

Table 4.23 Heat transfer coefficients α

where $1/(kA)$ is the total heat resistance, which is, again, the sum of the individual resistances

$$\frac{1}{kA} = \frac{1}{\alpha_i A} + \frac{\delta}{\lambda A} + \frac{1}{\alpha_o A} . \qquad (4.171)$$

The quantity k, defined by (4.170) is called the heat transmission coefficient (SI unit $W/(m^2K)$). If the wall consists of several homogeneous layers (Fig. 4.33) with thicknesses δ_1, δ_2, ... and thermal conductivities λ_1, λ_2, ..., (4.170) holds likewise with the total resistance

$$\frac{1}{kA} = \frac{1}{\alpha_i A} + \sum \frac{\delta_j}{\lambda_j A} + \frac{1}{\alpha_o A} . \qquad (4.172)$$

Example 4.16: The wall of a cold store consists of a 5 cm-thick, internal concrete layer ($\lambda = 1\,W/(Km)$), a 10 cm-thick cork stone insulation ($\lambda = 0.04\,W/(Km)$), and a 50 cm-thick external brick wall. The inner heat transfer coefficient is $\alpha_i = 7\,W/(m^2K)$ and the outer coefficient is $\alpha_o = 20\,W/(m^2K)$. What is the heat transfer rate through 1 m^2 of the wall if the temperatures inside and outside are −5 °C and 25 °C, respectively?

According to (4.172) the heat transmission resistance is

$$\frac{1}{kA} = \left(\frac{1}{7\times1} + \frac{0.05}{1\times1} + \frac{0.1}{0.04\times1} + \frac{0.5}{0.75\times1} + \frac{1}{20\times1}\right)\frac{K}{W}$$
$$= 3.41\,\frac{K}{W} .$$

The heat transfer rate is $\dot{Q} = \frac{1}{3.41}(-5-25)\,W$, $|\dot{Q}| = 8.8\,W$.

Heat Transmission Through Tubes.

For heat transmission through tubes, (4.170) again holds, where the thermal resistance is the sum of the single resistances

$$\frac{1}{kA} = \frac{1}{\alpha_i A_i} + \frac{\delta}{\lambda A_m} + \frac{1}{\alpha_o A_o} .$$

The heat transmission coefficient k is usually related to the outer tube surface $A = A_o$, which is often easier to determine. The following equation therefore holds

$$\frac{1}{kA_o} = \frac{1}{\alpha_i A_i} + \frac{\delta}{\lambda A_m} + \frac{1}{\alpha_o A_o} , \qquad (4.173)$$

where $A_m = (A_o - A_i)/\ln(A_o/A_i)$. If the tube consists of several homogeneous layers with thicknesses $\delta_1, \delta_2, \ldots$ and thermal conductivities $\lambda_1, \lambda_2, \ldots$, (4.170) likewise holds for the total resistance

$$\frac{1}{kA_o} = \frac{1}{\alpha_i A_i} + \sum \frac{\delta_j}{\lambda_j A_{mj}} + \frac{1}{\alpha_o A_o} , \qquad (4.174)$$

where the total resistance must be summed from the single layers j with their respective mean logarithmic areas

$$A_{mj} = (A_{oj} - A_{ij}) \ln\left(\frac{A_{oj}}{A_{ij}}\right) .$$

4.10.3 Transient Heat Conduction

During transient heat conduction, the temperatures vary with respect to time. In a plane wall with prescribed surface temperatures, the temperature profile is no longer linear as the heat transfer into the wall differs from the heat transfer out. The difference between transfer in and heat transfer out increases (or decreases) the internal energy of the wall and, thus, its temperature is a function of time. For plane walls with heat transfer in the direction of the x-axis, Fourier's heat conduction equation holds

$$\frac{\partial T}{\partial \tau} = a \frac{\partial^2 T}{\partial x^2} . \qquad (4.175)$$

Multidimensional heat conduction is represented by the following relation

$$\frac{\partial T}{\partial \tau} = a \left(\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2} \right) . \qquad (4.176)$$

In this form, both equations assume constant thermal conductivity λ (isotropic). The quantity $a = \lambda/(\varrho\, c)$ is defined as the thermal diffusivity (SI unit m^2/s), numerical values for which are given in Table 4.24.

For the solution of Fourier's equation, it is suitable to introduce – as in other heat transfer problems – dimensionless quantities, which reduce the number of variables. Equation (4.175) is considered in order to demonstrate the basic procedure. The dimensionless temperature is set to $\Theta = (T - T_c)/(T_0 - T_c)$, where T_c is a characteristic constant temperature and T_0 is the initial temperature. If the cooling of a plate with an initial temperature T_0 in a cold environment is considered, T_c could be, for example, the ambient temperature T_{env}. All lengths are related to a characteristic length X, e.g., half of the plate thickness. Furthermore, it is suitable to introduce the dimensionless time, which is called the *Fourier number*, as $\mathrm{Fo} = a\tau/X^2$. The solution of the heat conduction equation then has the form

$$\Theta = f(x/X, \mathrm{Fo}).$$

In many problems, the heat transfer to the surface of a body by convection to the surrounding fluid of temperature T_{env}. The energy balance then holds at the surface (index w = wall)

$$-\lambda \left(\frac{\partial T}{\partial x}\right)_w = \alpha(T_w - T_{env})$$

or

$$\frac{1}{\Theta_w}\left(\frac{\partial \Theta}{\partial \xi}\right)_w = -\frac{\alpha X}{\lambda} ,$$

where $\xi = x/X$, $\Theta = (T - T_{env})/(T_0 - T_{env})$, and $\Theta_w = (T_w - T_{env})/(T_0 - T_{env})$. The solution is also a function of the dimensionless quantity $\alpha X/\lambda$, which is defined as the Biot number Bi, where the thermal conductivity λ of the body is assumed to be constant, and α is the heat transfer coefficient between the body and the surrounding fluid. Solutions of (4.175) have the form

$$\Theta = f(x/X, \mathrm{Fo}, \mathrm{Bi}) . \qquad (4.177)$$

Semi-infinite Body

Temperature changes may also take place in a region that is thin in comparison to the overall dimensions

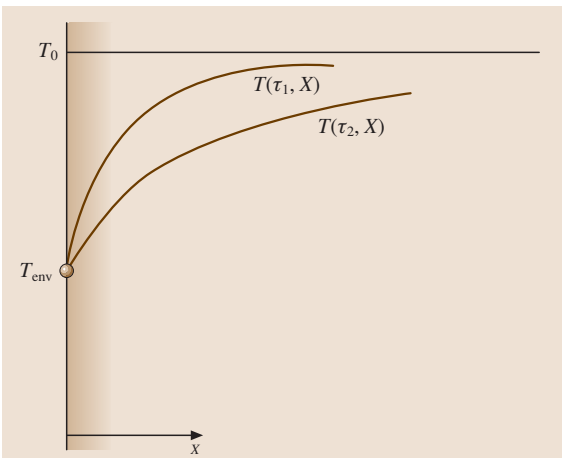

Fig. 4.34 Semi-infinite body

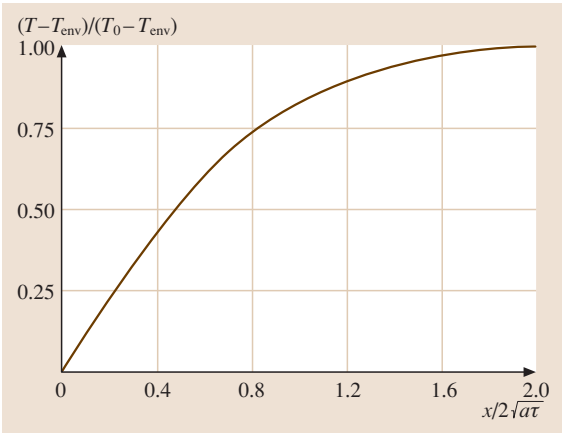

Fig. 4.35 Temperature course in a semi-infinite body

of the body. Such a body is called semi-infinite. In this case, a semi-infinite plane wall (Fig. 4.34) with a constant initial temperature T_0 is considered. At time $\tau = 0$, the surface temperature of the wall is reduced to $T(x = 0) = T_{env}$ and then remains constant. The temperature profiles at different times $\tau_1, \tau_2 \ldots$ are given by

$$\frac{T - T_{env}}{T_0 - T_{env}} = f\left(\frac{x}{2\sqrt{a\tau}}\right) \qquad (4.178)$$

with the Gaussian error function $f(x/(2\sqrt{a\tau}))$; see Fig. 4.35. The heat flux at the surface results from the differentiation $\dot{q} = -\lambda(\partial T/\partial x)_{x=0}$, which yields

$$\dot{q} = \frac{b}{\sqrt{\pi\,\tau}}(T_{env} - T_0)\,. \qquad (4.179)$$

The heat penetration coefficient $b = \sqrt{\lambda\varrho\,c}$ (SI unit $\mathrm{Ws^{1/2}/(m^2K)}$) (Table 4.25), is a measure for the heat transfer that has penetrated into the body at a given time, if the surface temperature was suddenly increased by the amount $T_{env} - T_0$ as compared to the initial temperature T_0.

Example 4.17: A sudden change in weather causes the temperature at the Earth's surface to drop from +5 °C to −5 °C. How much does the temperature decrease at a depth of 1 m after 20 days? The thermal diffusivity of the soil is $a = 6.94\times10^{-7}\ \mathrm{m^2/s}$. According to (4.178), the decrease is

$$\frac{T-(-5)}{5-(-5)} = f\left(\frac{1}{2\left(6.94\times10^{-7}\times20\times24\times3600\right)^{1/2}}\right)$$
$$= f(0.456)\,.$$

Figure 4.35 gives $f(0.456) = 0.48$, thus, $T = -0.2\,^\circ\mathrm{C}$.

Finite Heat Transfer at the Surface. According to Fig. 4.34, heat transfer is by convection from the surface of a body to the environment. At the surface, the relation $\dot{q} = -\lambda(\partial T/\partial x) = \alpha(T_w - T_{env})$ holds, with the ambient temperature T_{env} and the time-variable wall temperature $T_w = T(x = 0)$. In this case, (4.178) no longer holds. Instead, the heat transfer rate is given by

$$\dot{q} = \frac{b}{\sqrt{\pi\tau}}(T_{env} - T_0)\Phi(z)\,, \qquad (4.180)$$

where $\Phi(z) = 1 - \frac{1}{2z^2} + \frac{1\times3}{2^2z^4} - \ldots + (-1)^{n-1}\frac{1\times3\ldots(2n-3)}{2^{n-1}z^{2n-2}}$ and $z = \alpha\sqrt{a\tau}/\lambda$.

Two Semi-infinite Bodies in Thermal Contact

Two semi-infinite bodies of different, but initially constant, temperatures T_1 and T_2 with the thermal properties λ_1, a_1 and λ_2, a_2 are suddenly brought into contact at time $t = 0$ (Fig. 4.36). After a very short time at both sides of the contact area, a temperature T_m is present and remains constant. This temperature is given

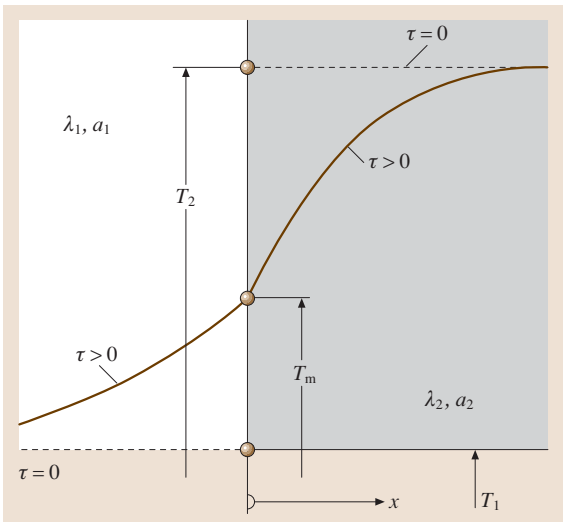

Fig. 4.36 Contact temperature T_m between two semi-infinite bodies

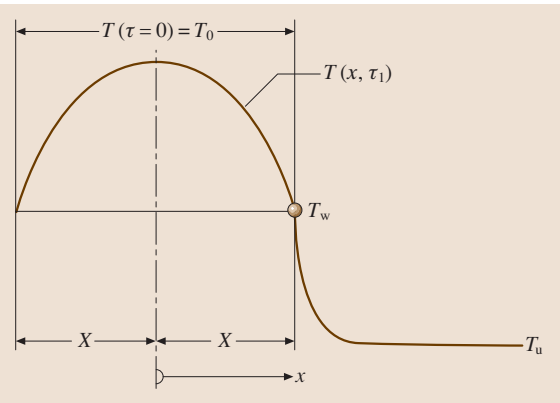

Fig. 4.37 Cooling of a flat plate

by

$$\frac{T_m - T_1}{T_2 - T_1} = \frac{b_2}{b_1 + b_2} .$$

The contact temperature T_m is closer to the temperature of the body with the higher heat penetration coefficient b. One of the values b can be determined by measuring T_m, if the other value is known.

Temperature Equalization in Simple Bodies

A simple body such as a plate, a cylinder, or a sphere may have a uniform temperature T_0 at time $\tau = 0$. Afterwards, however, it is cooled or heated due to heat transfer between the body and a surrounding fluid of temperature T_{env} given by the boundary condition $-\lambda(\partial T/\partial n)_w = \alpha(T_w - T_{env})$, where n is the coordinate perpendicular to the body surface.

Plane Plate. The temperature profile shown in Fig. 4.37 is described by an infinite series. However, for $a\tau/X^2 \geq 0.24$ (where $a = \lambda/(\varrho c)$ is the thermal diffusivity), the following relation provides a good approximation

$$\frac{T - T_{env}}{T_0 - T_{env}} = C \exp\left(-\delta^2 \frac{a\tau}{X^2}\right) \cos\left(\delta \frac{x}{X}\right) \qquad (4.181)$$

with less than a 1% error in temperature. The constants C and δ depend, according to Table 4.26, on the Biot number $\mathrm{Bi} = \alpha X/\lambda$. When $x = X$, (4.181) leads to the surface temperature T_w at the wall. The heat transfer rate follows from $\dot{Q} = -\lambda A(\partial T/\partial x)_{x=X}$.

Cylinder. The radial coordinate r replaces coordinate x in Fig. 4.37, and the radius of the cylinder is R. Again, the temperature profile is described by an infinite series, which can be approximated for $a\tau/R^2 \geq 0.21$ by

$$\frac{T - T_{env}}{T_0 - T_{env}} = C \exp\left(-\delta^2 \frac{a\tau}{R^2}\right) I_0\left(\delta \frac{r}{R}\right) \qquad (4.182)$$

with less than 1% error. The term I_0 is a Bessel function of zeroth order. Its values are presented in tables [4.22]. The constants C and δ depend, according to Table 4.27, on the Biot number. When $r = R$, the surface temperature at the wall results from (4.182) and the heat transfer rate from $\dot{Q} = -\lambda A(\partial T/\partial r)_{r=R}$, where the first derivative of the Bessel function $I_0' = I_1$ appears. The Bessel function of first order I_1 is also given in [4.23].

Sphere. The cooling or heating of a sphere of radius R is also described by an infinite series. For $a\tau/R^2 \geq 0.18$, temperature profile can be approximated by

$$\frac{T - T_{env}}{T_0 - T_{env}} = C \exp\left(-\delta^2 \frac{a\tau}{R^2}\right) \frac{\sin\left(\delta \frac{r}{R}\right)}{\delta \frac{r}{R}} \qquad (4.183)$$

with less than 2% error. The constants C and δ depend, according to Table 4.28, on the Biot number.

4.10.4 Heat Transfer by Convection

If heat transfer in fluids with bulk fluid motion is considered, in addition to (molecular) heat conduction, energy transport by convection must be taken into account. Each volume element of the fluid possesses internal energy, which is transported by the flow and, in the case considered here, is transferred by convection to a solid body.

Dimensionless Characteristic Numbers. The basis for the description of processes of convective transport is the use of similarity mechanics. These descriptions allow for the considerable reduction of the number of influencing parameters and for the expression of the general heat transfer laws for geometrically similar bodies and different substances. The following dimen-

\end{aligned}$$

The variables signify the following: λ – thermal conductivity of the fluid, l – a characteristic length of the flow domain l_1, l_2, ..., ν – the kinematic viscosity of the fluid, ϱ – density, $a = \lambda/(\varrho\, c_\mathrm{p})$ – thermal diffusivity, c_p – constant-pressure specific heat of the fluid, g – gravitational acceleration, $\Delta T = T_\mathrm{w} - T_\mathrm{f}$ – difference between the wall temperature T_w of a cooled or heated body and the mean temperature T_f of the fluid along the body, β – thermal volume expansivity at the wall temperature with $\beta = 1/T_\mathrm{w}$ for ideal gases. The Prandtl number is a fluid property (Table 4.24).

Forced and natural convection are distinguished as follows. In forced convection, the fluid motion is caused by outer forces, e.g., by the pressure increase in a pump. In natural convection, the fluid motion is caused by density differences in the fluid and the corresponding buoyancy effects in a gravitational field. These density differences usually arise due to temperature differences, rarely due to pressure differences. In mixtures, density differences are also caused by concentration differences. The heat transfer in forced convection is described by equations of the form

$$\mathrm{Nu} = f_1(\mathrm{Re}, \mathrm{Pr}, l_n/l) \tag{4.184}$$

and in natural convection by

$$\mathrm{Nu} = f_2(\mathrm{Gr}, \mathrm{Pr}, l_n/l) \,. \tag{4.185}$$

The desired heat transfer coefficient is obtained from the Nusselt number by $\alpha = \mathrm{Nu}\lambda/l$. The functions f_1 and f_2 can be determined theoretically only for special cases. In general, they must be determined through experimentation and depend on the shape of the cooling or heating areas (even, vaulted, smooth, rough or finned), the flow structure and, usually to a minor extent, on the direction of the heat transfer (heating or cooling).

Heat Transfer Without Change of Phase

Forced Convection.

Laminar Flow Along a Flat Plate. According to *Pohlhausen* [4.24], for the mean Nusselt number of a plate of length l, the following relation holds

$$\mathrm{Nu} = 0.664\,\mathrm{Re}^{1/2}\mathrm{Pr}^{1/3} \,, \tag{4.186}$$

where $\mathrm{Nu} = \alpha l/\lambda$, $\mathrm{Re} = wl/\nu < 10^5$, and $0.6 \leq \mathrm{Pr} \leq 2000$. The material properties must be evaluated at the mean fluid temperature $T_\mathrm{m} = (T_\mathrm{w} - T_\infty)/2$, where T_w is the wall temperature and T_∞ the free-stream temperature far beyond the wall surface.

Turbulent Flow Along a Flat Plate. From about $\mathrm{Re} = 5 \times 10^5$ the boundary layer becomes turbulent. The mean Nusselt number of a plate of length l in this case is

$$\mathrm{Nu} = \frac{0.037\,\mathrm{Re}^{0.8}\mathrm{Pr}}{1 + 2.443\,\mathrm{Re}^{-0.1}(\mathrm{Pr}^{2/3} - 1)} \,, \tag{4.187}$$

where $\mathrm{Nu} = \alpha l/\lambda$, $\mathrm{Re} = wl/\nu$, $5 \times 10^5 < \mathrm{Re} < 10^7$, and $0.6 \leq \mathrm{Pr} \leq 2000$. The material properties must be evaluated at the mean fluid temperature $T_\mathrm{m} = (T_\mathrm{w} - T_\infty)/2$. T_w is the wall temperature and T_∞ the free-stream temperature far beyond the wall surface.

Flow Through Pipes in General. Below a Reynolds number of $\mathrm{Re} = 2300$ ($\mathrm{Re} = wd/\nu$, where w is the mean cross-sectional velocity and d is the pipe diameter), the flow is laminar, while above $\mathrm{Re} = 10^4$, the flow is turbulent. In the range $2300 < \mathrm{Re} < 10^4$, whether the flow

is laminar or turbulent depends on the roughness of the pipe, the means of inflow, and the shape of the pipe in the inflow section. The mean heat transfer coefficient α over the pipe length l is defined by $\dot{q} = \alpha \Delta\vartheta$, with the mean logarithmic temperature difference described by

$$\Delta\vartheta = \frac{(T_w - T_{in}) - (T_w - T_{out})}{\ln \frac{T_w - T_{in}}{T_w - T_{out}}} , \qquad (4.188)$$

where T_w is the wall temperature, T_{in} is the temperature at the inlet, and T_{out} is the temperature at the outlet cross-section.

Laminar Flow Through Pipes. A flow is termed hydrodynamically developed if the velocity profile no longer changes in the flow direction. In a laminar flow of a highly viscous fluid, the velocity profile adopts the shape of a Poiseuillean parabola after only a short distance from the inlet. The mean Nusselt number at constant wall temperature can be calculated exactly via an infinite series (the Graetz solution), which, however, converges poorly. According to *Stephan* [4.25], as an approximate solution for the hydrodynamically developed laminar flow, the following equation holds

$$Nu_0 = \frac{3.657}{\tanh(2.264X^{1/3} + 1.7X^{2/3})} + \frac{0.0499}{X}\tanh X , \qquad (4.189)$$

where $Nu_0 = \alpha d/\lambda$, $X = l/(d\,Re\,Pr)$, $Re = wd/\nu$, and $Pr = \nu/a$. This equation is valid for laminar flow ($Re \leq 2300$) in the entire range $0 \leq X \leq \infty$ and the maximum deviation from the exact values of the Nusselt number is 1%. The fluid properties must be evaluated at the mean fluid temperature $T_m = (T_w + T_B)/2$, where $T_B = (T_{in} + T_{out})/2$.

If a fluid enters a pipe at an approximately constant velocity, the velocity profile changes along the flow path until it reaches the Poiseuillean parabola after a distance described by the equation $l/(d\,Re) = 5.75 \times 10^{-2}$. According to *Stephan* [4.25], for this case, that of a hydrodynamically developed laminar flow, the following equation holds for the range $0.1 \leq Pr \leq \infty$

$$\frac{Nu}{Nu_0} = \frac{1}{\tanh(2.43\,Pr^{1/6}X^{1/6})} , \qquad (4.190)$$

where $Nu = \alpha d/\lambda$ and the quantities are defined as above. The error is less than 5% for $1 \leq Pr \leq \infty$ but is up to 10% for $0.1 \leq Pr < 1$. The fluid properties must be evaluated at the mean fluid temperature $T_m = (T_w + T_B)/2$, where $T_B = (T_{in} + T_{out})/2$.

Heat Transfer for Turbulent Flow Through Pipes. For a hydrodynamically developed flow ($l/d \geq 60$) the McAdam equation holds in the range $10^4 \leq Re \leq 10^5$ and $0.5 < Pr < 100$

$$Nu = 0.024\,Re^{0.8}Pr^{1/3} . \qquad (4.191)$$

The fluid properties have to be evaluated at the mean temperature $T_m = (T_w + T_B)/2$ with $T_B = (T_{in} + T_{out})/2$.

For hydrodynamically undeveloped flow and for developed flow, Petukhov's equation (modified by Gnielinski) holds in the range $10^4 \leq Re \leq 10^6$ and $0.6 \leq Pr \leq 1000$

$$Nu = \frac{Re\,Pr\zeta/8}{1 + 12.7\sqrt{\zeta/8}(Pr^{2/3} - 1)}\left[1 + \left(\frac{d}{l}\right)^{2/3}\right] , \qquad (4.192)$$

where the friction factor $\zeta = (0.78 \ln Re - 1.5)^{-2}$, $Nu = \alpha d/\lambda$, and $Re = wd/\nu$. The fluid properties must be evaluated at the mean temperature $T_m = (T_w + T_B)/2$. Under otherwise similar conditions, the heat transfer coefficients are larger in pipe bends than in straight pipes with the same cross section. For a pipe bend with a bend diameter D, the following equation holds, according to Hausen, for turbulent flow

$$\alpha = \alpha_{straight}\left[1 + \left(21\,Re^{0.14}\right)(d/D)\right] . \qquad (4.193)$$

A Single Pipe Placed Transversely in a Flow. The heat transfer coefficient for a pipe placed transversely in a flow can be determined from Gnielinski's equation

$$Nu = 0.3 + \left(Nu_\ell^2 + Nu_t^2\right)^{1/2} , \qquad (4.194)$$

where the Nusselt number Nu_ℓ of the laminar plate flow is described according to (4.186), Nu_t of the turbulent plate flow is described according to (4.187), and $Nu = \alpha l/\lambda$, $1 < Re = wl/\nu < 10^7$, and $0.6 < Pr < 1000$. For length l, the overflowed length $l = d\pi/2$ must be inserted. The fluid properties must be evaluated at the mean temperature $T_m = (T_{in} + T_{out})/2$. This equation holds for mean turbulence intensities of 6–10%, which can be expected in technical applications.

A Row of Pipes Placed Transversely in a Flow. Mean heat transfer coefficients for a single row of pipes placed transversely in a flow (Fig. 4.38) can also be determined using (4.194). Now, however, the Reynolds number must be calculated with the mean velocity w_m in the pipe row placed transversely in the flow.

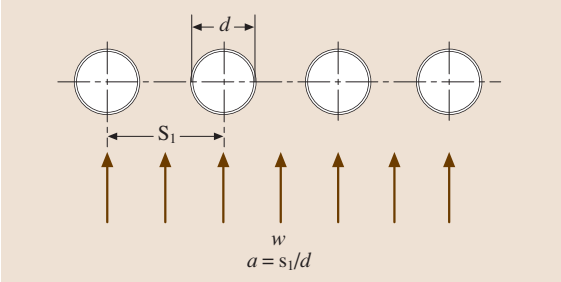

Fig. 4.38 A row of pipes placed transversely in a flow

The Reynolds number is described by the equation: $\mathrm{Re} = w_\mathrm{m} l/\nu$, where $w_\mathrm{m} = w/\psi$, w is the far-field velocity and $\psi = 1 - \pi/(4a)$ is the void space fraction, where $a = s_1/d$ (Fig. 4.38).

A Pipe Bundle. If the pipes are placed in straight lines (Fig. 4.39a), the axes of all pipes are consecutively in the flow direction. If the arrangement is staggered (Fig. 4.39b), the axes of a pipe row are shifted in comparison to the axes of the row in front. The heat transfer depends additionally on the crosswise and longwise division of the pipes, $a = s_1/d$ and $b = s_2/d$. The determination of the heat transfer coefficient starts with the calculation of the Nusselt number for a single pipe placed transversely in the flow, according to (4.194), in which the Reynolds number contains the mean velocity w_m in the pipe bundle: $\mathrm{Re} = w_\mathrm{m} l/\nu$, where $w_\mathrm{m} = w/\psi$, w is the far-field velocity of the pipe row, and ψ is the void space fraction $\psi = 1 - \pi/(4a)$ for $b > 1$ and $\psi = 1 - \pi/(4ab)$ for $b < 1$. The Nusselt number determined in this way must be multiplied by an arrangement factor f_A. This leads to the Nusselt number $\mathrm{Nu_B} = \alpha_\mathrm{B} l/\lambda$ (where $l = d\pi/2$) of the bundle

$$\mathrm{Nu_B} = f_\mathrm{A}\mathrm{Nu}\,. \tag{4.195}$$

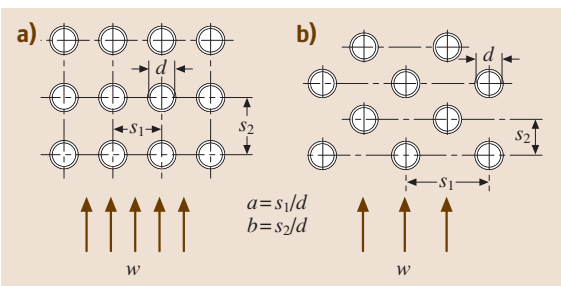

Fig. 4.39a,b Arrangement of pipes in pipe bundles: **(a)** in straight lines and **(b)** staggered

For a straight arrangement, the following holds

$$f_\mathrm{A} = 1 + 0.7(b/a - 0.3)/(\psi^{3/2}(b/a + 0.7)^2) \tag{4.196}$$

and for a staggered arrangement

$$f_\mathrm{A} = 1 + 2/(3b)\,. \tag{4.197}$$

The heat flux is $\dot{q} = \alpha\Delta\vartheta$ with $\Delta\vartheta$ according to (4.188). Equations (4.196) and (4.197) hold for pipe bundles consisting of ten or more pipe rows. For heat exchangers with fewer pipe rows, the heat transfer coefficient (4.195) must be multiplied by a factor $(1 + (n - 1) f_\mathrm{A}/n)$, where n is the number of pipe rows.

Natural Convection. The heat transfer coefficient for a vertical wall can be calculated with the equation of Churchill and Chu

$$\mathrm{Nu} = \left(\frac{0.825 + 0.387\,\mathrm{Ra}^{1/6}}{\left[1 + (0.492/\mathrm{Pr})^{9/16}\right]^{8/27}} \right)^2 , \tag{4.198}$$

in which the mean Nusselt number $\mathrm{Nu} = \alpha l/\lambda$ is formed with the wall height l, and the Rayleigh number is defined as $\mathrm{Ra} = \mathrm{GrPr}$, where the Grashof number is described by the following

$$\mathrm{Gr} = \frac{g l^3}{\nu^2} \frac{\varrho_\infty - \varrho_\mathrm{w}}{\varrho_\mathrm{w}}$$

and the Prandtl number by $\mathrm{Pr} = \nu/a$.

If natural convection is caused solely by temperature differences, the Grashof number can be written

$$\mathrm{Gr} = \frac{g l^3}{\nu^2} \beta (T_\mathrm{w} - T_\infty)\,,$$

where the volume expansivity is denoted by β, where $\beta = 1/T_\mathrm{w}$ for ideal gases. Equation (4.198) holds in the range $0 < \mathrm{Pr} < \infty$ and $0 < \mathrm{Ra} < 10^{12}$. The fluid properties must be evaluated at the mean temperature $T_\mathrm{m} = (T_\mathrm{w} - T_\infty)$. A similar equation holds according to Churchill and Chu also for natural convection in a horizontal cylinder

$$\mathrm{Nu} = \left(\frac{0.60 + 0.387\,\mathrm{Ra}^{1/6}}{\left[1 + (0.559/\mathrm{Pr})^{9/16}\right]^{8/27}} \right)^2 . \tag{4.199}$$

The same definitions used in (4.198) hold over the range of validity $0 < \mathrm{Pr} < \infty$ and $10^{-5} \le \mathrm{Ra} \le 10^{12}$, and the characteristic length is the diameter d. For *horizontal rectangular plates*, the following holds for $0 < \mathrm{Pr} < \infty$

$$\mathrm{Nu} = 0.766(\mathrm{Ra}\, f_2)^{1/5} \quad \text{if} \quad \mathrm{Ra}\, f_2 < 7 \times 10^4 \tag{4.200}$$

and

$$\mathrm{Nu} = 0.15(\mathrm{Ra}\, f_2)^{1/3} \quad \text{if} \quad \mathrm{Ra}\, f_2 > 7\times 10^4 \,, \tag{4.201}$$

where

$$f_2 = \left[1 + (0.322/\mathrm{Pr})^{11/20}\right]^{-20/11} \,,$$

where $\mathrm{Nu} = \alpha l/\lambda$, if l is the shorter side of the rectangle.

Heat Transfer in Condensation and in Boiling

Condensation. If the temperature of a wall surface is lower than the saturation temperature of adjacent vapor, the vapor is condensed at the wall surface. Depending on the wetting characteristics, the condensate forms drops or a continuous liquid film. The heat transfer coefficients are usually larger for dropwise condensation than for film condensation. However, in order to maintain dropwise condensation for a certain amount of time, particular measures such as the application of dewetting agents are necessary. Dropwise condensation therefore appears rather seldom.

Film Condensation. If the condensate flows as a laminar film on a vertical wall of height l, the mean heat transfer coefficient α is

$$\alpha = 0.943 \left(\frac{\varrho g r \lambda^3}{\nu (T_\mathrm{s} - T_\mathrm{w})} \frac{1}{l} \right)^{1/4} \,. \tag{4.202}$$

For condensation on horizontal single pipes with an outer diameter d, the following relation holds

$$\alpha = 0.728 \left(\frac{\varrho g r \lambda^3}{\nu (T_\mathrm{s} - T_\mathrm{w})} \frac{1}{l} \right)^{1/4} \,. \tag{4.203}$$

The equations require that no noticeable shear stress is exerted by the vapor on the condensate film. At Reynolds number $\mathrm{Re}_\delta = w_\mathrm{m}\delta/\nu$ (where w_m is the velocity of the condensate, d the film thickness, and ν the kinematic viscosity) between 75 and 1200 the transition to turbulent flow in the condensate film gradually takes place. In the transition range, the following relation holds

$$\alpha = 0.22\lambda/(\nu^2/g)^{1/3} \,, \tag{4.204}$$

whereas for turbulent film flow ($\mathrm{Re}_\delta > 1200$), the following relation according to Grigull holds

$$\alpha = 0.003 \left(\frac{\lambda^3 g\, (T_\mathrm{s} - T_\mathrm{w})}{\varrho \nu^3 r} l \right)^{1/2} \,. \tag{4.205}$$

Equations (4.204) and (4.205) are valid also for vertical pipes and plates but not for horizontal pipes.

Evaporation. If a liquid in a container is heated, evaporation starts after the boiling temperature T_s is exceeded. For small excess wall temperatures $T_\mathrm{w} - T_\mathrm{s}$ the liquid evaporates only on its free surface (silent boiling). Heat is transported by the buoyancy flow from the heating surface to the free surface of the liquid. For higher excess wall temperatures vapor bubbles are formed at the heating surface (nucleate boiling) and rise. They increase the movement of the liquid and thus the heat transfer. With increasing excess wall temperature, the bubbles merge more and more into a continuous vapor film, whereby the heat transfer is decreased (transition boiling). Figure 4.40 shows the different heat transfer ranges. The heat transfer coefficient α is defined as

$$\alpha = \dot{q}/(T_\mathrm{w} - T_\mathrm{s}) \,,$$

where the heat flux is $\dot{q}$ in $\mathrm{W/m^2}$.

Industrial evaporators work in the range of silent boiling or, more often, in the nucleate boiling range. In the silent boiling range the laws for heat transfer in natural convection hold, (i. e., (4.198) and (4.199)). In the nucleate boiling region

$$\alpha = c\dot{q}^n F\,(p) \;\text{ with } 0.5 < n < 0.8 \,.$$

For water at boiling pressures between 0.5 and 20 bar, according to *Fritz* [4.26], the following relation holds

$$\alpha = 1.95\dot{q}^{0.72} p^{0.24} \tag{4.206}$$

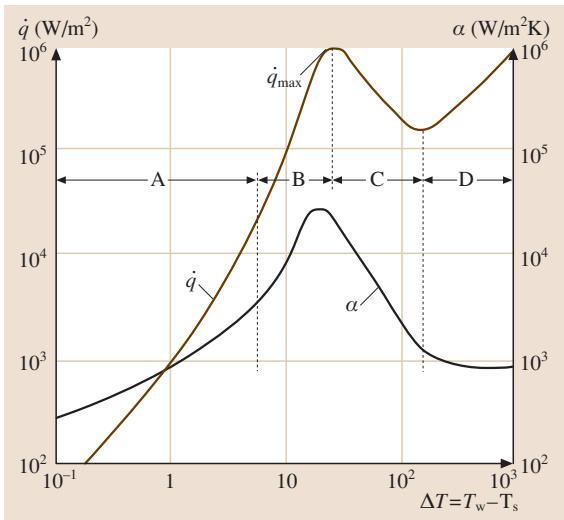

Fig. 4.40 Boiling ranges for water of 1 bar. A: natural convection (silent boiling), B nucleate boiling, C transition boiling, D film boiling

with α in W/(m^{2}K), $\dot{q}$ in W/m^2 and p in bar. According to Stephan and Preußer, for arbitrary liquids the following relation is valid for nucleate boiling close to ambient pressure

$$\mathrm{Nu} = 0.0871 \left(\frac{\dot{q}d}{\lambda' T_\mathrm{s}}\right)^{0.674} \left(\frac{\varrho''}{\varrho'}\right)^{0.156} \left(\frac{rd^2}{a'^2}\right)^{0.371} \times \left(\frac{a'^2\varrho'}{\sigma d}\right)^{0.350} (\mathrm{Pr}')^{-0.162} \ . \qquad (4.207)$$

$\mathrm{Nu} = \alpha d/\lambda'$ is formed with the detachment diameter of the vapor bubbles $d = 0.851\beta_0 \left[2\sigma/g(\varrho' - \varrho'')\right]^{1/2}$, where the contact angle is $\beta_0 = 45°$ for water, 1° for low-boiling and 35° for other liquids. Quantities denoted with a single prime relate to the boiling liquid, those with a double prime relate to the saturated vapor. The equations above are not valid for boiling in forced flow.

4.10.5 Radiative Heat Transfer

In addition to direct contact modes, heat can also be transferred by radiation. Thermal radiation (heat radiation) consists of a spectrum of electromagnetic waves in the wavelength range between 0.1 and 1000 µm. Visible light, as a reference, has a wavelength range between 0.4 and 0.76 µm. If a body is supplied with a heat transfer $\dot{Q}$ by radiation, the fraction $r\dot{Q}$ is reflected, the fraction $a\dot{Q}$ is absorbed, and the fraction $d\dot{Q}$ passes through (where $r + d + a = 1$). A body that reflects radiation completely ($r = 1,\ d = a = 0$) is called an ideal mirror, while a body that absorbs radiation completely ($a = 1,\ r = d = 0$) is called a black body. A body is called diathermal ($d = 1,\ r = a = 0$) if radiation passes completely through, where examples for this are gases such as O_2, N_2, etc.

Stefan–Boltzmann Law

Every body emits radiation corresponding to its surface temperature. The maximum radiation possible is emitted by a black body. It can be experimentally approximated by a blackened surface (e.g., with soot) or by a hollow space, whose walls have the same temperature everywhere, that has a small opening to let radiation out. The total radiation emitted by a black body per unit area is

$$\dot{e}_\mathrm{s} = \sigma T^4 \ , \qquad (4.208)$$

where $\dot{e}_\mathrm{s}$ is called the emission (W/m^2) of the black radiator, and $\sigma = 5.67 \times 10^{-8}$ W/m^{2}K^4 is the *radiation coefficient*, also called the Stefan–Boltzmann constant. The emission $\dot{e}_\mathrm{s}$ is an energy flux and thus equal to the heat flux $\dot{q}_\mathrm{s} = \mathrm{d}\dot{Q}/\mathrm{d}A$ a black radiator emits. With the emission $\dot{e}_\mathrm{n}$ in a normal direction and $\dot{e}_\varphi$ in the direction of angle φ to the normal, *Lambert's cosine law* $\dot{e}_\varphi = \dot{e}_\mathrm{n} \cos\varphi$ for black radiators holds true. Often the radiation of real bodies differs from this general law, however.

Kirchhoff's Law

Real bodies emit less than black radiators, where the energy emitted from real surfaces is

$$\dot{e} = \varepsilon \dot{e}_\mathrm{s} = \varepsilon\sigma T^4 \qquad (4.209)$$

with the emissivity being in the range $0 < \varepsilon < 1$ and in general depending on temperature (Table 4.29). In limited temperature ranges, many engineering surfaces (with the exception of shiny metal) can be interpreted as grey radiators. The energy radiated by them is distributed over wavelength in the same way as it is for black radiators, but reduced by a factor $\varepsilon < 1$. Strictly speaking, $\varepsilon = \varepsilon(T)$ holds true for grey radiators. For small temperature ranges, however, it is admissible to assume ε as constant. Assuming a body emitts the energy per unit area $\dot{e}$, and this energy flux strikes another body, this second body absorbs the energy or rather the heat transfer

$$\mathrm{d}\dot{Q} = a\dot{e}\ \mathrm{d}A \ . \qquad (4.210)$$

The absorptivity defined by this equation depends on the temperature T of the origin of the incident radiation and on the temperature T' of the receiving surface. For black bodies, this value is $a = 1$, as all radiation striking the surface is absorbed. For surfaces which are not black, this value is $a < 1$. For grey radiators, the absorptivity is $a = \varepsilon$. According to Kirchhoff's law, the emissivity is equal to the absorptivity, $\varepsilon = a$, for each surface which is in thermal equilibrium with its environment so that the temperature of the surface does not change in time.

Heat Exchange by Radiation

Between two parallel black surfaces of temperatures T_1 and T_2 and area A, which is very large in comparison to their separation, the heat transfer

$$\dot{Q}_{12} = \sigma A\left(T_1^4 - T_2^4\right) \qquad (4.211)$$

is exchanged by radiation. Between grey radiators with emissivities ε_1 and ε_2, the heat transfer is

$$\dot{Q}_{12} = C_{12} A\left(T_1^4 - T_2^4\right) \qquad (4.212)$$

$$\dot{Q}_{12} = \frac{\varepsilon_1 \varepsilon_2 \varphi_{12}}{1 - (1 - \varepsilon_1)(1 - \varepsilon_2)\varphi_{12}\varphi_{21}} \sigma A_1 \left(T_1^4 - T_2^4 \right) \tag{4.215}$$

exists, where φ_{12} and φ_{21} are the so-called view factors that depend on the geometric arrangement or the surfaces, values of which are given in [4.27].

Gas Radiation

Most gases are transparent to thermal radiation and neither emit nor absorb radiation. Exceptions are carbon dioxide, carbon monoxide, hydrocarbons, water vapor, sulfur dioxide, ammonia, hydrochloric acid, and alcohols. They emit and absorb radiation only in certain wavelength regions. The emissivity and absorptivity of these gases depend not only on temperature, but also on the geometric shape of the gas body.

5. Tribology

Ludger Deters

The main subjects of this chapter are the tribotechnical system, friction, wear and lubrication. Regarding the tribotechnical system essential information on structure, real contact geometry, tribological loads, operating and loss variables are provided. Concerning friction the different friction types, states and mechanisms are discussed. In the sections on wear a lot of details on types and mechanisms of wear, wear profiles and the determination of wear and the average useful life are introduced. The sections on lubrication contain relevant expositions on the lubrication states, like hydrodynamic, elastohydrodynamic, hydrostatic, mixed and boundary lubrication and lubrication with solid lubricants, on the lubricants, like mineral, synthetic and biodegradable oils and additives, lubricating greases and solid lubricants, and on the properties of lubricants, like the behaviour of the oil viscosity depending on temperature, pressure and shear rate and the consistency of lubricating greases.

5.1 Tribology

Tribology is the science and technology of interacting surfaces in relative motion. Tribology includes boundary-layer interactions both between solids and between solids and liquids and/or gases. Tribology encompasses the entire field of friction and wear, including lubrication [5.1].

Tribology aims to optimize friction and wear for a particular application case. Apart from fulfilling the required function, this means assuring high efficiency and sufficient reliability at the lowest possible manufacturing, assembly, and maintenance costs.

Friction and wear are frequently undesirable. While friction impairs the efficiency of machine elements, machines, and plants and thus increases the energy demand, wear diminishes the value of components and assemblies and can lead to the failure of machines and plants. On the other hand, many technical applications strive for high friction, e.g., brakes, clutches, wheels/rails, car tires/road, friction gears, belt drives, bolted joints, and press fits. To a limited extent, wear can also be advantageous in special cases, e.g., in breaking-in processes.

Friction and wear are not properties specific to the geometry or substance of only one of the elements involved in friction and wear, e.g., external dimensions, surface roughnesses, thermal conductivity, hardness, yield point, density or structure, but rather are properties of a system. The system's friction and/or wear behavior can already change seriously when one influencing variable of the tribotechnical system is marginally modified.

Lubrication is employed to lessen friction and minimize wear or to prevent them entirely. In the case of circulatory lubrication, the lubricant can additionally remove wear particles and heat from the friction contact. Other important tasks of lubrication are preventing corrosion (rusting) and, in the case of grease lubrication, sealing the friction points.

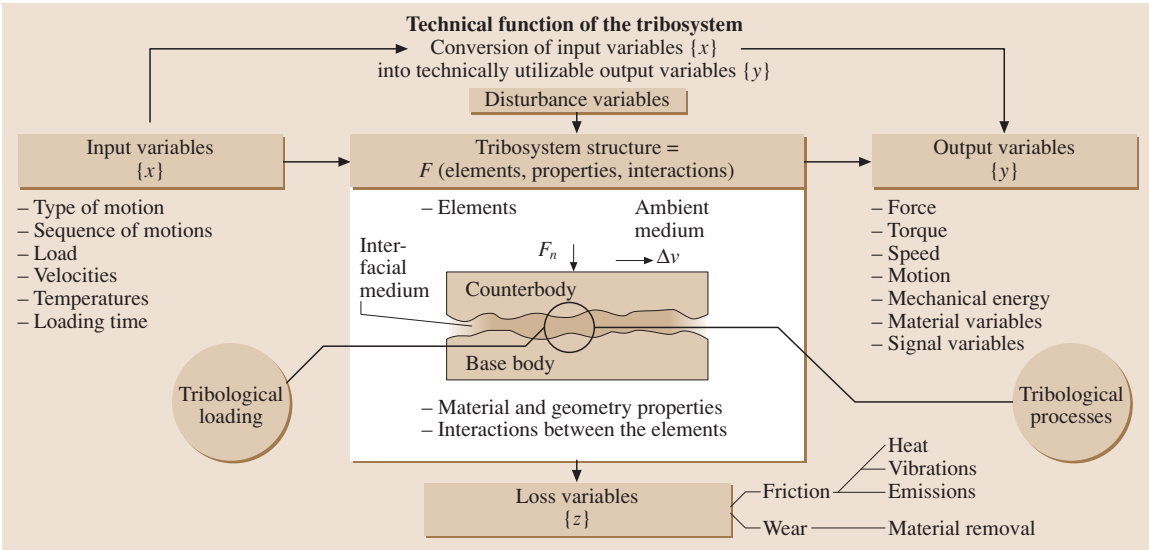

Fig. 5.1 Expanded representation of a tribotechnical system (TTS) (after [5.2])

5.1.1 Tribotechnical System

General Description

Friction and wear occur within a tribotechnical system (TTS). To delimit a TTS, a system envelope is appropriately placed around the components and materials directly involved in friction and wear, thus virtually isolating these from the remaining components. The materials and components involved in friction and wear are the elements of the TTS and are characterized by their material and shape properties. A tribotechnical system is described by the function to be fulfilled, the input variables (operating variables), the output variables, the loss variables, and the structure (Fig. 5.1).

Apart from desired *input variables*, undesired input variables, so-called *disturbance variables*, also arise. Together with the structure, they influence the *output* and *loss variables* of the TTS.

The function of a TTS is to use the system structure to convert input variables (e.g., input torque, input speed, input type of motion, and sequence of motions) into technically utilizable output variables (e.g., output torque, output speed, output motion) (Fig. 5.1).

Structure

The elements involved, their properties, and the interactions between the elements describe the structure of a TTS. The basic structure of all TTS consists of four elements: the base body, counterbody, interfacial medium, and ambient medium (Fig. 5.1). Table 5.1 displays some TTS with different elements. While the base body and counterbody are found in every TTS, the interfacial medium and, in a vacuum, even the ambient medium can be absent.

In transport and machining processes, the base body is constantly stressed by new material zones of the counterbody. Such systems are called *open* TTS. By contrast, the stressed zones of the base body and counterbody in *closed* TTS are repeatedly in contact. Examples of open and closed systems can also be found in Table 5.1. The function in open systems mainly depends on the wear of the base body. The counterbody generates the load; as a rule, the wear on it is not of interest. By comparison, when systems are closed, the ability to operate depends on the wear of both friction bodies. The elements of the TTS are characterized by a large number of *properties*, largely listed in Table 5.1.

A difference is made principally between geometry and material properties in the base body and counterbody, which are supplemented by physical variables. Interfacial medium and ambient medium can appear in different aggregate states, on which other important tribological properties depend. A difference in the material properties of the base body and counterbody is made between bulk material and the near-surface zone. The properties of the near-surface zone, e.g., structural composition, hardness, and chemical composition, are particularly important for the tribological processes. In addition, the surface roughnesses play an important role.

Figure 5.2 shows a diagram of the possible composition of *boundary layers* in metallic materials. The undisturbed *basic structure* generally has attached to it a hardened composition of machined or deformed layers endowed with a structure that is fine-grained compared with the basic structure. A reaction layer and an adsorption layer lie on top of this. Taken together they are also called the *outer boundary layer*. Wear is generally acceptable as long as it occurs in the outer boundary layer.

As a rule, not only the near-surface zone's material structure but also its chemical composition differs from those the bulk material. This is apparent in Fig. 5.3. The material beneath the surface already changes during manufacturing in terms of the concentration of elements present compared with the bulk material. Other considerable changes undergone by the near-surface zone's element concentrations are caused by breaking-in or occur after a short running time.

Contact Geometry

Not only the input variables, the material properties and the physical variables of the base body and counterbody, the interfacial medium, and the ambient medium but also the contact areas greatly influence friction and wear of the base body and counterbody and the tribotechnical system's lubrication state.

In turn, the contact areas appearing during operation depend on the form of contact (Table 5.2)), the input variables, the geometric properties of the base body and counterbody (Table 5.1), and the other system properties.

In the contact areas, a difference is made between the *nominal or apparent contact area* and the *real contact area* (Fig. 5.4).

The nominal or apparent contact area A_a corresponds to the macroscopic contact area of the bodies in contact, e.g., of the contact area *ab* of a cuboid on one plane or the Hertzian contact area between a cylin-

der and a plane. Not only the apparent contact area but also the real contact areas $A_{r,i}$ play a key role when the asperities of the friction bodies meet in the apparent contact area.

The real contact areas result from the asperity contacts, which occur when the friction bodies are not completely separated by a lubricating film or in cases of application in which no lubricant is used (dry friction). Not only the roughness but also the waviness on the friction body surfaces have to be taken into account when analyzing the real contact areas. The waviness causes so-called *contour areas* $A_{c,i}$ to form as well as the real contact areas on the asperity contacts within the contour areas.

As a rule, the total of the real contact areas A_r, which is dependent on the roughness distributions and the separation of the two friction body surfaces, is substantially smaller than the apparent contact area ($A_r \approx 10^{-1}$–$10^{-4} A_a$). Hence the real contact pressures in the asperity contacts are substantially higher than the nominal pressure. While the nominal pressure displays elastic macromaterial behavior, plastic deformation may already have begun for a majority of the microcontacts (real contact areas). Results of calculations have yielded that the total of the real contact areas is nearly proportional to the normal force F_n [5.5]. In addition, as the normal force increases, the number of real individual contacts increases, while the real individual contact area $A_{r,i}$ remains roughly constant.

Apart from the real contact area, the *overlap ratio* ε also plays an important role as well. It represents the ratio of the apparent contact area A_a to a friction body's friction area A_f. Thus, for example, the nonrotating bush of a sliding bearing with bearing clearance has an overlap ratio of $\varepsilon = 1$, since the apparent contact area A_a for the bearing bush corresponds to the friction area A_f. For the rotating shaft however, the friction area $A_f = \pi db$, with shaft diameter d and bearing bush width b, is larger than the apparent contact area $A_a = db\gamma/2$, with contact angle γ, so that the overlap ratio is $\varepsilon < 1$. For a constantly loaded friction body, an overlap ratio $\varepsilon = 1$ means permanent contact, no cyclical mechanical loads (macroscopic), permanent frictional heat absorption, and limited microchemical reaction with the ambient medium. For the friction body concerned, an overlap ratio of $\varepsilon < 1$ leads to an intermittent contact, to cyclical mechanical loading, to intermittent frictional heat absorption, and to tribochemical reactions with the ambient medium in the range A_f–A_a. When both friction bodies (the base body and counterbody) have an overlap ratio of $\varepsilon \approx 1$, the wear particles can remain in the contact area and hence adversely influence the further wear profile.

Tribological Loads and Interactions

Tribological loads in a TTS are generated by the input and disturbance variables' action on the system structure. They chiefly include contact, kinematic, and thermal processes [5.2]. According to [5.1], the tribological load represents "the loading of the surface of

a solid caused by contact and relative motion of a solid, liquid or gaseous counterbody." It is introduced via the real contact areas. Plastic deformation and wear can cause the real contact areas to change during TTS operation.

When mechanical energy is converted by friction, energy dissipates, which makes itself noticeable by changing the thermal situation. Since the thermal behavior also continuously adapts to the new conditions as a result of wear, changes to the contact geometry, and resulting changes in the friction, dynamic rather than static influencing variables determine the tribological loading in a real contact.

The contact geometry, the processes occurring in the contact, and the thermal behavior of a TTS are influenced by, among other things, the load, the motion conditions, the element properties, and the friction state.

While the apparent contact area alone is decisive in fluid lubrication, according to [5.6], in mixed lubrication, i. e., when the dimensionless film parameter

$$\Lambda = \frac{h_{\min}}{\left(R_{q1}^2 + R_{q2}^2\right)^{1/2}}\,, \tag{5.1}$$

with the minimum lubrication film thickness $h_{\min}$ and the root-mean-square (rms) surface roughnesses R_{q1} and R_{q2} of the base body and counterbody is in the range $\Lambda < 3$, in boundary lubrication with $\Lambda < 1$ and for dry friction both the apparent contact area and the real contact areas must be allowed for (Fig. 5.4).

When there are contacts between the friction bodies, *interactions* occur in the real contact areas and in the near-surface zones. *Atomic/molecular* interactions occur on the one hand and *mechanical* interactions on the other. Whereas the former cause adhesion on solid–solid boundary layers or are extremely important technically in the form of physisorption and chemisorption on solid–fluid boundary layers, the latter lead to elastic and plastic contact deformations and to the development of the real contact areas.

The type of interaction that primarily occurs depends greatly on the friction state. Thus, when a lubricant is present the atomic/molecular interaction can be disregarded more often than the mechanical.

Friction and wear in a given TTS ultimately depend on the interactions between the elements. The friction state, the effective mechanisms of friction and wear, and the contact state can be used to describe the interactions.

The tribological loads occurring in the real contact areas produce *tribological processes*. These subsume the dynamic physical and chemical mechanisms of friction and wear and boundary-layer processes that can be attributed to friction and wear.

Operating Variables (Input Variables)

According to [5.1], the operating variables are: type of motion, the time sequence of motions of the elements contained in the system structure, and a number of technical-physical load parameters, which act on the system structure when the function is executed. The operating variables originate from:

- Type of motion and time sequence of motions
- Load
- Velocities
- Temperatures
- Loading time

The type of motion can frequently be attributed to one of the basic types of motion *sliding*, *rolling*, *spin*, *impact* or *flowing* or can be composed from these. The time sequence of motions can occur regularly, irregularly, back and forth, or intermittently. The sequence of motions frequently also consists of different components. As a rule, the normal force F_n is decisive for the load.

Both the relative velocity between the friction bodies and the entraining velocity of the lubricant in the contact and the slippage as a ratio of the relative velocity to the average circumferential velocity play a role for the velocities. The friction body temperatures and the effective contact temperature produced in operation are critically important for the temperature variables. It is normally not possible to measure the contact temperatures. Apart from these desired input variables, which as a rule are specified by a technical function, *disturbance variables* such as vibrations or dust particles must be considered under certain circumstances.

Output Variables (Useful Variables)

The TTS provides output variables for subsequent utilization. These useful variables reflect the performance of a function of the TTS. The useful variables can differ over extremely wide ranges depending on the main task of the TTS. In an energy-determined system, for example, the following output variables may be desired:

- Force
- Torque
- Velocity
- Motion
- Mechanical energy

Particular material or signal variables could be interesting as useful variables in a material- or signal-determined TTS.

Loss Variables

The loss variables of a TTS are essentially represented by friction and wear. While friction leads to losses of force, torque or energy, wear means a progressive loss of material.

The energy losses produced when there is friction are converted into heat for the most part. This process is irreversible and is called energy dissipation. Along with the conversion of friction into heat and the generation of wear particles, the tribological process generates other tribologically induced loss variables such as vibrations that frequently become apparent through sound waves, photon emission (triboluminescence), electron, ion emission, etc.

5.1.2 Friction

General

Friction can be ascribed to the interactions between bodies' material zones that are in contact or moving relative to one another; it counteracts relative motion. External and internal friction are differentiated. When friction is external, the different friction bodies' material zones are in contact; when friction is internal, material zones that are in contact belong to one friction body or the interfacial medium.

A number of parameters can characterize friction. Thus, depending on the application, friction is characterized by the friction force F_f, the friction torque M_f or the coefficient of friction f. Instead of f the symbol μ is also frequently used for the coefficient of friction. The coefficient of friction f is formed from the ratio of the friction force F_f to the normal force F_n

$$f = \frac{F_f}{F_n} . \tag{5.2}$$

The work of friction or friction energy W_f is used to calculate the frictional heat or the amount of deformation of the friction force in solid friction. It is calculated as

$$W_f = F_f s_f; , \tag{5.3}$$

with the friction distance s_f. The friction power P_f is of interest for an energy balance or efficiency calculation. The friction power is a power loss and, disregarding signs, the following applies

$$P_f = F_f \Delta v, \tag{5.4}$$

with the relative velocity Δv. (The power loss is frequently defined negatively).

Types of Friction

Friction can be classified according to various features. Types of Friction are distinguished depending on the type of relative motion between the friction bodies. Figure 5.5 presents the most important types of friction with samples applications. There are three main types of friction:

- Sliding friction
- Rolling friction
- Spin friction

Apart from these three kinematically defined types of friction, there can be overlaps (mixed forms), namely:

- Sliding–rolling friction (rolling friction)
- Sliding–spin friction
- Rolling–spin friction

Along with the types of friction shown in Fig. 5.5, another type of friction is impact friction, which applies when a body strikes another body perpendicular or oblique to the contact surface and possibly withdraws again. The angular contact ball bearing is a machine element in which sliding and rolling and spin friction appear.

Friction States

Various friction states can be defined if friction is classified as a function of the aggregate state of the material zones involved. To illustrate this, Fig. 5.6 presents different states of friction based on the Stribeck curve using a radial sliding bearing as an example. Generally, the following friction states are differentiated:

- Solid friction
- Mixed friction
- Fluid friction
- Gas friction

In *solid friction* the friction acts between material zones that exhibit solid properties and are in direct contact. If the friction occurs between solid boundary layers with modified properties compared with the bulk material, e.g., between reaction layers, then this is *boundary-layer friction*. If the boundary layers on the contact surfaces each consist of a molecular film coming from a lubricant, then this is called *boundary*

friction. In boundary friction, the lubricant's hydrodynamic effect can be disregarded because the velocity is very low and/or only a very small quantity of lubricant, insufficient to fill the lubrication gap, is present.

Fluid friction is internal friction in the lubricating film between the friction body surfaces, the surfaces being completely separated by the lubricating film. A difference is frequently made between fluid friction in conformal contact surfaces (hydrodynamics) and in nonconformal contact surfaces (elastohydrodynamics). While rigid surfaces and lubricant viscosity only dependent on temperature are generally assumed in the first case, this cannot be assumed in the second case, in which not only the deformations of the surfaces but also the lubricant viscosity's dependence on pressure, temperature, and shear rate must be taken into account.

Mixed friction is a mixed form of the friction states, boundary friction and fluid friction to be precise.

Friction Mechanisms

Solid friction can be ascribed to interactions between the elements. As already addressed before, there are essentially two different types of interaction, i. e., atomic/molecular and mechanical. *Kragelski* [5.7] speaks of friction's 'dual nature.' Hence, the friction mechanisms can be divided into two groups. Generally a difference can initially be made between the following four friction mechanisms, compiled schematically in Fig. 5.7:

- Adhesive bond shearing
- Plastic deformation
- Abrasion
- Hysteresis losses in elastic deformation

Adhesion is an atomically/molecularly based friction mechanism. Its frictional effect is based on the bonds formed atomically or molecularly in the real contact areas that separate again when relative motion occurs, as a result of which energy loss occurs.

Deformation, abrasion, and hysteresis can be classified as mechanically based friction mechanisms. The action of friction in deformation and abrasion can above all be ascribed to the displacement of overlaps of asperities. Hysteresis is based on internal friction and

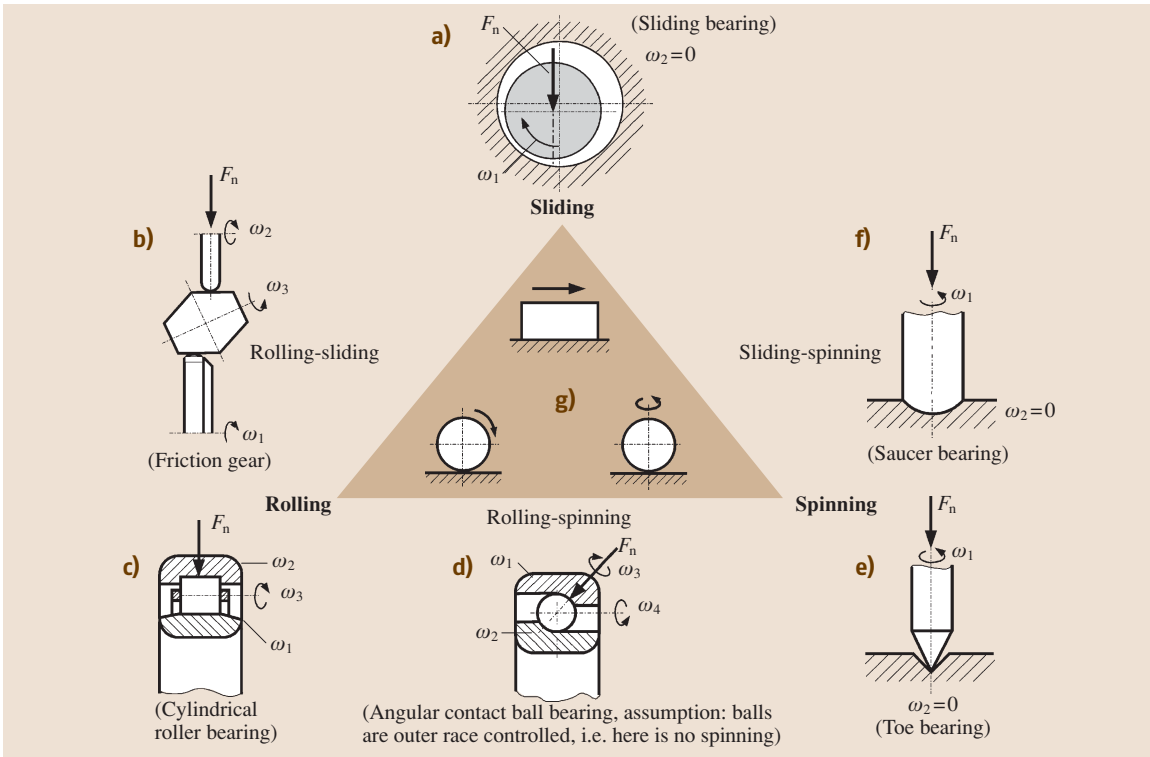

Fig. 5.5a–g Types of friction in dynamic friction

has a damping effect. Different friction mechanisms frequently appear at the same time. The friction mechanisms that are principally acting depends on the state of friction.

Coefficients of friction

Table 5.4 reproduces ranges of friction coefficients in various types and states of friction [5.8]. It should however be recalled that friction does not represent a constant property of a material or a combination of material properties but rather depends on the operating variables and the system structure, i. e., on the load and the elements involved in the friction process with their properties and interactions.

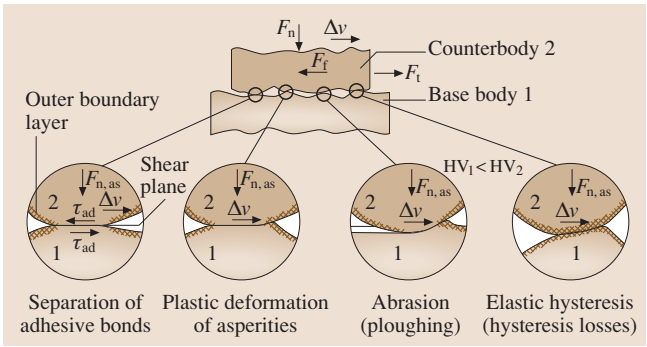

Fig. 5.7 Basic friction mechanisms viewed microscopically (F_n normal force on apparent contact area, F_f friction force between base body and counterbody, F_t tangential force, $F_{n,as}$ normal force on asperity contact, Δv relative velocity, τ_{ad} shear stress for shearing an adhesive bond, HV Vickers hardness)

5.1.3 Wear

General

As soon as the base body and counterbody come into contact, i. e., when the lubrication film thickness becomes too small or lubricant is unavailable, wear occurs. Wear is a progressive loss of material from the surface of a solid, brought about by mechanical causes, i. e., by contact and relative motion of a solid, fluid or gaseous counterbody [5.1]. Signs of wear are small detached wear particles, material removal from one friction body to the other, and material and shape changes of the tribologically loaded material zone of one or both friction partners.

Types and Mechanisms of Wear

Wear processes can be classified into different types according to the type of tribological load and the materials involved, e.g., sliding wear, fretting wear, abrasive

wear, and material cavitation. Wear is caused by a number of mechanisms, the following four being especially important:

- Surface fatigue
- Abrasion
- Adhesion
- Tribochemical reaction

Table 5.5 provides a breakdown of wear according to types of wear and wear mechanisms based on [5.1].

Figure 5.8 presents a chart of the effective wear mechanisms. The wear mechanisms can occur individually, successively or concomitantly.

Surface fatigue manifests itself through cracking, crack growth, and detachment of wear particles, brought about by alternating loads in near-surface zones of the base body and counterbody.

In *abrasion* microcuttings, fatigue due to repeated ploughing, and fracture of the base body caused by the counterbody's hard asperities or by hard particles in the interfacial medium lead to wear.

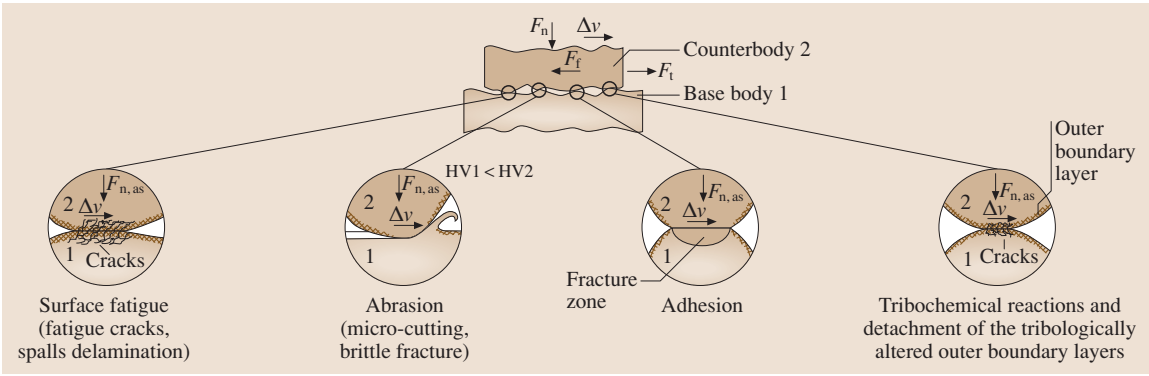

Fig. 5.8 Basic wear mechanisms viewed microscopically (F_n normal force on apparent contact surface, F_f friction force between base body and counterbody, $F_{n,as}$ normal force on asperity contact, Δv relative velocity, HV Vickers hardness)

In *adhesion*, after possibly extant protective surface layers have been broken through, atomic bonds (microwelds) form above all on the plastically deformed microcontacts between the base body and counterbody. If the strength of the adhesive bonds is greater than that of the softer friction partner, material eventually detaches from the deformed surface of the softer friction partner and is transferred to the harder one. The transferred material can either remain on the harder friction partner or detach, or even return.

In *tribochemical reactions*, friction-induced activation of loaded near-surface zones causes elements of the base body and/or counterbody to react chemically with elements of the lubricant or ambient medium. Compared with the base body and counterbody, the reaction products exhibit changed properties and, after reaching a certain thickness, can be subject to brittle chipping or even exhibit properties reducing friction and/or wear.

Apart from the types and mechanisms of wear, *wear phenomena* are also extremely interesting for interpreting the result of wear (Table 5.6). These mean the changes of a body's surface layer resulting from wear and the type and shape of the wear particles accumulating. Light or scanning electron microscope images can present this extremely clearly.

Wear Profiles and Measurable Variables

Estimating the service life of components necessitates knowing the wear profile over the loading time and/or the rate of wear (amount of wear per loading time). According to [5.1] and [5.8], different wear profiles are frequently generated depending on the effective wear mechanism (Fig. 5.9).

Three phases are distinguished: break-in, steady state, and failure. During breaking-in, increased wear, so-called break-in wear, with a degressive profile can occur and, for example, switch over into a long-lasting state with a constant increase of the amount of wear (constant rate of wear) until failure is announced by a progressive increase of wear (Fig. 5.9a).

If surface fatigue takes effect as the primary mechanism of wear, then measurable wear after break-in frequently only becomes noticeable after a certain incubation period during which microstructural changes, cracking, and crack growth commence. Wear particles only detach after the incubation period (Fig. 5.9b). A negative amount of wear is even occasionally measured at the beginning of the wear process. This is caused by material transfer from the wear partner (Fig. 5.9c).

In principle, the profile of the amount of wear W over the loading time t can be progressive, linear or degressive (Fig. 5.9d).

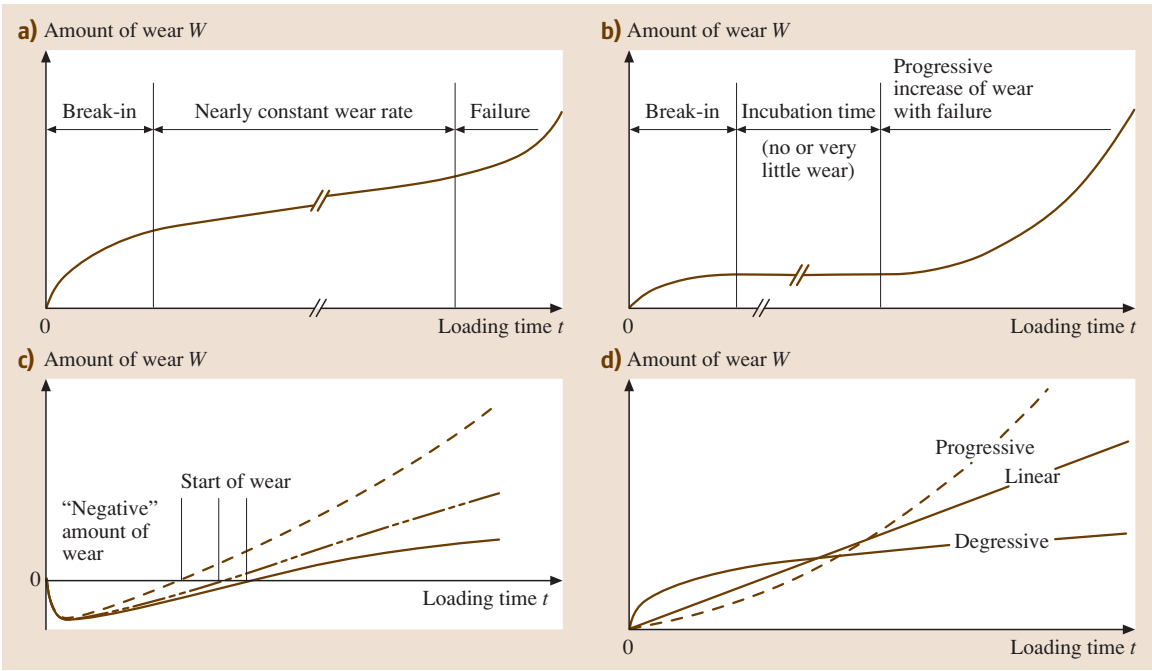

Fig. 5.9a–d Amount of wear as a function of loading time: **(a)** typical wear profile with a nearly constant wear rate; **(b)** wear profile with an incubation time; **(c)** wear profile with negative amount of wear; **(d)** different wear profiles

A difference is made between directly measurable wear variables, such as linear, planimetric, volumetric and mass amount of wear, and related measurable wear variables (wear rates), such as rate of wear, wear–distance ratio, and wear–throughput ratio. As a rule, the amount of wear can be measured. It is advisable to use specific or relative amounts of wear in comparative wear tests whenever the operating variables or the properties of the elements involved in the wear cannot be kept constant or are intentionally changed.

Determination of Wear and Useful Life

In unlubricated tribological systems and in systems operated in the boundary or mixed lubrication range, practically usable information about friction and wear can frequently only be found through experimentation since the physical and chemical mechanisms occurring here frequently cannot be described sufficiently exactly theoretically so that a precise calculation of friction and wear is often impossible.

However, mathematical equations for an approximate preliminary determination of friction and wear provide the energy balance of the friction process. If friction is approached as an energetic problem, the energy balance forms the basis for determining the friction and wear [5.9]. The friction force F_f and the friction coefficient f can be determined from the friction energy W_f

$$W_f = W_{el,\,hys} + W_{pl} + W_{abr} + W_{ad} = fF_n s_f = fF_n \Delta v t \,, \quad (5.5)$$

where $W_{el,\,hys}$ is the proportion of the work of friction from the hysteresis during elastic deformation, W_{pl} is the work of friction from plastic deformation, W_{abr} is the work of friction caused by abrasion, W_{ad} is the work of friction caused by separation of adhesive bonds, f is the friction coefficient, F_n is the normal force, s_f is the friction distance, Δv is the relative velocity between the friction bodies, and t is the friction time [5.9].

The action time of a friction pair usually depends on the wear. The anticipated useful life L_h under specific operating conditions is frequently determined by calculation. A function-based maximum allowable wear is assumed. Thus, the useful life L_h corresponds to the action time for which the friction pair can be safely operated.

Wear properties as a function of the friction time are presented in Fig. 5.10. The development of wear with its scatter as a function of the friction time is shown for various operating conditions. The height of wear h_w serves

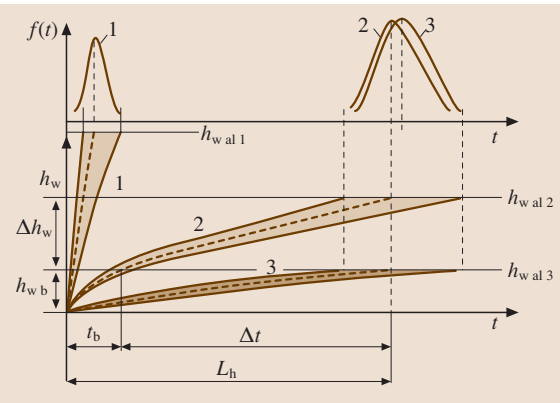

Fig. 5.10 Courses of height of wear h_w and distribution density $f(t)$ as a function of the friction time t when allowable height of wear values have been reached for differently high stresses and different frictional states (after [5.10])

as the gauge of wear. The function-based wear limit is characterized by the maximum allowable height of wear $h_{w,al}$. As a rule, a wear profile exists, which is composed of a break-in process and a steady state (Fig. 5.10, cases 2 and 3). In addition, Fig. 5.10 also shows the distribution densities $f(t)$ for the useful lives L_h defined by $h_{w,al}$.

Despite a large allowable height of wear, case 1 is not practicable since the friction pair here fails early and does not reach a steady state. Case 2 shows a normal progression in pure solid friction. More favorable conditions exist in case 3 (e.g., mixed friction), but the allowable height of wear is small.

The average useful life (action time) for the median of the distribution density results from the expression

$$L_h = t_b + \Delta t = t_b + \frac{h_{w,al} - h_{w,b}}{I_h \Delta v}\,, \tag{5.6}$$

with the linear wear intensity I_h formed from the ratio of the height of wear h_w to the friction distance $s_f (I_h = \Delta h_w / \Delta s_f)$, the break-in time t_b, and the break-in height of wear h_{wb}. If it is assumed that the wear volume V_w and the work of friction W_f are proportional ($W_f \propto V_w$), and the value e_w as a proportionality factor is introduced as the wear energy density, as a result of which the basic wear equation becomes $W_f = e_w V_w$, and if the probabilistic nature of real operation is allowed for (through the introduction of $L(\gamma)_h$ as γ percentage useful life, x as the quantile (random variable) of the standardized normal distribution, and v as an empirical coefficient of variation that represents a measure of the scatter of the wear rate), then the following expression can be set up for the useful life [5.10]

$$L(\gamma)_{h1,2} = t_{b1,2} + \frac{(h_{w,al1,2} - h_{w,b1,2}) e_{w1,2}}{\alpha_{f1,2} \tau_f \Delta v (1 - x v_{1,2})} \tag{5.7}$$

with the friction shear stress $\tau_f = f F_n / A_a$, where A_a stands for the apparent contact area, and the energy proportion factor $\alpha_{f1,2}$ is used to quantify the share of the work of friction induced in friction body 1 or 2.

For a survival probability of $\gamma = 50\%$, when there is a standardized normal distribution, the quantile is $x = 0$, whereas $x = -1.28$ applies for $\gamma = 90\%$. The coefficient of variation depends on the operating conditions (common values based on [5.11] are $v = 0.2$–0.8; when there is fatigue wear, $v = 0.2$–0.4).

Determining the useful life by using (5.7) not only requires knowledge of the break-in time t_b, the allowable height of wear $h_{w,al}$, the break-in height of wear $h_{w,b}$, the energy proportion factor α_f, the normal force F_n, the apparent contact surface A_a, the relative velocity Δv, and the statistical variables quantile x and coeffi-

and wear. Most lubricants are fluids (mineral oils, synthetic oils, water, etc.), yet they can also be solid, e.g., for use in dry sliding bearings [polytetrafluoroethylene (PTFE), graphite, molybdenum disulfide (MoS_2), etc.]. Greases are also applied, e.g., in ball bearings and sliding bearings and occasionally in gears too. Gases (air) are also employed, e.g., in gas-lubricated bearings. Figure 5.12 reproduces the areas of application of different lubricants. Powders, lubricating varnishes, and pastes can be classified as solid lubricants [5.14].

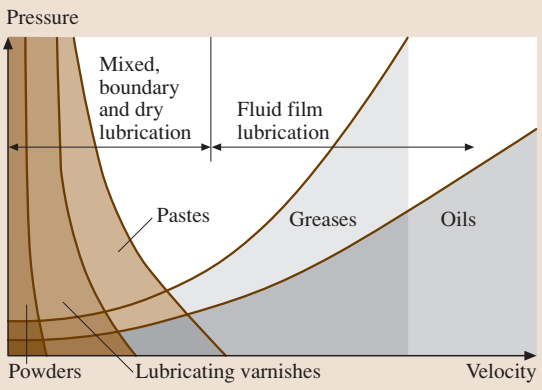

Fig. 5.12 Areas of lubricant application (after [5.14])

Similar to friction states, different lubrication states can also be defined (Table 5.7), to be precise: fluid film lubrication, mixed lubrication, boundary lubrication, and solid lubrication (lubrication with solid lubricants and surface coatings).

Fluid Film Lubrication

Fluid film lubrication, i. e., the complete separation of the frictional surfaces by a lubricating film, can be achieved by hydrodynamic, elastohydrodynamic or hydrostatic lubrication (Table 5.8). A load-dependent pressure is developed in the lubricating film, as a result of which the load can be carried.

Hydrodynamic Lubrication

The following conditions must be met to produce hydrodynamic lubrication. A viscous lubricant that adheres to both the moving and the fixed friction body must be used (adhesive effect of the lubricant). Furthermore, the friction body surfaces must be converging and the lubricant must be dragged into the converging gap. The entraining velocity depends on the velocity at which the lubricant is dragged into the contact and is frequently confused with the relative velocity. The latter is decisive for friction, while the entraining velocity is essential for load-carrying capacity.

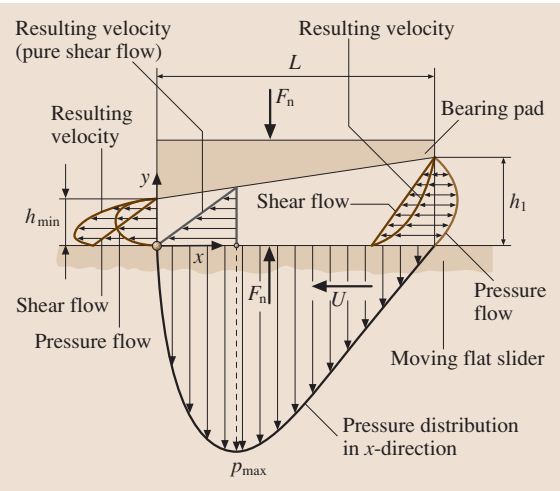

Fig. 5.13 Velocity distributions and pressure distribution in a bearing pad

The lubricant adhering to the surface is dragged into the lubrication gap by the friction bodies moving relative to the minimum lubrication film thickness. Since the gap converges in the direction of motion, the quantity of oil dragged by the friction bodies accumulates in front of the narrowest gap cross section and cannot be completely transported by the moving friction bodies' drag effect alone through the minimal cross section.

Thus, overpressure is inevitably produced in the converging zone in between the sliding surfaces, which grows to be just large enough that the difference between the quantities supplied and discharged by the drag flow are squeezed out of the lubricant gap as a result of compressive flows (satisfaction of the condition of continuity). The overpressure produces the friction contact's load-carrying capacity in equilibrium with the external load.

Figure 5.13 presents examples of velocity distributions at various points in the lubrication gap and the pressure distribution for an inclined plane bearing pad. The level of the average pressure developed (normally < 7 MPa) is usually not high enough to cause significant elastic deformation of the surfaces. The hydrodynamic pressure is dependent on the friction bodies' geometry, the inclination of the surfaces to each other, the viscosity of the lubricant, the load, and the velocity of the lubricant dragged into the converging lubrication gap.

Table 5.8 specifies the correlation between the minimum lubrication film thickness h_{min} and the entraining velocity, the viscosity of the lubricant, and the load. It is evident that the minimum lubrication film thickness increases as the entraining velocity increases and the viscosity becomes greater, and that it decreases as the load grows, although only with an exponent of 0.5 in each case. The minimum lubrication film thickness is normally greater than 1 μm.

Above all, it is the lubricant's viscosity that determines the lubricating effect in hydrodynamic lubrication. Friction is only generated by the shear of the viscous lubricant. Apart from the viscosity, the relative velocity between the moving bodies' lubrication gap surfaces and the lubrication gap height are decisive for friction. If both surfaces slide with the same sliding velocity, the relative velocity is $\Delta v = 0$, i. e., friction does not occur. However, when the sliding conditions are identical, the entraining velocity in the lubrication gap can be high (e.g., in the case of radial sliding bearings, in which the shaft and bushing rotate with the same speed in the same direction) so that the tribotechnical system then has a high load-carrying capacity and a friction force of zero.

Elastohydrodynamic Lubrication (EHL). Elastohydrodynamic lubrication (EHL) is a form of hydrodynamic lubrication in which elastic deformations of the lubricated surfaces become significant. The essential prerequisites for hydrodynamic lubrication, such as a converging lubricating film, the lubricant entraining velocity in the converging gap, and a viscous lubricant between the surfaces, are also important in EHL. Elastohydrodynamic lubrication is normally connected with nonconformal surfaces (Table 5.3). There are two different forms of EHL: for hard surfaces (hard EHL) and soft surfaces (soft EHL).

Hard EHL. Elastohydrodynamic lubrication for hard surfaces (hard EHL) refers to materials with high moduli of elasticity, e.g., metals. Both the elastic deformations and the viscosity's pressure dependence are equally important in this type of lubrication. The maximum occurring lubricating film pressure is typically between 0.5 and 4 GPa. The minimum lubrication film thickness normally exceeds 0.1 μm. When the loads are those normally occurring in nonconformal contacts of machine elements, the elastic deformations in hard EHL exhibit values several magnitudes greater than the minimum lubrication film thicknesses. Furthermore, the lubricant viscosity in the lubrication film can change by a magnitude of 3–4 or more, depending on the lubricant, pressure, and temperature.

The minimum lubrication film thickness h_{min} is a function of the same parameters as in hydrodynamic

lubrication, but these must be augmented by the effective modulus of elasticity E^* and the lubricant's viscosity–pressure coefficients α. Table 5.8 indicates that, in the relationship for the minimum lubrication film thickness, the exponent for the normal load in hard EHL is approximately seven times smaller than it is in hydrodynamic lubrication. This means that, in contrast to hydrodynamic lubrication, the load only marginally influences the lubrication film thickness in hard EHL. The reasons are to be found in the increase of the contact area as the load increases in hard EHL, as a result of which a larger lubrication area is provided to bear the load. The exponent for the lubricant entraining velocity in hard EHL is greater than in hydrodynamic lubrication. Typical applications for hard EHL are toothed gears, rolling element bearings, and cam–follower pairs.

Soft EHL. Elastohydrodynamics for soft surfaces (soft EHL) refers to materials with low moduli of elasticity, e.g., rubber. In soft EHL, sizeable elastic deformations occur even at low loads. The maximum occurring pressures in soft EHL are typically 1 MPa, in contrast to 1 GPa for hard EHL. This low lubricating film pressure only negligibly influences the viscosity during the flow through the lubrication gap. The minimum lubrication film thickness is a function of the same parameters as in hydrodynamic lubrication with the addition of the effective modulus of elasticity E^*. The minimum lubricating film thickness in soft EHL is typically 1 μm. Applications for soft EHL are seals, artificial human joints, tires and nonconformal contacts in which rubber is used.

A common feature that hard and soft EHL exhibit is the generation of coherent lubricating films as a result of local elastic deformations of the friction bodies and thus the prevention of interactions between asperities. Hence, only the lubricant's shear generates frictional resistance to motion.

Hydrostatic Lubrication. In hydrostatic lubrication of friction bodies, a pocket or recess is incorporated in one friction body's loaded surface into which a fluid is forced from outside at constant pressure. A pump outside the bearing generates the lubricant pressure. Hence, the lubricant pump and the lubricating pocket into which the lubricant is fed under pressure are the most important features of hydrostatic lubrication. The lubricating pocket is normally positioned opposite the external load. The load-carrying capacity of a contact with hydrostatic lubrication is also assured when surfaces are not moving. When the volumetric flow of lubricant into the lubricating pocket is constant, the minimum lubrication film thickness is proportional to the cube root of the ratio of the average lubricant viscosity in the lubrication gap and the load, i. e., the minimum lubrication film thickness is less dependent on the viscosity and the load than is the case in hydrodynamic lubrication.

Hydrostatic lubrication is mainly used: where the friction partners' surfaces do not have any metallic contact, i. e., wear may not occur, not even when ramping up and ramping down a machine or at low speed; where as low a friction coefficient as possible must be produced at low speeds; and where, as a result of less effective lubricant entraining velocities in the lubrication gap, the wedge effect cannot produce any bearing lubricating film hydrodynamically.

Boundary Lubrication

In *boundary lubrication*, the friction bodies are not separated by a lubricant, the hydrodynamic lubricating film effects are negligible, and there are extensive asperity contacts. The physical and chemical properties of thin surface films of molecular thickness control the lubricating mechanisms in the contact. The base lubricant's properties are of little importance. The coefficient of friction is on the whole independent of the lubricant's viscosity. The frictional characteristic is determined by the properties of the solids involved in the friction process and the boundary layers forming on the material surfaces, which primarily depend on the lubricant's properties, particularly the lubricant additives, as well as the material surfaces' properties. These boundary layers are formed by physisorption, chemisorption, and/or tribochemical reaction. The thickness of the surface boundary layer varies between 1 and 10 nm, depending on the molecule size.

In *physisorption*, additives contained in the lubricant [e.g., antiwear (AW) additives] such as saturated and unsaturated fatty acids, natural and synthetic fatty acid esters, and primary and secondary alcohols are adsorbed on the tribologically loaded surfaces. Such materials have in common a high dipole moment because of at least one polar group in the molecule (Fig. 5.14).

The coverage of the surfaces follows the laws of adsorption and is dependent on temperature and concentration. A prerequisite for the adsorption of polar groups is that the material surface exhibits a polar character so that van der Waals bonds can form. This is usually attained for metallic materials by oxide films

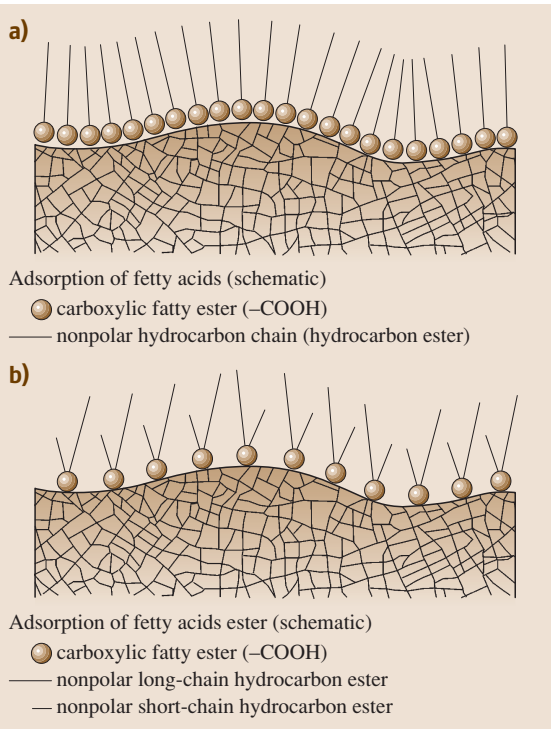

Fig. 5.14a,b Adsorption on metal surfaces (after [5.16])

forming on the surfaces. Problems can arise for ceramic materials however. While, for example, adsorption of fatty acids with polar end groups occurs easily on aluminum oxide with ionic bonding so that friction is diminished from a certain chain length onward, adsorption apparently does not occur on silicon carbide with covalent bonds so that the friction coefficient is not influenced [5.2].

In *chemisorption*, molecules are bonded to the surface. Substantially more-stable boundary layers develop because chemical bonds with greater bonding force are formed on the surface (e.g., the reaction of stearic acid with iron oxide when water is present, as a result of which metallic soap forms as iron stearate). Chemisorbed layers have excellent lubricating properties up to their melting point. At medium loads, temperatures, and velocities, they produce a sustained reduction of friction.

Tribochemical reactions between elements of the lubricant and the metallic material surface form reaction layers that generally have more thermal and mechanical load-carrying capacity than layers formed by physisorption or chemisorption. For this, chlorine, phosphorous or sulfur compounds are added to the lubricants as

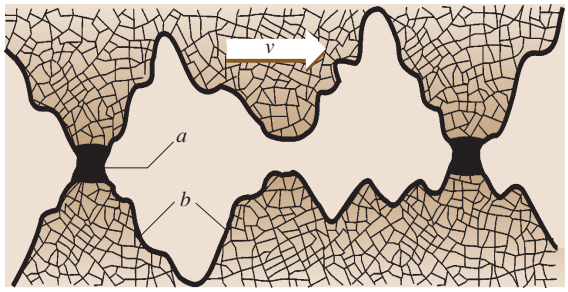

Fig. 5.15 Formation of a protective layer by EP active ingredients of sulfur compounds. a: metal–sulfide compound; b: metal surface (after [5.16])

additives [extreme-pressure (EP) additives]. The effectiveness of such EP additives depends on the speed of reaction layer formation, which is influenced by the reaction's activation energy, the surface temperature, and the concentration of the additive. EP active ingredients themselves, or their thermal cleavage products, react with the surface metallic oxide in very short time (10^{-6}–10^{-7} s), forming a reaction layer that adheres well and shears easily (Fig. 5.15).

While only very little or no wear appears in hydrodynamic and elastohydrodynamic lubrication because there are no asperity contacts, the number of asperity contacts grows in boundary lubrication and thus so does the rate of wear as the load increases. However, compared with unlubricated conditions, the rates of wear in boundary lubrication are substantially lower.

Partial or Mixed Lubrication

If the load in hydrodynamically or elastohydrodynamically lubricated machine elements grows too large or the lubricant entraining velocity in the lubrication gap is too small, the lubricating film becomes too thin so that asperity contacts appear at some points. This is mixed friction, in which the states of boundary friction and fluid friction coexist. The lubricating film is no longer coherent because individual surface asperities of the paired parts penetrate it and cause direct contact of the sliding surfaces. In partial or mixed lubrication, the normal load is partly carried by hydrodynamic film pressures and partly by contact of the frictional surfaces at the asperity contacts. The transition from hydrodynamic or elastohydrodynamic lubrication to partial lubrication does not happen suddenly when the load is increased but rather the share of the load carried by the hydrodynamic pressure buildup decreases gradually, while the share carried by the asperities grows in equal measure.

Lubrication with Solid Lubricants and Surface Coatings

In lubrication with solid lubricants and in coatings, the most important measures for improving friction, preventing scuffing or seizing, and minimizing wear are applying metallic (e.g., indium) or nonmetallic layers (e.g., synthetic resin coatings), forming reaction layers through chemical transformation (e.g., phosphatizing), and using solid lubricants. Nonmetallic layers also include layers obtained by physical vapor deposition (PVD) or chemical vapor deposition (CVD) from the gas phase; the layer has a thickness in the micron range and can be made of, for example, titanium nitride (TiN), titanium aluminum nitride (TiAlN), chromium nitride (CrN) or tungsten carbide/carbon (WC/C).

Among the solid lubricants, crystalline solids with layer lattices (lamina structure) appear particularly suitable. Their structure is characterized by lamellae that can be displaced slightly with respect to each other along glide planes. Typical representatives are graphite (C) and molybdenum disulfide (MoS_2). Certain plastics such as PTFE are also used as solid lubricants.

Apart from these, coating layers on metals, which are adhesive, act as lubricants, and are firm to the touch, so-called lubricating varnishes, also play a role (Fig. 5.16). They have a large proportion of solid lubricants and can be used as dry films over a wide range of temperatures.

5.1.5 Lubricants

Gaseous, fluid, consistent or solid lubricants are used in mechanical engineering. Gaseous lubricants are utilized, for example, in high-speed, lightly loaded machines (e.g., ultracentrifuges, gas pumps for nuclear power plants) or in equipment technology. The most important group of substances for fluid lubricants are the mineral oils, as well as synthetic, animal, and vegetable oils and even water in special applications. Greases and adhesive lubricants are consistent lubricants. Greases consist of mineral or synthesis oils that are thickened with, for instance, soaps. There are bitumen-based adhesive lubricants as well as bitumen-free adhesive spray lubricants. These are principally used to lubricate larger, open-toothed gears. Solid lubricants are frequently introduced into fluid or consistent carrier substances. Solid lubricants are used in pure form only under special operating conditions. Among others substances, solid lubricants include graphite, molybdenum disulfide, PTFE, etc.

During operation, pressure and shear stresses, among others, act on a lubricant at different temperatures. The lubricant comes into contact with gases (e.g., air), liquids (e.g., water), and solids (e.g., metals, sealing materials, wear particles). In addition, contact with human skin cannot be ruled out. This results in a number of requirements that a good lubricant should have. For a particular application, it should have an appropriate viscosity–temperature and viscosity–pressure behavior, a low pour point, and preferably not be volatile, exhibit high-temperature, shear, and oxidation stability, and be hydrolysis and radiation resistant in special cases. Beyond this, a good lubricant should be compatible with the constructional materials used and be nontoxic and not cause any disposal problems.

Lubricating Oils

Among the fluid lubricants, a difference is made between mineral oils and synthetic oils.

Mineral Oils. Mineral oils are obtained from naturally deposited crude oil with the aid of distillation and refining. Crude oils chiefly consist of hydrocarbons and organic oxygen, sulfur, and nitrogen compounds. The exact composition of a crude oil depends on its origin (provenance). When mineral oils are manufactured, systematic selection of the base oil and control of the manufacturing process can produce particular compositions and thus influence desired properties. Mineral oils are mixtures of hydrocarbons, which can be subdivided as a function of their structure into open-chain hydrocarbons (paraffins) and cyclic hydrocarbons (naphthenes, aromatics), which can each be saturated or unsaturated.

Mineral oils' performance characteristics change as their working life increases. A primary reason for diminished performance is gradual oxidization of hydrocarbon chains, with aromatics reacting more than naphthenes and naphthenes more than paraffins. As a result, sludge-like deposits can form, which impede the oil supply by clogging oil feed lines and filters. Moreover, the formation of organic acids can be boosted,

which can cause corrosion of machine parts. This can be prevented in part by admixing additives (e.g., antioxidants, detergent, and dispersant agents). More information on their effect and the use of additives can be found in the section on "Additives."

Synthetic Oils. Synthetic-base lubricating oils are produced by chemical synthesis from chemically defined structural elements (e.g., ethylene). Their development has made it possible to systematically satisfy even extreme requirements (e.g., lubricant temperature $> 150\,°C$). According to their chemical composition, synthetic lubricants are subdivided into synthetic hydrocarbons, which only contain carbon and hydrogen [e.g., polyalphaolefines (PAO), dialkylbenzenes (DAB), polyisobutenes (PIB)], and synthetic fluids (e.g., polyglycols, carboxylic acid esters, phosphoric acid esters, silicon oils, polyphenyl ethers, fluorine–chlorine–carbon oils). Typical characteristics of synthetic oils are provided in Table 5.9 and a comparison of the properties of synthesis oils with those of mineral oil is presented in Table 5.10.

Synthetic oils have a number of advantages over mineral oils. They have better resistance to aging (thermal and oxidative stability) and thus their useful life is three to five times longer. They exhibit a more favorable viscosity–temperature behavior (with a significantly lower dependence of viscosity on temperature), display better flow properties at low temperatures and lower volatility at high temperatures, can cover applications operating at a substantially expanded range of temperature, and are radiation and flame resistant. Moreover, synthetic lubricants can be used to obtain specific frictional properties, e.g., lower friction coeffi-

Table 5.11 Examples of use of the most important synthetic lubricants (after [5.17])

Product group	Examples of use
Polyalphaolefins (synthetic hydrocarbons)	– High-performance oils for diesel engines – Multigrade engine oils – Gear lubrication at high thermal stress – Compressor oils
Carboxylic acid esters	– Aircraft engine oils – Fuel economy oils (low-friction engine oils) – Base oil for high- and low-temperature greases – Applications requiring good and fast biodegradability
Neopentyl polyol esters	– Applications similar to those for carboxylic acid esters but especially wherever oxidation stability and better additive solubility are required
Polyalkylglycols (polyglycols)	– Metalworking fluids – Gear oils (worm gears) – Hydraulic fluids (flame resistant) – Lubricant for compressors and pumps
Polyphenyl ethers	– High-temperature lubricants (up to 400 °C) – Applications requiring resistance to ionizing radiation (γ rays and thermal neutrons)
Phosphoric acid esters	– Plasticizers – Flame-resistant hydraulic oils – Safety lubricants for air and gas compressors – EP additives
Silicone oils	– Special lubricants for high temperatures – Base oil for lifetime lubricating greases (e.g., for clutch release bearings for motor vehicle clutches, starters, brakes, and axle components)
Silicate esters	– Hydraulic oils for lower temperatures – Heat exchange fluids
Fluorine-chlorine-carbon oils	– Lubricants for oxygen compressors and for pumps for aggressive fluids

cients to minimize power loss in ball bearings or gears, or higher friction coefficients to increase the transmittable torque in friction gears.

On the other hand, synthetic lubricants often cannot be used as universally as mineral oils since they have been developed for specific properties. In addition, they are more strongly hydroscopic (water attracting), display only slight air release characteristics (risk of foaming), mix poorly or not at all with mineral oils, are toxic to a large extent, and are characterized by poor compatibility with other materials (risk of chemical reaction with seals, paints, and nonferrous metals) and by poor solubility for additives. They are not always available, most notably in certain viscosity classes, and they frequently cost substantially more. Table 5.11 details examples of typical areas of application of synthetic oils.

Biodegradable Oils. Environmentally compatible lubricating oils are increasingly being used, for example, in motor vehicles and equipment in water protection areas and in hydraulic engineering, in vehicles for agriculture and forestry, and in openly running gears with loss lubrication (excavators, mills). They are readily and rapidly degradable, have a low water hazard class, and are toxicologically harmless. Their base substances have to be degraded in a degradability test (e.g., CEC L-33-T-82) by a defined amount within a specified time and the additives used (up to a maximum of 5%) should be potentially degradable. Native oils and native base synthetic esters as well as fully synthetic esters and polyglycols are used. Native oils (e.g., rape oil and natural esters) are unsuitable for high temperatures (> 70 °C) and additionally have low thermal stability and resistance to aging. The synthetic oils suitable for continuous high temperatures are often used as hydraulic oils in agricultural and forestry machines. Polyglycols are used, for example, as readily biodegradable oils in water engineering.

Table 5.12 Additives, typical types of additives, applications, and active mechanisms (after [5.18])

Additive	Types of additive	Application	Active mechanisms
Antiwear (AW) additive	Zinc dialcyldithiophosphates, tricresylphosphates	Decrease of inordinate wear metal surfaces	Reaction with metal surfaces produces layers that are plastically deformed and improves the contact pattern
Extreme pressure (EP) additives	Sulfurized greases and olefines, chlorohydrocarbons, lead salts of organic acids, aminophosphates	Prevention of microwelding between metal surfaces at high pressures and temperatures	Reaction with metal surfaces produces new bonds with lower shear resistance than the base metal. There is constant shearing off and reformation
Friction modifiers	Fatty acids, fat amines, solid lubricants	Reduction of friction between metal surfaces	Highly polar molecules are absorbed on metal surfaces and seperate the surfaces, solid lubricants form friction-reducing surface film
Viscosiy index improvers	Polyisobutylenes, polymethylacrylates, polyacrylates, ethylenepropylene, styrene maleic acid esters, copolymers, hydrogenated styrene-butadiene-copolymers	Reduction of dependence of viscosity on temperture	Polymer molecules are strongly balled in cold oil (poor solvent) and take on greater volume in warm oil (good solvent) by unballing. This produces a relative thickening in oil
Pour point depressants	Paraffin-alkylated naphthalenes and phenols, polymethylacrylates	Decrease of pour point of the oil	Encasing prevents the agglomeration of paraffin crystals
Detergent additives	Normal or alkaline calcium, barium or magnesium-sulfinates, phenates or phosphonates	Reduction or prevention of deposits in engines at high operating temperatures	Reaction with the oxidation products controls the formation of coating and sludge. Products are produced that are oil soluble or suspendet in oil
Dispersant additives	Polymers such as nitrogenous polymethylacrylates, alkyl succunimides and succinate esters, high molecular weight amines and amides	Prevention or delay of the development and deposition of sludge at low operation temperatures	Dispersantshave a pronounced affinity for impurities and encase these with oil soluble molecules that suppress the agglomeration and deposition of sludge in the engine
Oxidation inhibitors	Inhibited phenols, amines, organic sulfides, zinc dithiophosphates	Minimization of the formation of resin, coating, sludge, acid, and polymer-like compounds	Reducing the organic peroxides ends the oxidation chain reaction. reduced oxygen intake by the oil decreases the acid formation. Catalytic reactions are prevented
Corrosion inhibitors	Zinc dithiophosphates, sulfurized terpenes, phosphorized, sulfurized olefines	Protection of bearing and other metal surfaces against corrosion	Acts as an anticatalyst; film forms on metal surfaces as protection against attacks from acids and peroxides
Rust inhibitors	Amine phosphates, sodium, calcium, and magnesium sulfates, alkyl succinic acid, fatty acids	Protection of ferrous surfaces against rust	Metal surfaces prefer to adsorb polar molecules and they serve as a barrier against water neutralization by acids

Additives. Additives are substances that either give new characteristics to mineral, synthesis or vegetable oils or enhance already existing positive properties. The quantity of additive used differs greatly. Thus, circulating or hydraulic oils may only contain 0.1%, whereas special engine and gear oils may contain up to 30% additives.

All properties of lubricants cannot be changed by additives. However, using additives a clear improvement in lubrication can be obtained by modifying some properties. Thus, for example, heat dissipation, viscosity–density properties, and temperature resistance cannot be influenced by additives. Improvements brought about by additives are obtained for low-temperature performance, aging stability, viscosity–temperature properties, and corrosion protection. Only additives can attain good cleaning performance, favorable dispersion behavior, antiseizing properties, and foam inhibition.

Additives have to be matched to the base oil in terms of quantity and composition and the presence of other additives since they respond differently to the base oil and are not mutually compatible in every case. For example, there are antagonistic effects between viscosity index improves and antifoam additives, between detergent/dispersant additives and antiwear, antiseizing, and

Table 5.12 (cont.)

Additive	Types of additive	Application	Active mechanisms
Metal deactivators	Triarylphosphate, sulfur compounds, diamines, dimercaptothiadiazop deriviatives	Suppression of the catalytic influence on oxidation and corrosion	A protective film is adsorbed an metal surfaces, which inhibits the contact between the bases metal and the corrosive substance
Foam inhibitors	Silicon polymers, tributylphosphates	Protection of the development of stable foam	Attacking the oil film surrounding every air bubble reduces the boundary surface stress. As a result smaller bubbles coalesce into larger bubbles that rise to the surface
Adhesion improvers	Soaps, polyisobutylenes and polyacrylate polymers	Increase of the oils's adhesive ability	Viscosity is increased. Additives are viscous and sticky
Emulsifier	Sodium salts of sulfonic acids and other organic acids, fat amine salts	Emulsification of oil in water	Adsorbing the emulsifier in the oil/water boundary surface reduces boundary surface stress, as a result of which one fluid disperse into another
Demulsifier	Anionic sulfon acid compounds (dinonylnaphthalinsulfonat)	Demulsification of water	A boundary layer develops between water and oil form substances active in the boundary surface

antifoam additives, and between corrosion inhibitors and antiwear and antiseizing additives [5.16].

A difference can be made between additives that form surface layers and those that change the properties of the lubricant itself. Additives forming surface layers act as a lubricating film above all when there is insufficient lubrication, as a result of which friction is reduced and the load-carrying capacity of sliding–rolling pairs is improved. Among others, this group of additives includes antiwear (AW) additives, extreme pressure (EP) additives, and friction modifiers. Adding additives that form surface layers also has drawbacks though. Thus, lubricants with additives oxidize faster than normal mineral oils and corrosive acids and insoluble residues frequently form. Hence these additives should only be used when necessitated by the operating conditions. Additives that modify lubricants influence, for example, foaming behavior, corrosion behavior, sludging, and pour point. Table 5.12 provides an overview of the most important types of additives and their applications.

During operation, the effectiveness of some additives can decrease (exhaustion) since reaction with the materials or the atmospheric oxygen causes their concentration to drop. Once the concentration of the additive falls below a certain value, an oil change is necessary.

Consistent Lubricants (Lubricating Greases)

Consistent lubricants have a flow limit. No movement occurs below a shear stress that is specific to the lubricant. Only when this flow limit has been exceeded does the viscosity drop from a virtually infinitely high to a measurable value.

Lubricating greases consist of three components: a base oil (75–96 wt %), a thickener (4–20 wt %), and additives (0–5 wt %). Suitable thickeners can be dispersed both in mineral oils and in synthetic or vegetable oils so that consistent lubricants are produced. By far, most greases are manufactured using soaps (metallic salts from fatty acids) as thickeners. Thus, fatty acids are dissolved in the base oil at relatively high temperatures and a suitable metal hydroxide (e.g., hydroxides of sodium, lithium, and calcium or to a lesser extent barium and aluminum) is added subsequently. Long-chain fatty acids come from vegetable or animal oils and can be hydrogenated. Occasionally, not only long-chain fatty acids but also short-chain acids such as acetic, propionic, benzoic acid, etc. are used. Then so-called complex soaps are produced [5.16]. Most soap compounds form a fibrous matrix of interlocking particles, which retains the base oil (Fig. 5.17).

By contrast, aluminum soaps contain a spherical gel structure. The grease's lubricating action is based on the base oil being dispensed slowly and sufficiently in operation under load. The delivery of the base oil depends strongly on the temperature. The lubricating grease releases less and less oil as the temperature drops and the grease becomes stiffer and stiffer (consistency). Beyond a certain temperature limit, this eventually leads to insufficient lubrication in the friction contact. As the

Fig. 5.17 Fiber structure of a grease with soap thickener [5.19]

temperature increases, more and more oil is released. Simultaneously, the grease ages and oxidizes faster and the deterioration products produced have an adverse effect on the lubrication. A standard value is to cut the grease's working life and thus the relubrication interval in half for every 15 °C rise in temperature above approximately 70 °C. Below 70 °C, the grease's working life and consequently the relubrication interval can be extended unless the temperature drops below the lower limit. The type of base oil, its viscosity, and the additives it contains are decisive for the lubricating properties.

Lubricating greases are predominantly used at low speeds since the lubricant results in lower frictional heat transportation than oil lubrication. The relevant temperature ranges are generally between −70 °C to +350 °C. Lubricating greases also frequently have the job of protecting lubricating points from the infiltration of water and dirt and keeping out small quantities of dirt without disrupting the function. Tables 5.13 and 5.14 present performance the characteristics and applications of different lubricating greases.

Additives mainly serve to improve particular performance characteristics of the base oils. They must be uniformly distributed and be dissolved. Additives can improve the following properties of greases in particular: oxidation stability, corrosion protection, water resistance, adhesiveness, and antiwear properties.

The greatest care is necessary when mixing different types of lubricating greases since not all types of lubricating greases are mutually compatible (Table 5.15). Thus, for example, sodium soap grease is incompatible with nearly all other lubricating greases with the exception of barium complex soap grease. Lithium soap grease is incompatible with sodium soap grease, aluminum complex soap grease, and bentonite grease. In

Solid Lubricants

Solid lubricants are used especially whenever fluid and consistent lubricants cannot provide the lubricating action required. This is frequently the case under the following operating conditions: low sliding speeds, oscillating motions, high specific loads, high or low operating temperatures, extremely low ambient pressures (vacuum), and aggressive ambient atmospheres. Solid lubricants are also used to improve particular properties of fluid and consistent lubricants, i. e., as additives, for example, to minimize friction and wear and to guarantee antiseizure performance. Solid lubricants in the form of powders, pastes or lubricating varnishes contribute directly to the build up of the lubricating film on the one hand or improve the lubricating properties in oils, greases or bearing materials on the other hand.

Substances with a layer lattice structure (graphite, the sulfides MoS_2 and WS_2), selenides (WSe_2), organic substances [polytetrafluoroethylene (PTFE), amides, imides], soft nonmetals (lead sulfide, iron sulfide, lead oxide, and silver iodide), soft nonferrous metals (gold, silver, lead, copper, and indium), and reaction layers on the surface (oxide, sulfide, nitride, and phosphate layers) are used as solid lubricants. Graphite needs water to adhere and to reduce shear strength (low friction) and hence is unsuitable for use in a dry atmosphere or vacuum. Molybdenum disulfide (MoS_2) adheres well to all metal surfaces with the exception of aluminum and titanium. It is a highly suitable solid lubricant for temperatures up to 350 °C but costs more than graphite. Polytetrafluoroethylene (PTFE or Teflon) exhibits a low friction factor at low speeds and high loads and is suitable for temperatures from −250 °C to +250 °C.

Their high proportion of solid lubricants (graphite, molybdenum disulfide or PTFE) distinguishes lubricating varnishes from decorative industrial varnishes. They can be used as a dry film at temperatures between −180 °C and +450 °C. Lubricating varnishes with oil-resistant binders can also be used in oily systems and are suitable, for example, for bypassing the critical break-in phase without damage or for shortening the break-in time.

Properties of Lubricants

The properties of fluid and consistent lubricants are specified by data predominantly determined with standardized test procedures. It should be noted that not all results from laboratory tests are meaningful for lubrication applications. Along with viscosity, other properties of lubricants are density, specific heat, thermal conductivity, pour point, flashpoint, fire point, foaming behavior, compatibility with sealing materials, and consistency in the case of lubricating grease. Furthermore, aging resistance is vital since it characterizes the abatement of the lubricity and thus the useful life of lubricating oils and determines the oil change interval (Fig. 5.18).

Viscosity. One of a lubricant's most important rheological properties is its viscosity. A fluid's dynamic (or absolute) viscosity η is a measure of the amount it resists a relative motion. The dynamic viscosity η is defined as the shear force F required to realize the relative movement between two planes, acting in the direction of the lubricant flow between the two planes and related to the friction area A and the velocity gradient $\mathrm{d}v/\mathrm{d}y$ between the planes (Fig. 5.19).

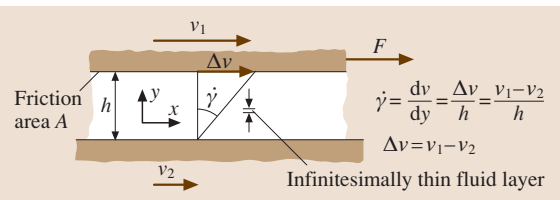

Fig. 5.19 Gap flow and velocity gradient for a Newtonian fluid

Since the shear force per friction area corresponds to the shear stress τ and the velocity gradient to the local shear strain rate $\dot{\gamma}$ (also called shear rate), the following relationship applies

$$\eta = \frac{F/A}{\mathrm{d}v/\mathrm{d}y} = \frac{\tau}{\dot{\gamma}}\,, \tag{5.8}$$

with $\dot{\gamma} = \mathrm{d}v/\mathrm{d}y = \Delta v/h$, where Δv stands for the relative velocity between the two friction bodies and h is the lubrication gap height. The absolute value of the shear force F equals that of the frictional force F_f.

Fluids that can be characterized with (5.8) at constant temperatures and pressures are also called *Newtonian fluids*. Many common fluids, especially those with relatively simple molecular structures, fall into this group (e.g., undoped mineral oils, synthetic fluids, vegetable oils, water, and gases). The unit for dynamic viscosity η is $\mathrm{N\,s/m^2} = \mathrm{Pa\,s}$. Engineering generally uses mPa s however, which corresponds to cP (centipoise), which was common earlier.

The viscosity is measured with commercially available viscosimeters, which are standardized as rotation, capillary, falling ball, and falling rod viscosimeters. Rotation and falling ball viscosimeters determine the dynamic viscosity η, while the capillary viscosimeter used most determines the ratio of the dynamic viscosity η and the density ρ. This ratio is known as the kinematic viscosity ν, so that the following applies

$$\nu = \frac{\eta}{\rho}\,. \tag{5.9}$$

The kinematic viscosity ν is a mathematical value, i. e., it is not a material property. Its units are $\mathrm{m^2/s}$. Usually however $\mathrm{mm^2/s}$ is used, corresponding to cSt (centistokes), which was used earlier. The kinematic viscosity has become generally established in industry and commerce to designate the viscosity of lubricants.

The viscosity of substances that do not behave like a Newtonian liquid is dependent on the temperature, pressure, shear rate, and mean molecular weight. In addition, shear strains are dependent not only on the instantaneous shear rate but also on the past shear history (the lubricant's *memory properties*).

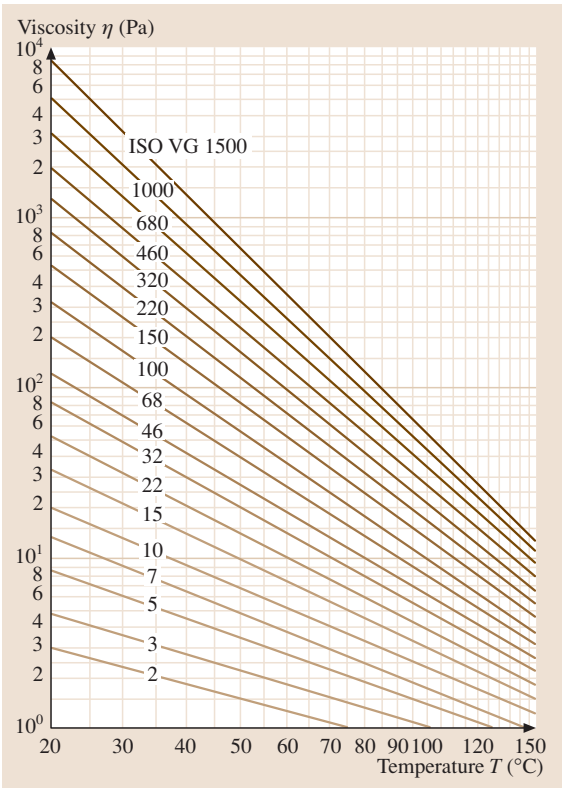

Fig. 5.20 Dependence of the dynamic viscosity η on the temperature T at density $\rho = 900\,\mathrm{kg/m^3}$ in accordance with ISO

Dependence of Viscosity on Temperature and Pressure. The viscosity of lubricating oils greatly depends on the operating temperature. As the temperature increases, the viscosity of the lubricating oil decreases considerably.

To design lubricated tribological contacts it is important to know the viscosity at the operating temperature since this decisively influences the lubrication film thickness between the surfaces to be separated. The lubricant's viscosity–temperature behavior (η–T behavior) is determined metrologically with viscosimeters and is frequently specified by simple power and exponential equations. The following equation from Vogel has proven to be valuable for lubricating oils used in the field

$$\eta(T) = A \exp\left(\frac{B}{C+T}\right) . \qquad (5.10)$$

In this equation, η stands for the dynamic viscosity in Pa s, A, B, and C are values specific to lubricants that have to be determined for every lubricant, and T is the operating temperature in °C. Figure 5.20 presents the viscosity–temperature behavior for industrial fluid lubricants subdivided into 18 viscosity classes (ISO VG) in ISO 3448. The selection of a logarithmic scale on the ordinate axis and a hyperbolic scale on the abscissa gives the viscosity curves a straight gradient. This makes it possible to determine the η–T behavior with only two measurements.

The ISO viscosity index (VI) is also frequently used in practice to specify viscosity–temperature behavior. The viscosity index is a measure of the slope of the *straight lines* of viscosity–temperature compared with a reference lubricant. The higher the VI, the more favorable the η–T behavior. A high VI is characterized by a relatively mild change of viscosity as temperature changes and a low VI by a relatively intense change. Oils that hardly tend to thicken at low temperatures and

that do not become low viscosity too fast at high temperatures, i. e., oils with a high VI, should be preferred when machine parts to be lubricated have to operate over a wide range of temperatures. Common paraffin basic oils exhibit a VI of 90–100, synthetic lubricants have a VI of approximately 200 and above.

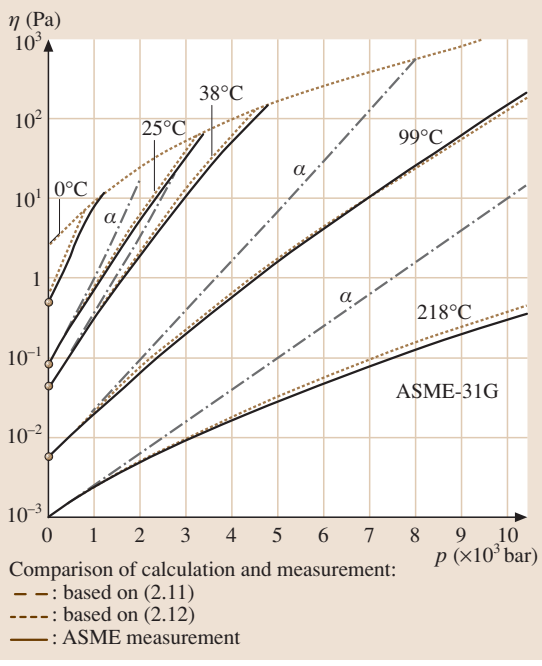

Fig. 5.22 Viscosity of the lubricating oil ASME-31G as a function of pressure and temperature [5.20] (ASME-31G is roughly equivalent to a lubricating oil ISO VG 46)

The viscosity of lubricating oils increases as the pressure rises. The viscosity's pressure dependence only really becomes noticeable at high pressure though. The influence of the pressure decreases as the temperature increases. The viscosity of mineral oil increases more strongly as the pressure increases as the viscosity–temperature curve becomes steeper. The viscosity–pressure behavior can be approximated by the following equation

$$\eta(p) = \eta_0(T) \exp\left[\alpha\left(p - p_u\right)\right] . \qquad (5.11)$$

In the equation, $\eta_0(T)$ is the viscosity at 1 bar and the corresponding operating temperature, α is the

viscosity–pressure coefficient, and p_u is the ambient pressure; α has a new characteristic value for every lubricant and is chiefly influenced by the composition (paraffin–naphthene–hydrocarbons and aromatics content) as well as the base oil's physical properties but less by chemical additives (Table 5.16).

Reference [5.1] provides an expression that simultaneously reproduces the dependence of the dynamic viscosity η on the state variables pressure p and temperature T

$$\eta(T, p) = A \exp\left[\frac{B}{C+T}\left(\frac{p-p_u}{2000}+1\right)^{\left(D+E\frac{B}{C+T}\right)}\right]. \tag{5.12}$$

The dependence of the dynamic viscosity on the temperature is represented by the coefficients A, B, and C (Vogel equation) and the dependence on the pressure is described by the coefficients D and E. Tests are employed to determine the coefficients A–E. Figure 5.22 presents the viscosity of a lubricating oil as a function of pressure and temperature.

Dependence of Viscosity on Shear Rate. When the rheological properties are independent of time, the flow properties of viscous lubricants can be easily described. Then the shear stress τ in the lubricant is a simple function of the local shear rate $\dot{\gamma}$, i. e., $\tau = f(\dot{\gamma})$. If this function is linear so that the shear stress is proportional to the shear rate, then a Newtonian fluid exists and the proportionality coefficient is the dynamic viscosity, which also remains constant when shear rates vary (Fig. 5.23a). Pure mineral oils generally exhibit Newtonian properties up to relatively high shear rates of 10^5–$10^6\ s^{-1}$. At higher shear rates, which occur relatively often in tribotechnical contacts such as toothed gears, ball bearing, cam-follower pairs, etc., the viscosity's constancy frequently disappears and the viscosity decreases as the shear rate increases. The lubricant begins to behave like a non-Newtonian fluid, i. e., the viscosity now depends on the shear rate.

Pseudoplastic behavior, also known as shear thinning, is characterized by a decrease of viscosity as the shear rate increases (Fig. 5.23a). Dilatant fluids manifest the opposite of pseudoplastic behavior, i. e., thickening of the lubricant as the shear rate increases (Fig. 5.23a). Dilatant fluids are normally suspensions with a high solid content.

The flow properties of greases can be compared with those of a Bingham substance. In order to generate a flow, a threshold shear stress must first be overcome (Fig. 5.23b). This means that grease behaves like a solid at first. Once the threshold shear stress τ_0 is exceeded, the lubricating grease then flows, for example, with constant viscosity like a Newtonian fluid or even pseudoplastically or dilatantly.

Consistency of Lubricating Greases. The behavior of a lubricating grease is frequently described by its consistency (plasticity). Penetration according to ASTM D-217 and ASTM D-1403 is used as a characteristic. To determine the penetration, the penetration depth of a standard cone with predetermined dimensions into the surface of a lubricating grease is measured in a penetrometer after a penetration time of 5 s at a temperature of 25 °C (in units of 1/10 mm). A difference

is made between unworked and worked penetration. Unworked penetration is measured in the unused lubricating grease, whereas worked penetration in measured in already sheared grease that has been worked under standardized conditions in a standard lubricating grease mixer. The higher the worked penetration, the softer the grease. Table 5.17 shows the relationship between penetration and consistency class.

6. Design of Machine Elements

Oleg P. Lelikov

A machine generally consists of a motor, a drive, and an actuating element. The mechanical power driving a machine constitutes the rotary motion energy of a motor shaft. Electric motors, internal-combustion motors, or turbines are the most common types of motors. The mechanical power transmission from the motor to the actuating element is accomplished by various driving gears. These include gearings, worm gearings, belt drives, chain drives, and friction gears. Some examples of actuating elements are car steering wheels, work spindles, and screw propellers of ships. This chapter covers the advanced design of machine elements, in particular all common types of gearings and the needed machine components. The in-depth description including stress and strength analysis, materials tables and assembly recommendations allows for a comprehensive and detailed calculation and design of these most important drives. Shafts and axles, shaft-hub assemblies and bearings are included with design guidelines and machining options. Single machine elements, such as specific information about bolts and bolted joints, springs, couplings and clutches, friction drives and also sliding bearings are dealt with only where needed for the benefit of a more general view. The chapter provides the practicing engineer with a clear understanding of the theory and applications behind the fundamental concepts of machine elements.

6.1 Mechanical Drives

In general, three components (Fig. 6.1) can be specified in a machine: a motor, a drive, and an actuating element. The mechanical power driving a machine is the rotary motion energy of a motor shaft. Electric motors, internal-combustion motors, or turbines are the most common types of motors. The mechanical power transmission from the motor to the actuating element is carried out through different driving gears (hereinafter referred to as *gears*), including: gearings, worm gearings, belt drives, chain drives, and friction gears. Some examples of actuating elements are car steering wheels, work spindles, and the screw propellers of ships. A machine without a gear would be optimal; as examples we can consider electrical spindles, electric motors with grinding wheels on the shafts, which do not have transmission gears. This lack of a transmission gear is due to the coincidence of the required rotational work frequency of the grinding wheel and that of the motor shaft. However, in practice this coincidence occurs very rarely [6.1–26].

Gears are applied in order to obtain the required power and kinematic parameters of the actuating element.

Depending on the operating mode, the following mechanical drives can be distinguished:

- Gears working through meshing (gearings, worm gears, chain drives)
- Gears working through friction (friction gears, belt drives)

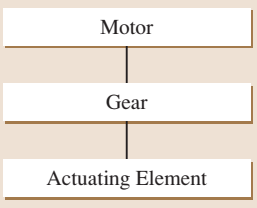

Fig. 6.1 Structural arrangement of a machine

When transmitting power, mechanical gears can simultaneously carry out one or more of the following functions:

1. *Decrease (or increase) the rotational frequency* from the motor shaft to the actuating element shaft (Fig. 6.2).

   The main parameters of the drive shaft (index 1) and the driven shaft (index 2) are: power P_1, P_2 (kW), torque T_1, T_2 (N m), and rotational frequency n_1, n_2 (min^{-1}).

   The torque T (N m) of every shaft can be calculated using the power P (kW) and rotational frequency n (min^{-1}) as

$$T = 9550P/n \; .$$

   Obviously, a decrease in the rotational frequency leads to a torque increase, and an increase in the rotational frequency leads to a torque decrease.

   An important characteristic of gears is the gear ratio u, determined as the ratio of the rotational frequencies of the n_1 drive shaft and the n_2 driven shaft or (without taking into account sliding in contact) as a diameter ratio of the driven (d_2) and drive (d_1) gear elements (Fig. 6.2)

$$u = n_1/n_2 = d_2/d_1 \; .$$

   If $u > 1$ the rotational frequency of the driven shaft is less than that of the drive shaft by a factor of

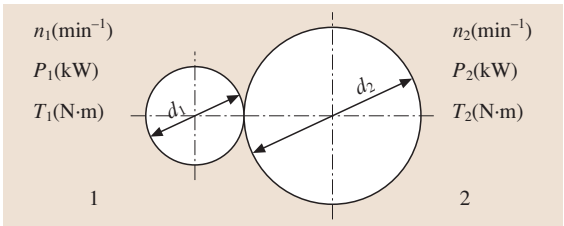

Fig. 6.2 Main parameters on the drive shaft (1) and driven shaft (2) of the gear

the gear ratio:

$$n_2 = n_1/u\ .$$

The decrease of rotational frequency is called reduction, and the enclosed drive decreasing the rotational frequency is called a reduction gear. Units subjected to increasing rotational frequency are called accelerators or multiplying gears. Hereinafter we will consider only reduction gears, which are more common in applications.

In most cases, in practice the rotational frequency of the motor shaft considerably exceeds the rotational frequency of the actuating element shaft; for example, the shaft rotational frequency of the internal-combustion engine of a car is 5000 min^{-1}, whereas the wheel rotational frequency due to the rate of car movement is 100 km/h (1000 min^{-1}).

The ratio of powers and torques: The power P_2 of the driven shaft is less than the power P_1 of the drive shaft due to friction losses in the gear, which are quantified by the efficiency factor η

$$P_2 = P_1\eta\ .$$

The torque of the driven shaft increases by a factor of the gear ratio (in accordance with the decrease of its rotational frequency)

$$T_2 = T_1 u\eta\ .$$

2. *Change of the power flow direction*: A back-axle gearing serves as an example in this case. The motor shaft axis of rotation in many cars forms an angle of 90° with the rotation axis of the wheels. For the transmission of mechanical power between shafts with intersecting axes, bevel gearings are used (Fig. 6.3).
3. *Speed regulation of the driven shaft*: The value of the torque changes with the variation of rotational frequency; a higher torque corresponds to a lower frequency. The necessity for a high torque, for a car for example, appears when starting motion or when driving on a slope. This is also the case, for example, when a lathe is removing thick metal chips. For speed regulation of the driven shaft, gearboxes and variable-speed gears can be used.

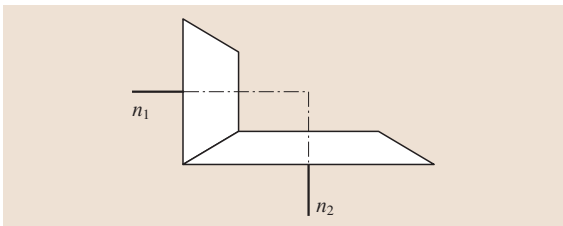

Fig. 6.3 Bevel gearing with intersecting shaft axes

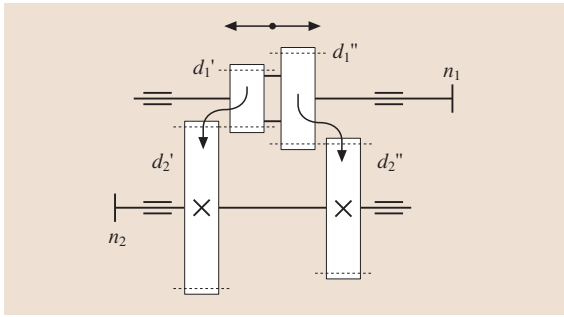

Fig. 6.4 Double gear cluster

Gearboxes ensure staging of the rotational frequency of the driven shaft, depending on the number of stages and the covered stage. For the double-stage gearbox (Fig. 6.4) we have

$$u_1 = n_1/n_2 = d_2'/d_1' \quad \text{and}$$
$$u_2 = n_1/n_2 = d_2''/d_1''\ .$$

Variable-speed gears provide an infinitely variable change of the rotational frequency of the driven shaft over a certain range. Variable-speed friction drive units with a power of up to 55 kW are mainly used in mechanical drives.

In the front variable-speed gear (Fig. 6.5) the change of the rotational speed of the driven shaft is achieved by moving a small roller (1) along the shaft, i. e., through a distance R_i towards the driven shaft axis. The gear ratio u_i falls in the range from

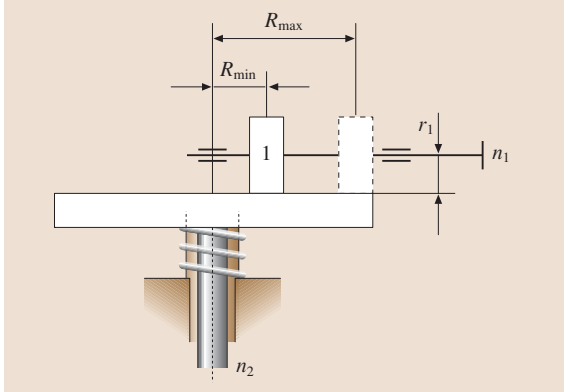

Fig. 6.5 Front variable-speed drive

$u_{min} = R_{min}/r_1$ to $u_{max} = R_{max}/r_1$. Hence the adjustment range is

$$D = u_{max}/u_{min} .$$

For the front variable-speed gear $D \approx 2.5$.

4. *Transformation of one kind of movement to another* (rotational movement to translational movement, uniform to discontinuous motion, etc.).
5. *Motion reversal* (in stroke and return motion).
6. *Motor power distribution* between a few actuating elements of the machine.

6.1.1 Contact Stresses

Contact stresses occur due to the interaction of bodies whose contact area dimensions are small in comparison with the dimensions of the contacting bodies themselves, for example, the contact of two circular steel cylinders along the *common generating line* (an analog of a toothing friction gear, and frictionless roller bearings); see Fig. 6.6. Due to the influence of the external force, when gears and rolling-contact bearings move, the contact occurs over small areas (an initial contact along a line or at a point); as a result, high stresses arise in the surface layer, and the material around this area suffers from volumetric stress.

In the field of the mechanics of contact interaction, the classical work of the German physicist Henry Hertz *About the Contact of Solid Elastic Bodies* (1882) was one of the first publications to appear.

For the initial fingertip action the direct force F_n is distributed throughout the contact area as a pressure diagram representing a semi-ellipsoid (in this particular case, a hemisphere). The pressure p_0 has a maximum value in the center of the contact area.

According to Hertz's theory the maximum *direct stress* acts in the center of the contact area and is equal to the maximum pressure p_0 in absolute value. These stresses are called *Hertz's stresses* and are identified as: $\sigma_H = p_0$. The maximum contact stress is denoted by the index "H", which stands for Hertz.

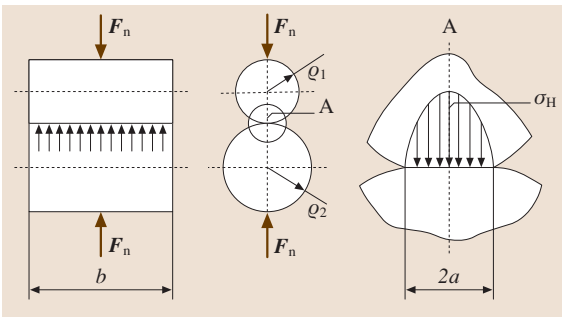

Fig. 6.6 Stress distribution in the contact of circular cylinders with parallel axes

The contact of cylinders without a load occurs at parallel axes along the generating line. Under the influence of a compressive force F_n, as a result of the cylindrical elastic strain, the initial contact along the line becomes a contact over an elongated rectangular area (a very narrow zone) whose width $2a$ is significantly smaller than its length b.

For an initial linear contact, the direct force F_n is distributed throughout the contact area as a pressure diagram representing an elliptic semicylinder. The pressures in the profile throughout the contact area change according to the elliptic law and reach a maximum value σ_H in the zone of peak deformations along the line of the compressive force action (remote element A). This particular feature of direct contact stress action is due to the fact that the stresses do not spread deeply into the bodies of the cylinders, being concentrated in a thin surface layer.

The contact area dimensions and the arising direct stresses σ_H depend on the loading F_n, the elastic material characteristics (Poisson's ratio and the coefficients of elasticity), and the form of the contact bodies.

In addition to the direct stress σ_H there are also tangential stresses τ in the contact area. The maximum tangential stress $\tau_{max} = 0.3\sigma_{H\,max}$ acts at a point located on the line of the compressive force action F_n at a distance of $0.78a$ from the contact surface.

The values of the contact stresses considerably exceed those of other stresses (tension, bending), as well as the material mechanical characteristics in the uniaxial stress state: σ_y, σ_t. Thus, in frictionless bearings $\sigma_H = 4600\,N/mm^2$, while for steel grade 100 Cr 6 (used in Europe) the yield strength is $\sigma_y = 1700\,N/mm^2$, and the ultimate strength is $\sigma_t = 1900\,N/mm^2$. The absence of destruction in the presence of such high stresses can be explained by the fact that in the zone of action the material is under overall volumetric compression.

The maximum value σ_H is used as the main criterion for the contact strength

$$\sigma_H \le [\sigma]_H ,$$

where $[\sigma]_H$ is an allowable contact stress determined from experiment or operating experience with similar conditions in the contact zone.

For the calculation of the maximum contact stress on the contact area, Hertz's formula is applied, obtained

from the contact solution of elasticity theory as

$$\sigma_H = \sqrt{\frac{1}{\pi\left[\left(1-\nu_1^2\right)/E_1 + \left(1-\nu_2^2\right)/E_2\right]}} \times \sqrt{\frac{F_n}{b}\sum\left(1/\rho_i\right)}\,, \qquad (6.1)$$

where b is the contact line length (the length of the cylinders), υ_1 and υ_2 are the Poisson's ratios of the contacting bodies materials, E_1 and E_2 are their coefficients of material elasticity, and ρ_1 and ρ_2 are the radii of curvature of the contact areas.

For the contact of two convex surfaces (Fig. 6.7a)

$$\sum(1/\rho_i) = 1/\rho_1 + 1/\rho_2\,,$$

whereas for the contact of a convex and a concave surface (Fig. 6.7b)

$$\sum(1/\rho_i) = 1/\rho_1 - 1/\rho_2\,,$$

so that in general this can be written

$$\sum(1/\rho_i) = 1/\rho_1 \pm 1/\rho_2\,.$$

Hertz's formula is derived under the following conditions:

- The materials of the contacting bodies are uniform and isotope.
- The compressive forces are directed along the straight line joining the centers of curvature of the body surface at the point of initial contact and are such that only elastic strains take place in the contact zone.
- Frictional forces in a contact are absent.
- Body surfaces are absolutely smooth and have an ideal form.
- There is no lubricant on the contact surfaces.
- The cylinder length is infinite.

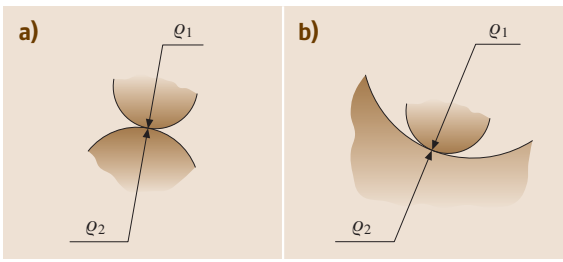

Fig. 6.7a,b Surface contacts: **(a)** convex and **(b)** convex and concave

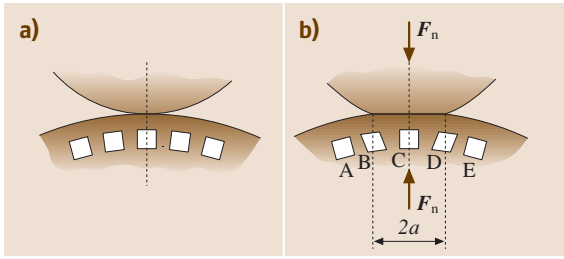

Fig. 6.8a,b Deformations of microvolumes of material due to the rolling of cylinders: **(a)** without load and **(b)** under load

The contact line length of real products is finite, frictional forces act on the contact area, and the surfaces are lubricated. The applicability of the stated Hertz formula is allowed by the fact that the allowable stresses $[\sigma]_H$ are found experimentally for conditions similar to the operating conditions of the design product.

Deformations of the material microvolume in the contact zone with cylinder rolling are sketched in Fig. 6.8a (without load) and b (with load). The material of each body contacted by free rolling is subject to repeated loading and unloading as it passes through the strain area (Fig. 6.8). Here the assigned material microvolume experiences a cycle of reversible slip and compression A–B–C–D–E. Nevertheless, the material behaves as an ideal elastic body in macrovolumes under a relatively small load.

6.1.2 Nature and Causes of Failure Under the Influence of Contact Stresses

Rumpling of Contact Surfaces

The rumpling of the contact surfaces occurs due to impacts as well through the application of vibrational loads, or under the action of considerable loads, when plastic strains occur in addition to elastic ones.

Fatigue Flaking

Every point on the surface during the rotation of the cylinders experiences the action of the contact stresses σ_H (point A in Fig. 6.9a), and the surface itself experiences strain cycling. The fatigue crack (2) arising from repeated microplastic slips appears near the surface (1) of the cylinder (Fig. 6.10a), on the site of stress concentration through the presence of micro-irregularities or nonmetallic inclusions, which are always present in steel.

Within the distorted layer the crack spreads obliquely to the surface and then along the border of the

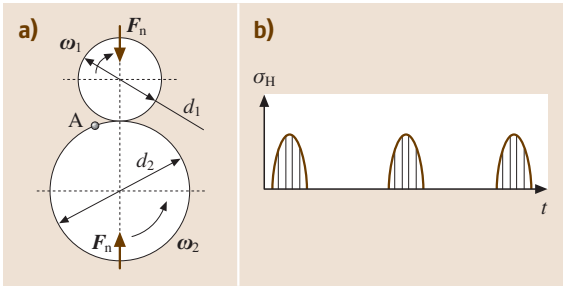

Fig. 6.9a,b Repeated loading at the point A **(a)** with contact stresses σ_H **(b)**

distorted layer. Fatigue crack propagation into deeper layers is connected with the wedging action of the lubricant.

The lubricant (3) before the contact area under the action of the high pressure developing in the hydrodynamic layer is discharged into the crack opened by the frictional forces (2) (Fig. 6.10b). Within the contact area under the loading the crack is closed and increased pressure of the lubricant is produced (Fig. 6.10c), which assists in crack propagation until the abruption of the metallic particle (4) from the surface (Fig. 6.10d). This first occurs for shallow cavities (the size of a fraction of a millimeter) and then through chipping of their edges, after which the cavities join together to form large cavities with a typical flaw dimension of 2–5 mm. Flaking violates the formation conditions for a continuous oil film (i.e., oil squeezes into the cavities), which results in surface wear and tear.

Due to the small thickness of the hardened case and considerable contact stresses, cracks can arise in the depth of the material under the hardened case or on the border of the hardened case as a result of bond cleavage on the borders of metal grains. The imbalance of intracrystalline bonds results in flaking of the hardened case.

Microplastic slips, the range of which depends on the hardness of the material, underlie material accumulation of fatigue damage. The contact strength increases with increasing hardness.

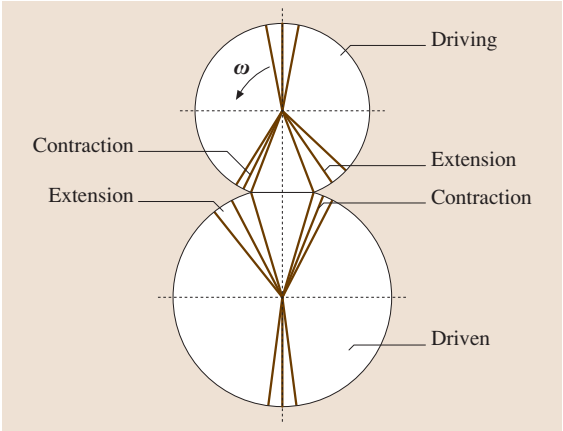

Fig. 6.11 Hoop strains on the drive and driven cylinders

Wear

Frictional forces in the contact area produce compressive strain in the circle line on the surface of the *drive cylinder* before the contact area, and they produce tensile strain after it. On the driven cylinder the opposite is true: before the contact area there is tensile strain, and after it there is compressive strain. These strains are schematically shown in Fig. 6.11 by the angular separations of the radii. When passing through the contact area a relative point displacement of the drive and driven cylinders is observed, i. e., *relative slip*, which is the cause of wear.

Seizing

In the absence of lubricants or in the case of breakage of an oil layer under strong loading, relative slip results in a considerable local temperature increase and molecular adhesion (microwelding) with subsequent breaking and picking up of torn-out parts of the material onto the corresponding mated surface.

6.2 Gearings

6.2.1 Basics

In gearings, movement is transmitted using the toothing of gear wheel pairs. The smaller gear wheel is called a *pinion* and a larger one is called a *wheel*. The term *gear wheel* refers to both the pinion and the wheel.

Advantages of gearings are:

1. Relatively small dimensions and mass of gear wheels, with high load-carrying capacity and safety
2. High efficiency factor (97–98%)
3. Applicability over a wide range (circumferential forces from 0.01 N in instrumental devices to 1000 kN in rolling mill drives)
4. Applicability over a wide velocity range (circumferential velocity from about 0 m/s in systems for telescope displacement to 250 m/s in the drive of helicopter rotors)
5. Comparatively small loads on the shafts and bearings
6. Persistence of the average value of the gear ratio
7. Easy maintenance

Disadvantages of gearings are:

1. The necessity for high accuracy in manufacture and mounting
2. Noise when operating gearings with high rotational frequencies, which results from varying tooth rigidity and imprecision of step and teeth profiles

Wheel teeth must be obtained through cutting or rolling.

Gearings are applied in a wide range of fields and working conditions, for example, in watches and measuring instruments, transmissions of cars, tractors, other vehicles, and road-building machines, lifting and steering crane devices, machine gearboxes, drives of rolling mills, carriers, etc.

Gearings are divided according to the form of the pitch surface into a number of types: cylindrical gearings (with external or internal toothing), and bevel gearings.

Cylindrical Gearings with External Toothing

In these gearings the toothing is equivalent to rolling without slip of cylinders with diameters of d_{w1} and d_{w2}, which are called the initial diameters. In gearings with external toothing the initial surfaces of the gear wheels are located one outside the other. The pinion in the reducing gear is a drive element and all its characteristics are indicated by the index 1, for example, rotational frequency n_1 (min^{-1}) and teeth number z_1. The characteristics of the driven element of the wheels are referenced by the index 2: n_2 and z_2 (Fig. 6.12).

The intersection lines between the teeth side faces and any circumferential cylindrical surface coaxial with the initial surface are called *teeth lines*. If teeth lines are parallel to the gear wheel axis this is called a *spur* (Fig. 6.12a). If these lines are helical with constant pitch the gear wheel is described as *helical* (Fig. 6.12b). With

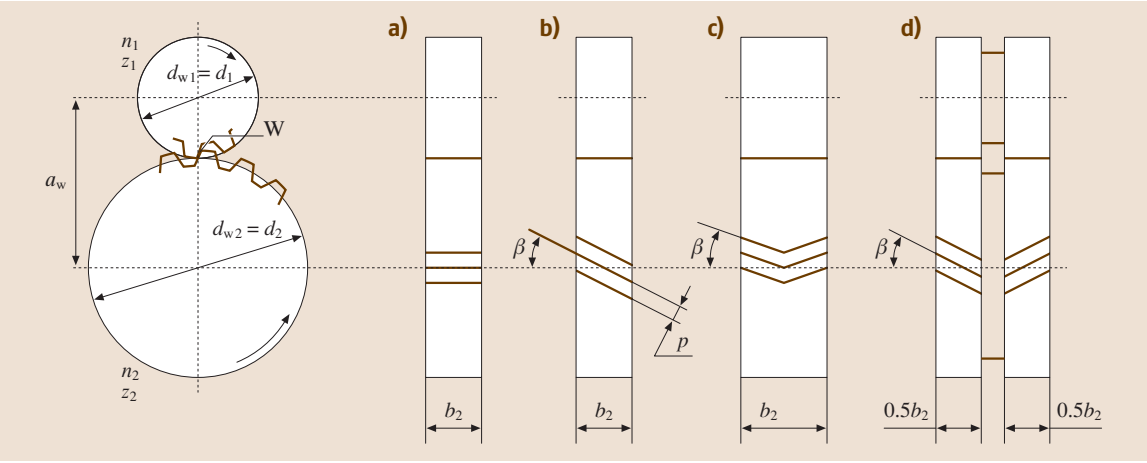

Fig. 6.12a–d Cylindrical gearing with external toothing. **(a)** Straight-toothed, **(b)** helical, **(c)** and **(d)** herring-bone, respectively, with and without a groove as an outlet of the tooth-cutting tool

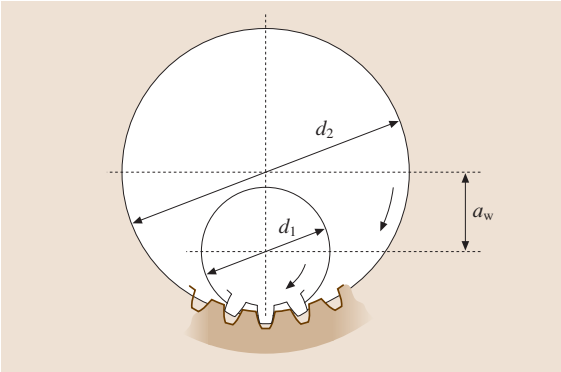

Fig. 6.13 Cylindrical gearing with internal toothing

increasing tooth angle tilt β the load-carrying capacity of the gearing increases, but an axial force arises, which influences bearings and shafts (usually $\beta = 8-18°$).

Another type of helical gear wheel is the herringbone gear, either without a flute (Fig. 6.12c) or with a flute for run-out of tooth-cutting instruments (Fig. 6.12d). In such a gear, as a consequence of the teeth being tilted in opposite directions on the semi-chevrons, axial forces are mutually balanced on the wheel and do not load the bearing; normally $\beta = 25-40°$.

The tangent point W of the initial circumferences of the pinion d_{w1} and the wheel d_{w2} is called the *pitch point*.

The pitch surface (pitch cylinder) is a cylinder where the gear wheel spacing is equal to the spacing of the original profile, i. e., to the spacing of the generating rack. For simplicity of presentation we will consider gearings without displacement so that the initial d_w and pitch d diameters of their gear wheels coincide: $d_1 = d_{w1}$ and $d_2 = d_{w2}$. However, in designating the axle base the index "w" is retained, as in a_w.

The distance between analogous profile points of adjacent teeth on the pitch diameter measured in the section normal to the teeth line is called a *normal spacing* p. The ratio p/π is called a *module* and is designated by m. The module is the main characteristic of the teeth dimensions. It is measured in millimeters and is chosen from a standard series 2, 2.5, 3, 4, etc.

The main features of a gearing can be written using the characteristics of the gear wheels as follows:

- The gear ratio, taking into account that $d = mz$,

$$u = n_1/n_2 = d_2/d_1 = z_2/z_1$$

- The axle base $a_w = 0.5(d_2 + d_1)$

The width b_2 of the gear wheel is normally less than the width of the pinion. In calculations the ratio $\psi_{ba} = b_2/a_w$, known as the *width coefficient*, is used. The values ψ_{ba} of are standardized to 0.1, 0.125, 0.16, 0.2, 0.25, 0.315, 0.4, 0.5, 0.63, and 0.8. For gearboxes, narrow wheels ($\psi_{ba} = 0.1–0.2$) are applied to decrease the dimensions in the direction of the shaft axes, and wide reduction gear wheels (with $\psi_{ba} = 0.315–0.63$) are used.

Cylindrical Gears with Internal Toothing

In gears with internal toothing (Fig. 6.13) the initial surfaces of the gear wheels are located one inside the other. In this case, the axle base is $a_w = 0.5(d_2 - d_1)$.

In general,

$$a_w = 0.5(d_2 \pm d_1)\,,$$

where the plus sign refers to gears with external toothing and the minus sign refers to gears with internal toothing.

Compared with gearings with external toothing, gearings with internal toothing have smaller dimensions

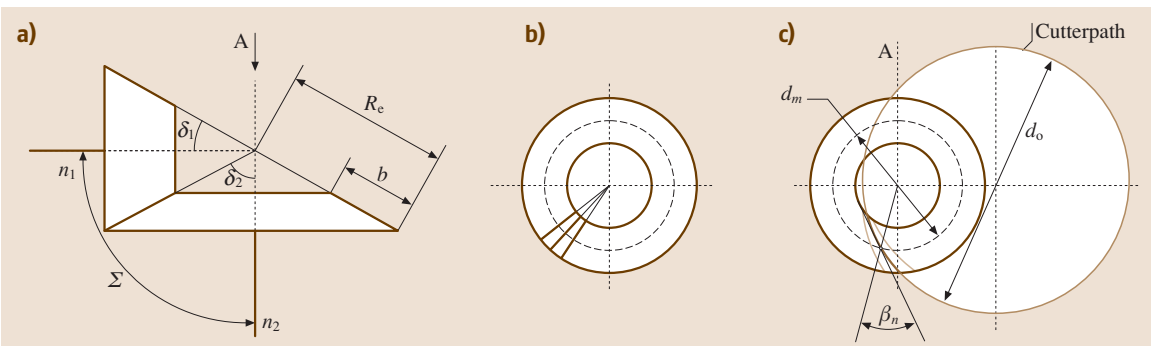

Fig. 6.14 (a) Bevel gearing with intersecting shaft axes, (b) with straight teeth, and (c) with circular teeth

and mass, and operate more smoothly due to the higher contact ratio and the fact that teeth contacting at convex and concave surfaces have a larger equivalent curvature radius. Moreover, they have a lower slip velocity.

Bevel gearings transmit mechanical power between shafts with intersecting axes. Normally, $\Sigma = \delta_1 + \delta_2 = 90^\circ$ (Fig. 6.14a). The toothing of the bevel wheels can be considered as a rolling of the pitch circular cones of the pinion and the wheel. The main characteristics of bevel gearings are the angles of the pitch cones, δ_1 and δ_2, and the external cone distance R_e. Intersection lines of the teeth side faces with the pitch cone surface are called *teeth lines*. Depending on the form of the tooth line there are gearings with *straight teeth* (Fig. 6.14b), where teeth lines go through the vertex of the pitch cone, and *circular teeth* (Fig. 6.14c), which are circular arcs d_0.

Bevel wheels with circular teeth are characterized by the tooth line tilt in the middle section according to the width of the gear ring. The *tilt angle* β_n is the acute angle between the tangent to the tooth line and the generation of the pitch cone (Fig. 6.14c).

Another version of bevel gearings is the *hypoid* gearing, where the rotation axes of the gear wheels do not intersect but cross.

6.2.2 Accuracy of Gearings

The working capacity of gearings depends considerably on the production accuracy of the gear wheels. Production errors are unavoidable due to: deviation in pitch, profile, tooth direction; radial run-out of the gear ring; deviation from parallelism and misalignment of the gear wheel axes; center distance variation; etc. These errors result in increased noise, loss of rotational accuracy of the driven wheel, failure of precision and smooth toothing, torsional vibration, dynamic increase and decrease of distribution evenness along the contact line acting in the load toothing, and other detrimental effects.

Standards regulate the accuracy of gear wheels as well as cylindrical and bevel gearings. Twelve degrees of accuracy are specified and are designated in decreasing accuracy order by the numbers from 1 to 12. Most often, degrees 6, 7, and 8 are applied, where degree 6 corresponds to high-accuracy speed gears, degree 7 corresponds to gears with a normal grade of accuracy that operate with high speed and moderate load, or with moderate speed and large load, and degree 8 corresponds to low-accuracy gears. Gears rated for manufacture according to the sixth degree of accuracy can have a mass of the gear set that is 30% less than that required with the eighth degree of accuracy. For each degree of accuracy there are three standards of tolerances, which are detailed below.

The standard for kinematic accuracy regulates the difference between the actual and nominal rotation angles of the driven gear wheel. The indices of kinematic accuracy influence external gearing dynamics and the positional accuracy of the output shaft with respect to the input shaft. Because of the risk of torsional and resonance oscillations, and noise, these are important in the pitch circuits of machines, control systems, and high-speed power trains.

The standard for smooth operation regulates rotary speed fluctuations per wheel revolution, which cause high-frequency variable, dynamic loads, and noise.

The standard for teeth contact regulates the teeth adjacency in the mounted gearing and the degree of load distribution in contact lines, and determines the efficiency of power trains.

The gearing *side clearance* is also regulated. This is the distance between the teeth side faces, which determines the free rotation of one of the gear wheels by a fixed double gear wheel. Side clearance is required to avoid teeth seizing in the gearing as a result of their expansion at the working temperature, as well as to provide a location for lubricant and for the provision of free-wheel rotation. Side clearance is provided in conjunction with tolerances of teeth thickness and the axle base. The clearance dimension is specified by a coupling type of gear wheel in the gearing: H = 0 clearance, E = small, D and C = reduced, B = standard, A = increased. Mostly coupling types B and C are applied. For reverse gears it is recommended to use couplings with reduced clearances. An example of the accuracy designation of a cylindrical gearing with grade 7 according to the standards of kinematic accuracy, grade 6 according to the standards of drive operation smoothness, grade 6 in accordance with the standards of teeth contact, and with coupling type C is 7-6-6-C.

6.2.3 Gear Wheel Materials

The choice of the gear wheel material is made to provide contact strength and teeth bending resistance for the functioning gearing under its operating conditions. Steel is the most commonly used material in power trains. In some cases cast iron and plastic are also used. The important criteria for the selection of materials are the mass and dimensions of the gearing.

The materials used for gear wheel production in Russia are discussed below. The correspondence between Russian and foreign materials is provided in Appendices 6.A and 6.B.

Steel: Gearings with steel gear wheels have the lowest mass and dimensions. Moreover, the mass and dimensions decrease with greater hardness of the teeth effective area, which in turn depends on the steel grade and the heat treatment applied.

Heat *refining* treatment is a combination of quenching and high-temperature tempering; it provides the most favorable combination of hardness, viscosity, and plasticity.

Heat refining treatment is carried out before teeth cutting. Materials for the wheels are carbon steel grades C36, C35, C46, C45 (EN), 50Г, and alloy steel grades 37Cr4 (DIN), 5145 (ASTM), 40NiCr6 (DIN), etc. The hardness of the tooth core and the tooth effective area are equal for improved wheels, 235–302 HB. Wheel teeth made from refined steel have good running in ability and are not subject to fracture failure, although they have restricted load-carrying capacity. They are applied in lightly and medium loaded gearings.

High hardness ($H > 350$ HB) of the surface layer with viscous core preservation is achieved using thermal or chemicothermal surface hardening of previously refined gear wheels. This includes surface hardening, cementation, nitrocementing with tempering, and nitriding.

Surface hardening of teeth with high-frequency current heating is appropriate for gear wheels with module values > 2 mm. For low modules a small tooth is annealed through, which results in warpage and embrittlement of the tooth. Steel grades C46, C45 (EN), 37Cr4 (DIN), 40NiCr6 (DIN), and 34CrMo4KD (DIN) are applied for quenching with high-frequency current heating; their surface hardness is 45–53 HRC. For $H > 350$ HB material hardness is measured according to the C-Rockwell scale. The tooth core hardness corresponds to the heat refining *treatment*.

Cementation (surface diffusion carburizing) with subsequent quenching along with high surface hardness also provides a high bending strength for the teeth. For gear wheels of medium size, the carburized case constitutes 15% of the tooth thickness (but not more than 1.5–2 mm). Only the surface layer saturated with hydrocarbon is annealed. Steel grades 5120 (ASTM), 14NiCr10 (5732) (DIN), and 20MnCr5G (DIN) (hardness of the tooth surface 56–63 HRC) are used for cementation.

Nitrocementing (nitrocarburizing) of the teeth surface layers in a gaseous medium with subsequent quenching provides high contact and bending strength, wear, and sliding strength. Steel grades 5120 (ASTM), 20CrMo5 (DIN), and 30MnCrTi (DIN) are applied. The nitrocarburizing layer thickness is 0.1–1.2 mm. Warpage (tooth distortion) is insignificant, and subsequent grinding is not required. The hardness of the tooth surface is 58–64 HRC

Nitriding (surface diffusion nitrogen saturation) provides particularly high hardness of the teeth surface layers. It is characterized by insignificant warpage and enables the production of teeth of high accuracy without development operations. Nitrided wheels are not used under impact loads (because of the risk of cracking the hardened case). Steel grades 41CrAlMo7 and 40NiCrMo4KD (EN) (hardness 58–65 HRC) are applied for nitrided wheels.

Strengthening heat treatment is carried out before nitriding, i. e., quenching with subsequent high-temperature tempering. The teeth are not ground after nitriding and nitrocementing because of the minimum warpage. This is why these kinds of chemicothermal hardening can be successfully used for wheels with internal teeth and in cases when teeth grinding is difficult to carry out. Nitriding is not used as often as cementation and nitrocementing due to the long process involved (several tens of hours) and the resulting thin layer (0.2–0.8 mm).

Wheel teeth with hardness $H > 45$ HRC are cut before heat treatment. *Teeth finishing* (grinding, etc.) is carried out *after the heat treatment*, as required. Gearings with hard ($H > 45$ HRC) work surfaces of the teeth run in badly.

Throughout surface heat or chemicothermal treatment of the teeth, previous heat treatment (refining) defines the mechanical characteristics of the tooth core.

The load-carrying capacity of gearings corresponding to the contact strength is higher when the surface teeth hardness is higher. Thus it is advisable to use surface thermal or chemicothermal hardening. These kinds of hardening allow one to increase the load-carrying capacity of the gearing several fold in comparison with refined steels; for example, the allowable contact stresses $[\sigma]_H$ of cemented gear wheels are twice as high as the values of $[\sigma]_H$ of heat-refined wheels, which allows one to decrease their mass by four times. However when defining the hardness of the teeth work surfaces, it must be borne in mind that *higher hardness corresponds*

to a *more difficult manufacturing technique for the gear wheels* and moderate gearing dimensions (which can result in difficulties with the structural unit).

Core-mold casting is used in the manufacture of large gear wheels ($d > 600$ mm). The steel grades used are GS52 to GS55 (DIN). Cast wheels are subjected to *normalization* [heating to 750–950 °C, soaking, and subsequent air cooling (austenization)].

Cast iron is used in manufacturing gear wheels of slow speed, large dimensions, and open gearings. The cast-iron grades used are GG20 to GG35 (DIN). The teeth of cast-iron wheels grind well and can operate with poor lubrication. They have low bending strength; therefore the dimensions of cast-iron wheels are considerably larger than those of steel wheels.

Plastics are applied in high-speed low-load gearings for wheels working together with steel or cast-iron wheels (because of the low thermal conductivity of plastic and the risk of jamming).

Plastic wheels are produced to be narrower than mating metallic wheels in order to avoid increased wear of the edges of the mating wheels. Plastic gear wheels are remarkable for their silence and running smoothness. However, they cannot be used in high-loaded gearings. The most common plastics used are textolite, caprolan, polyacetal resin, and phenylone.

6.2.4 The Nature and Causes of Gearing Failures

As the gearing operation passes through the meshing zone the teeth are subjected to repeated loading. In addition the direct force on the surface and frictional forces act on the contacting teeth surfaces. *For every tooth, stresses change in time according to a zero-to-tension stress cycle, which is the cause of fatigue damage*, which may result in flaking of the work surfaces or teeth breakage. Slipping and frictional forces during meshing produce wear and teeth jamming.

Fatigue flaking of the work teeth surfaces, which is *the main fracture mode of teeth for most closed well-lubricated gearings*, is a consequence of the cycling of the contact stresses. The fracture starts near the pitch line (1) (Fig. 6.15a), where the highest load (the zone of one-pair contact) acts. This is also the location of the highest frictional force (near the pitch line the slip velocity is minimum), which assists in the production and propagation of the microcracks and grooves (2) on the surface of the teeth. *In open gearings* (without lubrication) flaking is not observed; wear of the teeth surface surpasses fatigue crack propagation.

Bearing failure of the teeth work surface occurs under the action of considerable loads or impacts on load application.

Teeth breakdown, in comparison with work surface damage, is uncommon. However, it is the most dangerous type of failure because it results in total operational failure. Teeth breakdown belongs to the category of sudden and complete failure and is a consequence of the zero-to-tension stress cycle action of bending or overload. Fatigue breaking is related to crack propagation (3) (Fig. 6.15b) at the tooth root on the side where lower strains arise because of bending. Straight short teeth are completely broken off along the profile at the tooth root. Following fatigue failure a *concave* surface A is left on the wheel body after tooth breakage. Following damage as a consequence of overload a *convex* surface B remains.

Teeth wear is *the main type of teeth fracture observed in open gearings, gearings with a solid-lubrication coating, and gearings with a very small coating thickness* (up to 3 μm). Wear is determined by the slip ratio of the contact teeth surfaces. Frictional forces of the drive teeth are directed away from the initial circle, whereas forces of the driven teeth are directed towards the initial circle. When it becomes worn the tooth becomes thinner, its dedendum is loosened, and meshing gaps increase, which results in a loss of kinematic accuracy and, in the case of considerable wear, leads to teeth breakdown. Teeth fracture is preceded by increased noise during the operation of the gearing.

Teeth seizure is a molecular adhesion (bonding process) of the mated teeth surfaces as a consequence of

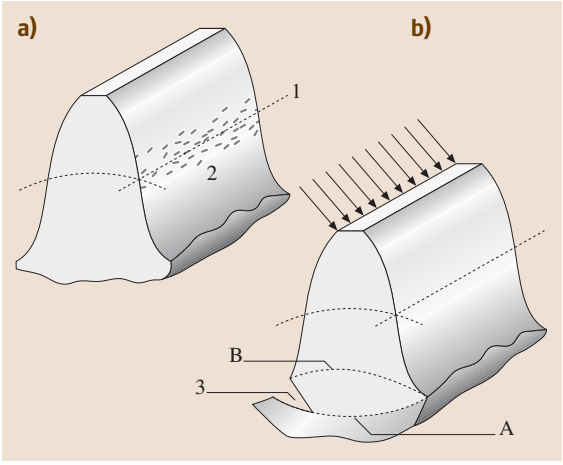

Fig. 6.15a,b Types of fatigue failure of teeth. **(a)** Flaking of the effective area, **(b)** fracture at the tooth root

damage to the lubricating film and an increase in local temperature, which is caused by the relative slip in the contact zone. Scales due to molecular adhesion tear the work surfaces of the mated teeth, furrowing them in the slip direction. Teeth seizing can be avoided through increase in hardness, reduction of the roughness of the surface of the work teeth, teeth modification, and matching of extreme-pressure oils.

6.2.5 Choice of Permissible Contact Stresses Under Constant Loading Conditions

During the operation of gearing meshing the teeth are subjected in turn to the action of a zero-to-tension stress cycle. If the cycle operation factors are constant in time, the loading conditions are called *regular*. The cycle of variable in time loading conditions is called irregular.

The loading law is described by a *sequence diagram*, which consists of a load curve (torque T, force F) as a function of operation time (or number N of loading cycles). A sequence diagram under constant loading conditions is represented in Fig. 6.16, where T_1 is the torque and N_k is the gearing lifetime in number of stress-change cycles.

The choice of permissible stresses is based on the stress-cycle diagram. *Stress-cycle diagrams* obtained experimentally on specimen prototypes of the *gear wheels* define in the coordinates σ (the highest cycle stress) and N (the number of stress changing cycles, which the specimen had before the fracture) (Fig. 6.17a). Experiments show that these diagrams have two typical areas: a left area that is sloping and a right area that is horizontal (Fig. 6.17a) or that has a slight tilt towards the cycle axis (Fig. 6.17b). A logarithmic scale is often used on the abscissa axis. In this case the tilted area of the stress-cycle diagram is substituted by a straight line (Fig. 6.17b). The limit number $N_{\lim}$ of cycles is called the *abscissa of inflection* of the stress-cycle diagram. $N_{\lim}$ is also called the base number of loading cycles. The stress-cycle diagram of the tilted area is described by the power function

$$\sigma_i^q N_i = C \,,$$

where C corresponds to the experimental conditions (material hardness, specimen dimensions, etc.).

The fatigue limit point σ_{RN} is defined by a given value N_k of the cyclic service time in the stress-cycle diagram (Fig. 6.17a), and the limit value of the cycle number N_1 before fracture is determined by the given stress level σ_1 (Fig. 6.17b). If $N_k \geq N_{\lim}$, the stress $\sigma_{\lim}$ is a fatigue point with a zero-to-compression stress cycle. The limit number $N_{\lim}$ of stress cycles corresponds to the fatigue point $\sigma_{\lim}$.

The diagrams are curved for different stress types (contact or bending), for different materials, and heat treatment types; they differ in values $\sigma_{\lim}$, $N_{\lim}$, exponent q, number C.

The stress-cycle diagram for the contact stresses is shown in Fig. 6.18, where the logarithmical coordinates have two tilted areas with exponents $q = 6$ (left) and 20 (right), respectively. The number $N_{H\,lim}$ of cycles corresponding to the change of the stress-cycle diagram is defined by the average hardness of the teeth surface according to

$$N_{H\,lim} = 30\,HB_m^{2.4} \leq 12 \times 10^7 \,.$$

The fatigue contact point $\sigma_{H\,lim}$ is calculated from empirical formulas depending on the material and type of heat treatment for the gear wheel and the average hardness H_m of the teeth surface. Thus, for the heat refining treatment: $\sigma_{H\,lim} = 2\,HB_m + 70\,N/mm^2$.

Contact stresses with a number of changing stress cycles of N_i are calculated in accordance with the equation for the stress-cycle diagram

$$\sigma_{Hi}^q N_i = \sigma_{H\,lim}^q N_{H\,lim} \,.$$

Hence

$$\sigma_{Hi} = \sigma_{H\,lim} \sqrt[q]{N_{H\,lim}/N_i} \,.$$

Then contact stresses by the specified lifetime N_k

$$\sigma_H = \sigma_{H\,lim} \sqrt[q]{N_{H\,lim}/N_k} = \sigma_{H\,lim} Z_N \,,$$

where

$$Z_N = \sqrt[q]{N_{H\,lim}/N_k} \,.$$

The specified lifetime N_k by the rotational frequency n in min^{-1} and the lifetime action period L_h in h

$$N_k = 60 n n_t L_h \,,$$

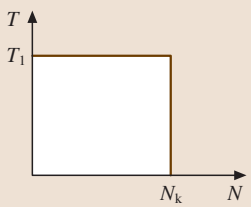

Fig. 6.16 Sequence diagram of constant loading conditions

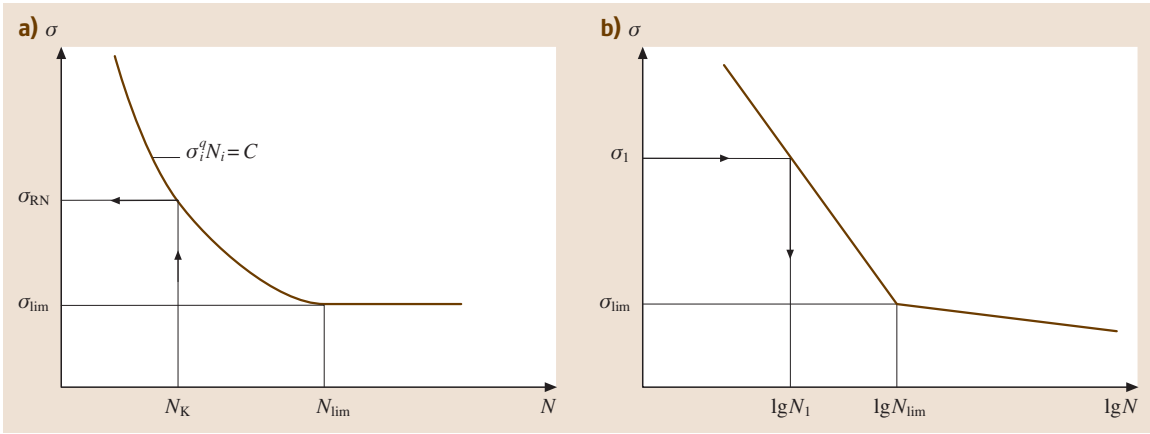

Fig. 6.17a,b Stress-cycle diagram in different coordinates: **(a)** common and **(b)** logarithmic in the abscissa axis

where n_t is the number of tooth matings of the wheel per revolution (Fig. 6.19).

Allowable stresses for the pinion ($[\sigma]_{H1}$) and for the wheel ($[\sigma]_{H2}$) are defined according to the general formula (but with substitution of the appropriate parameters for the pinion and the wheel, respectively), taking the influence of the lifetime on the contact strength, the roughness of the mated teeth surfaces, and the circumferential velocity into account

$$[\sigma]_H = \sigma_{H\,lim} Z_N Z_R Z_V / S_H \,.$$

The service life ratio Z_N takes into account the *influence of lifetime*.

For $N_k \le N_{H\,lim}$ (the left-hand area of the stress-cycle diagram)

$$Z_N = \sqrt[6]{N_{H\,lim}/N_k}\,, \qquad (6.2)$$

on the condition that $Z_N \le Z_{N\,max}$, where $Z_{N\,max} = 2.6$ for materials with homogenous structure (normalized, refined, volume-quenched), and $Z_{N\,max} = 1.8$ for surface-hardened materials (quenching, cementation, nitriding).

Inequality limits allowable stresses according to the conditions preventing of plastic strain or the brittle fracture of the surface layer.

For $N_k > N_{H\,lim}$ (the right-hand area of the stress-cycle diagram)

$$Z_N = \sqrt[20]{N_{H\,lim}/N_k}\,,$$

on the condition that $Z_N \ge 0.8$.

The ratio Z_R, taking into account the influence of the initial roughness of the mated teeth surfaces, is accepted for the gear wheel of the pair with the roughest surface, depending on the roughness parameter *Ra*

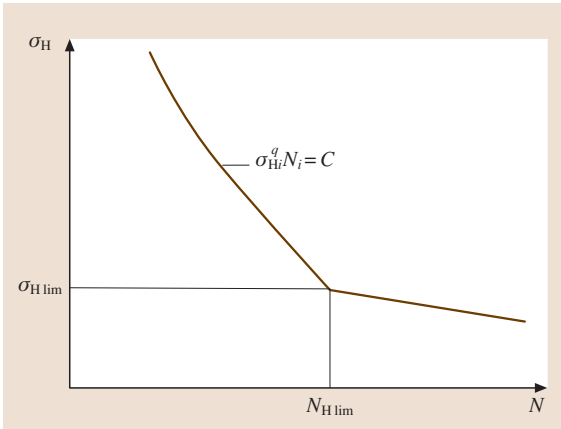

Fig. 6.18 Stress-cycle diagram for contact stresses

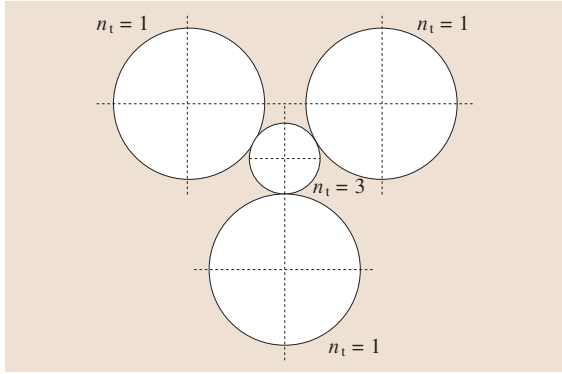

Fig. 6.19 Determination of the loading number of a tooth per revolution of the gear wheel

($Z_R = 1–0.9$). High values of Ra correspond to a polished and ground face ($Ra = 0.63–1.25\,\mu m$).

The ratio Z_V takes into account the influence of the circumferential velocity ($Z_V = 1–1.15$). Lower values correspond to fixed gearings that operate with low circumferential velocities ($v < 5\,m\,s^{-1}$). With higher values of the circumferential velocity better conditions arise for the formation of a reliable oil layer between the contact teeth areas, which enables the allowable stresses to be increased.

Minimum values of the *load factor* for gear wheels with a homogenous material structure (normalized, refined, volume-quenched) are $S_H = 1.1$; for gear wheels with surface hardening the value is $S_H = 1.2$.

The allowable stress $[\sigma]_H$ for cylindrical gearings with straight teeth is the lowest of the permissible stresses of the pinion $[\sigma]_{H1}$ and the wheel $[\sigma]_{H2}$.

For cylindrical gearings with indirect teeth as a result of the contact line location on the angle to the pitch line the allowable stresses can be increased to the value

$$[\sigma]_H = \sqrt{0.5\left([\sigma]_{H1}^2 + [\sigma]_{H2}^2\right)}\,,$$

in the case of the execution condition $[\sigma]_H \le 1.2[\sigma]_{H\,min}$, where $[\sigma]_{H\,min}$ is the lower of $[\sigma]_{H1}$ and $[\sigma]_{H2}$.

The allowable stress for bevel gearings with straight and indirect teeth is the lowest of the permissible stresses of the pinion $[\sigma]_{H1}$ and the wheel $[\sigma]_{H2}$.

6.2.6 Choice of Permissible Bending Stresses Under Constant Loading Conditions

The stress-cycle diagram for bending stress is shown in Fig. 6.20. The exponent $q = 6$ applies for normalized and refined gear wheels, while $q = 9$ applies for quenched and face-hardened teeth. The index F is attached to all the parameters concerned with the bending stress calculation performed for the tooth foot. The cycle number corresponding to the change of the stress-cycle diagram is $N_{F\,lim} = 4\times10^6$. The fatigue point $\sigma_{F\,lim}$ in the case of the zero-tension stress cycle is taken from experimental data or is calculated in agreement with an empirical formula. Thus, for heat refining treatment: $\sigma_{F\,lim} = 1.75\,HB_m$, where HB_m is the average hardness of the tooth core.

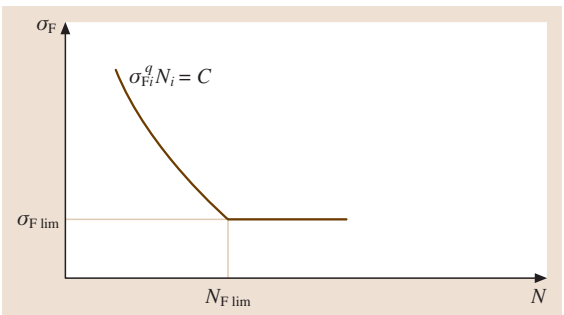

Fig. 6.20 Stress-cycle diagram for bending stresses

The bending stress by the cycle number of stress changing N_i is calculated in accordance with the equation of the stress-cycle diagram (Fig. 6.20)

$$\sigma_{Fi}^q N_i = \sigma_{F\,lim}^q N_{F\,lim}\,.$$

Hence

$$\sigma_{Fi} = \sigma_{F\,lim}\sqrt[q]{N_{F\,lim}/N_i}\,.$$

Then bending stresses with the given lifetime N_k

$$\sigma_F = \sigma_{F\,lim}\sqrt[q]{N_{F\,lim}/N_k} = \sigma_{F\,lim}Y_N\,,$$

where $Y_N = \sqrt[q]{N_{F\,lim}/N_k}$ on the condition that $Y_N \ge 1$. The given lifetime N_k is calculated in the same way as in contact stresses calculations.

In compliance with the stress-cycle diagram stresses σ_F cannot have values lower than $\sigma_{F\,lim}$, which is why $N_k > N_{F\,lim}Y_N = 1$.

Allowable stresses $[\sigma]_{F1}$ for the pinion and $[\sigma]_{F2}$ for the wheel are assigned according to the general relation (but with substitution of the appropriate parameters for the pinion and the wheel) taking into account the influence of the lifetime on the bending fatigue resistance, the surface roughness of the concave molding (the fillet surface between the adjacent teeth), and the reversing gear (for double-sided applications) of the load

$$[\sigma]_F = \sigma_{F\,lim}Y_N Y_R Y_A / S_F\,.$$

Application of modern hardening methods (knurling, cavity stamping or electropolishing) allows an increase in the breaking strength of approximately 25%.

The service life ratio Y_N takes into account the influence of lifetime

$$Y_N = \sqrt[q]{N_{F\,lim}/N_k}\,, \qquad (6.3)$$

with $1 \le Y_N \le Y_{N\,max}$, where $Y_{N\,max} = 4$ for normalized and refined wheels, and $Y_{N\,max} = 2.5$ for quenched and surface-hardened wheels.

For long-term running (a few years) of high-speed gearings, $N_k \ge N_{F\,lim}$, and therefore $Y_N = 1$, which corresponds to the first inequality sign in (6.3). The second

inequality sign limits the allowable stresses according to the condition for the prevention of plastic strain and tooth brittle fracture.

The ratio Y_R, which takes into account the influence of the roughness of the fillet surface between the teeth, is assigned the value $Y_R = 1$ in the case of grinding and gear milling with roughness parameter $Rz \leq 40\,\mu m$, and $Y_R = 1.05–1.2$ in the case of polishing (high values with refining and after quenching with high-frequency current).

The ratio Y_A takes into account the influence of the double-sided load application (reversing gear). In the case of one-sided load application $Y_A = 1$. In the case of reversing loading (reversed cycle) $Y_A < 1$.

The minimum value of the load factor is $S_F = 1.7$, whereas for cemented and nitrocemented gear wheels it takes the value $S_F = 1.55$.

6.2.7 Choice of Permissible Stresses Under Varying Loading Conditions

Most gearings operate under varying loading conditions in which the cycle parameters, e.g., the load value and consequently the stress value, change in time.

In Fig. 6.21a a gearing loading sequence is characterized by the moment sequence diagram, where the torques T_i that act during the functioning of the target life N_k are represented in decreasing order. With the help of the torque sequence diagram n_{ki} can be determined, a period (measured in loading cycles) of the torque operation T_i with rotational frequency n_i, and N_{ci}, a period (in loading cycles) of the torque operation that does not exceed T_i.

A sequence diagram of the moments can be represented in increasing order of the torques and by application of relative units (Fig. 6.21b) $\nu_i = T_i/T_{max}$ and $n_{ci} = N_{ci}/N_k$, where $N_{ci} = (n_{ki})$ is a cumulant (accumulated sum) of the loading cycle numbers. The abscissa n_{ci} in Fig. 6.21b corresponds to the part of the general loading cycle with relative torque that does not exceed the value of ν_i. The period of influence of moments higher than ν_i is characterized by the relative cycle number $(1 - n_{ci})$.

In operation the maximum possible torques (e.g., on starting) are short-term (single) and are not taken into consideration in calculations of fatigue resistance. In calculations of fatigue resistance the actual varying loading conditions are changed into equivalent (in terms of fatigue action) constant conditions.

Let us suppose that the component is operating under varying loading conditions, which have some

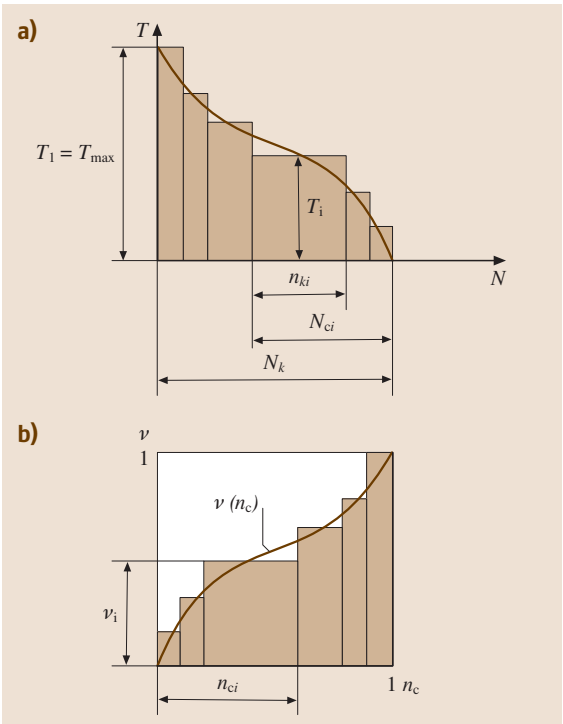

Fig. 6.21a,b Sequence diagram of the varying loading conditions in coordinates. **(a)** Absolute, **(b)** relative

phases, and that at phase i it experiences a number of fluctuation cycles n_{ki}. It is known from experience that detail fracture under periodical loading with constant parameters of the stress cycle (operating on the same phase) follows the stress-cycle diagram (Fig. 6.22) after N_i loading cycles as a result of step-by-step accumulations of damage in the material (e.g., minute cracks). Then the damage level of the detail operating on the phase i can be evaluated by using the relative life n_{ki}/N_i.

It has been determined experimentally that, by working on a few loading phases, damage continues to accumulate independently in proportion to the appropriate relative life. Thus, it can be summed up *arcwise* (the hypothesis of linear summing up of fatigue damage). In this case, fracture will take place when the sum of the relative service life is 1

$$\sum (n_{ki}/N_i) = 1\,.$$

Let us do the transformations: multiply and divide the expression with the index of summation by σ_i^q

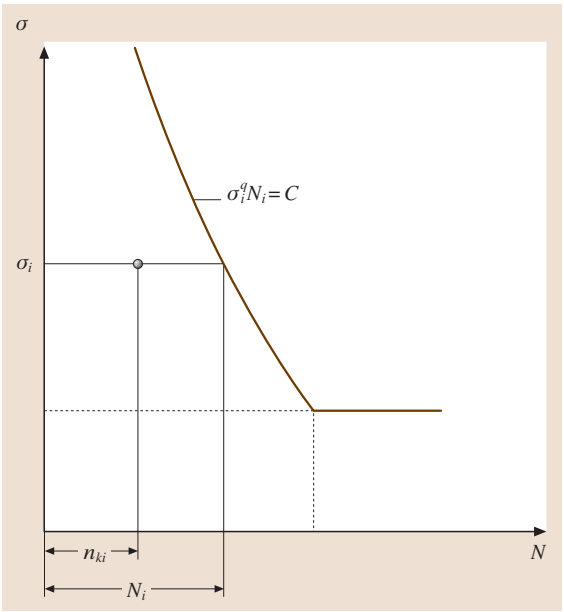

Fig. 6.22 Determination of the relative service life

stresses corresponding to the loading lever i

$$\sum \frac{\sigma_i^q n_{ki}}{\sigma_i^q N_i} = 1 \, .$$

In accordance with the equation of the stress-cycle diagram, $\sigma_i^q N_i = C$ is a constant value and can be taken out of the index of summation

$$\sum \left(\sigma_i^q n_{ki}\right) = \sigma_i^q N_i \, ,$$

and then written using parameters σ^q and N_E of the equivalent constant loading conditions

$$\sum \left(\sigma_i^q n_{ki}\right) = \sigma_i^q N_i = \sigma^q N_\mathrm{E} \, .$$

In other words, the actual varying loading conditions can be associated with the equivalent constant conditions, when the detail reaches the same degree of fatigue damage. As an equivalent the constant conditions with the nominal torque T (the highest of the long-term ones $T = T_1 = T_{\max}$ in Fig. 6.23) that generates stresses σ and with equivalent number N_E of loading cycles. From the last ratio we obtain a relation for the calculation of the equivalent number of stress change cycles

$$N_\mathrm{E} = \sum \frac{\sigma_i^q}{\sigma^q} n_{ki} \, ,$$

where $n_{ki} = 60 n_\mathrm{t} n_i L_{hi}$ is the number of stress change cycles on the loading level i for L_{hi} hours of work.

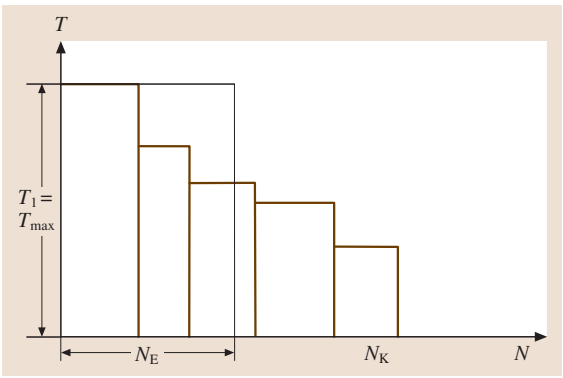

Fig. 6.23 Conformity of the equivalent constant loading conditions with real varying loading conditions

After the right-hand side of the given equation is multiplied and divided by $N_k = \sum n_{ki}$, it can be written as

$$N_\mathrm{E} = \sum \left(\frac{\sigma_i}{\sigma}\right)^q \frac{n_{ki}}{N_k} N_k = \mu N_k \, ,$$

where $\mu = \sum (\sigma_i/\sigma)^q \, n_{ki}/N_k$ is a reduction ratio.

Because contact stresses are proportional to the degree 0.5 load, and bending stresses are proportional to the degree 1 load, by substituting stresses through the torques in the expression for the reduction ratio we have

$$\mu_\mathrm{H} = \sum \left(\frac{T_i}{T_{\max}}\right)^{q/2} \frac{n_{ki}}{N_k} \quad \text{for contact stress,}$$

$$\mu_\mathrm{F} = \sum \left(\frac{T_i}{T_{\max}}\right)^{q} \frac{n_{ki}}{N_k} \quad \text{for bending stress.}$$

The equivalent numbers N_HE and N_FE of loading cycles needed to calculate the contact and bending strength are determined as

$$N_\mathrm{HE} = \mu_\mathrm{H} N_k; \quad N_\mathrm{FE} = \mu_\mathrm{F} N_k \, .$$

Calculation of the allowable stresses under varying loading rates is performed according to the formulas for the constant loading rate with substitution in agreement with (6.2) and (6.3) of the service life ratio Z_N and Y_N values of cycle numbers N_k for equivalent cycle numbers N_HE and N_FE, respectively. *Thus load variability is taken into account by the choice of the allowable stresses.*

6.2.8 Typical Loading Conditions

On the basis of statistical loading analysis of different machines it has been ascertained that the wide

variety of torque (loads) sequence diagrams can be brought together to a few *typical* ones by using the relative coordinates $\nu, (1-n_c)$ in the sequence diagram construction. Having substituted a step sequence diagram for a smooth enveloping curve (Fig. 6.21a,b) a graphical presentation of constant (zero) and five typical loading conditions that are characteristic for most modern machines (Fig. 6.24) is obtained. In this figure the varying rates are: I = *heavy* (most of the time loads are close to nominal values); II = the *average equiprobable* (the same working time with all load values); III = the *average normal* (most of the time under operation with average loads); IV = *light* (most of the time operation with loads below the average); and V = *especiallylight* (most of the time under operation with light loads).

The heavy rate (I) is typical of gearings of mining machines, the average equiprobable (II) and normal (III) rates are typical for vehicles, and light (IV) and especially light (V) rates are typical for versatile machine tools.

The typical rates (heavy, light, and especially light) can be described mathematically with integral beta distribution functions with appropriate parameters. The average equiprobable rate corresponds to a uniform distribution, and the average normal rate is of normal distribution. The equivalence ratios μ_H and μ_F are initial points of order k of the load distribution function. The order k of the initial point is determined according to the exponent q of the stress-cycle diagram equation and to the type of stress.

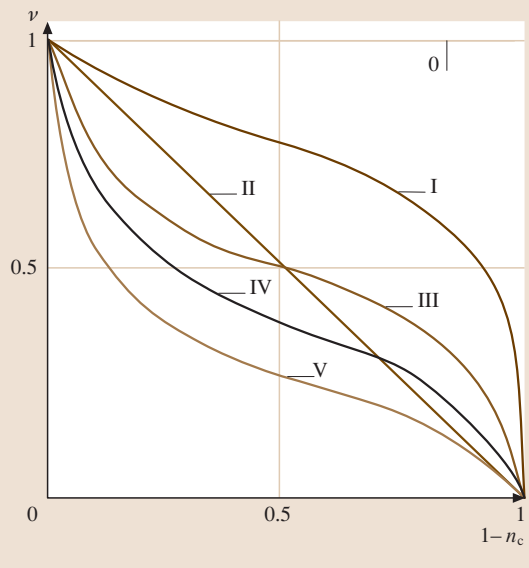

Fig. 6.24 Typical loading conditions: 0 – constant, I – heavy, II – average equiprobable, III – average normal, IV – light, and V – especially light

The values of the equivalence ratios μ_H and μ_F for the typical loading rates are calculated and given in GOST 21354-87 (in Russia) [6.27–37].

A typical rate nearest to the actual rate in the range of high loads can be taken as the calculation rate. The use of typical rates considerably simplifies these calculations.

6.2.9 Criteria for Gearing Efficiency

For well-lubricated gearings operating in the closed case the main efficiency criteria are contact strength and bending strength. *Contact strength* is the capability of the contacting teeth surfaces to provide the required safety against progressive fatigue flaking. Calculation of the prevention of fatigue failure results in the condition

$$\sigma_H \le [\sigma]_H ,$$

where σ_H is the contact stress at the pitch point, and $[\sigma]_H$ is the allowable contact stress. Calculation of the prevention of bearing failure in the case of overload results in the condition

$$\sigma_{H\,max} \le [\sigma]_{H\,max} ,$$

where $\sigma_{H\,max}$ and $[\sigma]_{H\,max}$ are, respectively, the actual and allowable contact stresses under the action of the peak load (e.g., under operation).

The bending strength is the capability of the teeth to provide the required safety against tooth fatigue fracture. Calculation for the prevention of fatigue fracture results in the condition

$$\sigma_F \le [\sigma]_F ,$$

where σ_F is the bending stress in a weak section and $[\sigma]_F$ is the allowable bending stress of a tooth.

Calculation of the prevention of overload breakage results in the condition

$$\sigma_{F\,max} \le [\sigma]_{F\,max} ,$$

where $\sigma_{F\,max}$ and $[\sigma]_{F\,max}$ are, respectively, the actual and allowable bending stresses under the action of the peak load.

The aim of gearing calculations is efficiency in accordance with all the considered criteria. In the planning calculation the gearing geometry is determined by the

given loading conditions. In the verification calculation the load-carrying capacity or compliance with the main efficiency criteria are determined by the known gearing parameters. Most often the dimensions of the closed gearing are determined through contact strength analysis, and bending analysis of the teeth is checked in order to determine the minimum possible module value.

In the case of very high teeth hardness ($H \geq 56$ HRC) gearing dimensions are determined through bending analysis of the teeth and verified by contact strength analysis.

6.2.10 Calculated Load

Due to the additional load of the gearing, additional loads act on the toothing. These are caused by loading conditions; manufacturing errors; yielding of the teeth, shafts, and bearings; and production errors of the single parts comprising a gearing unit. In calculations this is taken into consideration by multiplication of the nominal torque T or force F by the load ratio K, thereby determining the calculated load according to

$$T_c = KT \quad \text{or} \quad F_c = KF\,.$$

In contact stress analysis the load ratio is

$$K_H = K_A K_{H\beta} K_{HV} K_{H\alpha}\,.$$

With the ratio K_A the environmental dynamic load of the gearing is taken into account by the combined action of the motor and the actuating element, which is not taken into consideration in the loading sequence diagram. The value of K_A depends on the degree of loading evenness of the motor and the actuating element ($K_A \geq 1$).

Typical loading characteristics of motors are *even* (electric motors, and steam and gas turbines) and *with average unevenness* (multicylinder internal-combustion engines). The typical loading rates of the actuating element are *even* (evenly functioning belt and apron conveyors) and with *slight unevenness* (the same conveyors for piece loads). For an even loading rate of the motor and loading rate of the actuating element with slight unevenness, $K_A = 1.25$. If environmental dynamic loads are taken into account in the loading sequence diagram then $K_A = 1$.

The index of the $K_{H\beta}$ unbalance factor along the contact lines is chosen because load distribution unevenness is caused by changing the initial tilt angle β of the tooth. The ratio K_{HV} takes into account internal loading dynamics, which is caused by circular pitch errors and teeth profile faults of the pinion and the wheel. The index emphasizes the main influence on K_{HV} circumferential velocity value.

The index of the $K_{H\alpha}$ load distribution coefficient between the teeth in connection with circular pitch errors and tooth direction is caused by the fact that the load distribution between the teeth is considered in the normal plane where the angle of action a is measured.

Load Distribution Unevenness Along the Contact Lines (*Factor* $K_{H\beta}$)

Deviation from the contact line position is the result of manufacturing errors (tooth direction error) and elastic strains of the shafts and bearings. This deviation

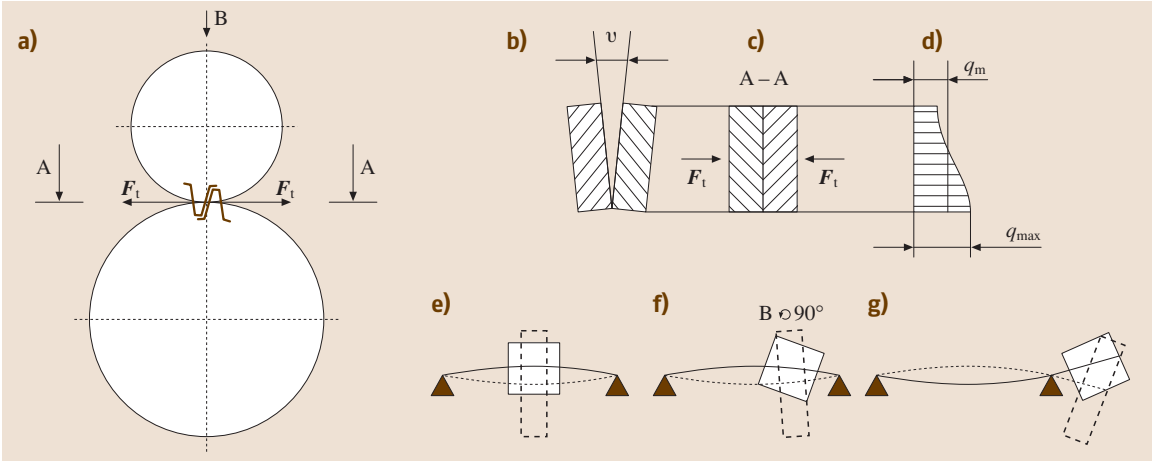

Fig. 6.25a–g Change of the nominal gradient angle β of the tooth due to **(a)**–**(d)** manufacturing errors, **(e)**–**(g)** resilience of the shaft to bending

produces a relative warp ϑ of the teeth in initial contact without load (Fig. 6.25a,b). As a consequence of yielding of the teeth and their distortion under the action of the force F_t in the toothing, the contact occurs along the whole length (Fig. 6.25c). However, resiliency along the tooth lengths are not equal, which results in an uneven load distribution, which is quantified by the ratio q_{max}/q_m (Fig. 6.25d). The relative teeth warp ϑ as a result of the elastic shaft flexure strain depends on the gearing position relative to the bearings (Fig. 6.25e–g). There is no teeth warp in a symmetrical arrangement; the greatest warp is observed in the case of the cantilever location (Fig. 6.25g). The directional tooth error is regulated by the degree of gearing accuracy according to the contact standards.

Torsional strain of the pinion body under the action of the torque produces tooth contortion, i. e., a change of direction of the tooth along the crown width. From the direction of the torque supply T_1 on the pinion end 1 (Fig. 6.26) the angle of torsion γ is maximum, but at end 2, $T = 0$, and torsional strains are absent, $\gamma = 0$. The degree of the change of direction of the tooth and the load distribution unevenness are higher for larger width b_2 of the gear. Moreover, how low the angular hardness c of the pinion is depends on the diameter d_1. This is why the factor $K_{H\beta}$ is chosen depending on the ratio $\psi_{bd} = b_2/d_1$.

The gear wheel teeth can *grind* and, as a result of increased local wear, the load distribution becomes even. Therefore, the unbalance factors are considered *at the initial time of functioning* $K^0_{H\beta}$ and after *grind* $K_{H\beta}$.

The value of the coefficient $K^0_{H\beta}$ is determined by the degree of accuracy required by the contact standards, the ratio $\psi_{bd} = b_2/d_1$, the layout of the gearing with regard to the bearings, and the teeth hardness ($K^0_{H\beta} = 1.05–1.5$). The value ψ_{bd} is computed from $\psi_{bd} = 0.5\psi_{ba}\ (u \pm 1)$, where ψ_{ba} is the gear face ratio.

The factor $K_{H\beta}$ is computed from

$$K_{H\beta} = 1 + \left(K^0_{H\beta} - 1\right) K_{Hw} ,$$

where K_{Hw} is a coefficient that takes into account teeth burn-in; its value is found in dependence on the circumferential velocity of the gear wheel with lower hardness. The grind capability decreases (K_{Hw} increase) with increasing hardness and circumferential velocity. The increase in the circumferential velocity assists in producing a steady oil layer between the teeth, which protects them from wear.

To lower the unbalance factor $K_{H\beta}$ along the contact line the wheels should be positioned symmetrically relative to the bearings, and the hardness of the gear wheels, shafts, and bearings should be increased (roller bearings should be applied instead of ball bearings), the manufacturing accuracy (of the gear wheels themselves, the bores for the bearings in the cases, etc.) should be increased, and barrel teeth should be used (Fig. 6.27).

The internal dynamic load in the toothing (the ratio K_{HV}) is caused by impact of the teeth on entry into the toothing due to production errors of the pitch and teeth distortion under loading. For nonimpact functioning, it is necessary that the teeth mesh and leave the toothing along the line of action, i. e., circular pitches must be equal under load. If the circular pitch is less than the wheel pitch, untimely meshing of the second teeth pair occurs and *edge impact* (at the tooth point of the driven wheel) is observed. When the circular pitch of the pinion is larger than the wheel pitch delay, the preceding teeth pair leaves the meshing, and thus the following pair does not make contact at the beginning of the impact, but rather in the middle of the working area of the contact line, a phenomenon known as *middle impact*.

Nominal force F in the toothing increases in F_{im} at impact. Then the full dynamic load is

$$F_{dy} = F + F_{im} = F(1 + F_{im}/F) = FK_{HV} .$$

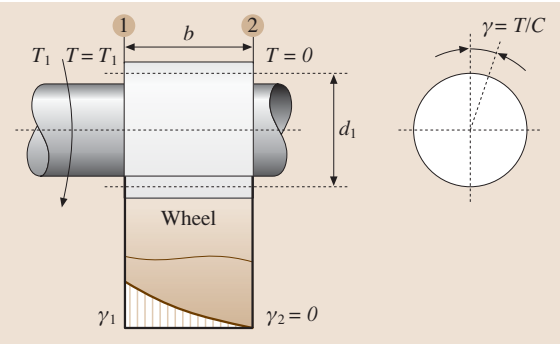

Fig. 6.26 Change of the tooth line as a consequence of torsional deformation of the pinion body

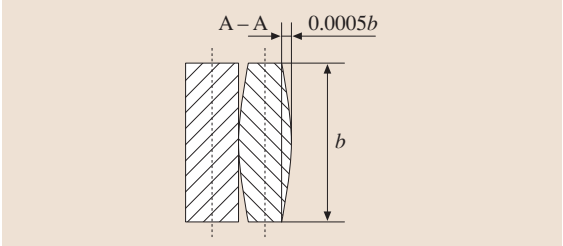

Fig. 6.27 Barrel-type form of the tooth

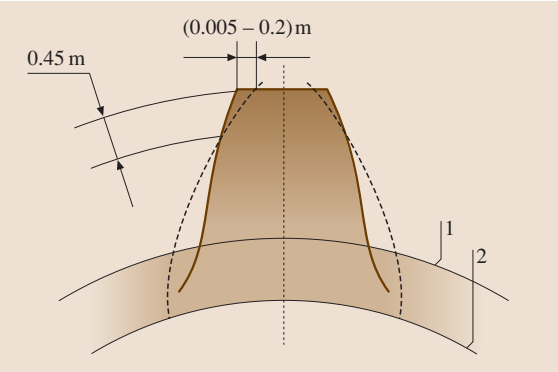

Fig. 6.28 Modification of the tooth point

From this formula it follows that higher surface hardness corresponds to a lower value of the ratio K_{HV}. It is caused by the fact that the nominal force is higher for greater hardness of the working teeth surfaces, whereas the impact force F_{im}, which depends on the degree of manufacturing accuracy and circumferential velocity, is the same.

The ratio of the internal dynamic load K_{HV} depends on the degree of gearing accuracy according to the smoothness standards, the circumferential velocity, and the hardness of the working surfaces ($K_{HV} = 1.01–1.6$). Lower values of K_{HV} correspond to higher-accuracy, helical, hard gearings that function with low circumferential velocity.

To reduce internal dynamic load production the accuracy should be increased according to the smoothness standards, helical or herring-bone gears should be used, and the tooth tip (teeth with a cut-off crest) should be modified. In order to obey the toothing theorem, cutting off is carried out according to the evolvent of the main circle 2 with diameter less than that of than the main circle 1 (Fig. 6.28).

The values of the coefficients $K^0_{H\beta}$, K_{HV}, and K_{Hw} are given as tables and charts [6.35].

The unevenness of the load distribution between the teeth (the ratio $K_{H\alpha}$) depends on production errors (pitch errors and teeth direction). Consequently, with the touching of one teeth pair of mating wheels, clearance is possible in another pair. Owing to teeth distortion on load application the clearance can disappear, but in this case load distribution unevenness is unavoidable: teeth with initial contact are more heavily loaded, while teeth with initial clearance are less heavily loaded. The ratio $K_{H\alpha}$ is determined by taking into account possible grinding as a result of increased local wear, which is why load distribution coefficients in the *initial operating period* $K^0_{H\alpha}$ and *after grinding* $K_{H\alpha}$ are considered

$$K_{H\alpha} = 1 + \left(K^0_{H\alpha} - 1\right) K_{Hw} ,$$

where K_{Hw} is a coefficient taking teeth grind into account.

In the bending stress calculation the load ratio is

$$K_F = K_A K_{F\beta} K_{FV} K_{F\alpha} ,$$

where K_A is the ratio of the *internal dynamic load* and is determined in the same way as in contact strength calculations. $K_{F\beta}$ is a ratio taking the *load distribution unevenness at the tooth root along the width of the gear ring* into consideration.

A lower influence of the load distribution unevenness on the bending stress ($K_{F\beta}$ is less than $K^0_{H\beta}$) is caused by bending stresses act throughout the tooth volume in contrast to contact stresses concentrated in the contact area.

K_{FV} is a ratio taking the *internal dynamic load* into account, and depends on the accuracy degree of the gearing according to the smoothness standards, circumferential velocity, and surface hardness of the wheel teeth ($K_{FV} = 1.01–2$). Lower values correspond to helical hard gearings of high accuracy that function with low circumferential velocities.

$K_{F\alpha}$ is a ratio taking *the influence of the production errors of the pinion and the wheel on the load distribution between the teeth* into account and is determined the same way as in contact strength calculations: $K_{F\alpha} = K^0_{H\alpha}$.

The influence of the grind on the bending strength is less favorable than it is on the contact strength. This can have severe consequences due to inaccuracy in the determination of bending stresses if the grind is not taken into consideration in the calculations of the ratios $K_{F\beta}$ and $K_{F\alpha}$.

6.3 Cylindrical Gearings

6.3.1 Toothing Forces of Cylindrical Gearings

It is customary to determine the interacting teeth forces at the pitch point. The load q is distributed throughout the contact area; in the toothing it changes into the resultant F_n normal to the tooth surface.

For the calculation of the shafts and bearings it is convenient to represent the force F_n by its components F_t, F_a, F_r (Fig. 6.29).

The circumferential force is

$$F_t = 2\times 10^3 T/d \,,$$

and the axial force is

$$F_a = F_t \tan\beta \,.$$

On the driven wheel the direction of the circumferential force F_t coincides with the rotational direction, whereas on the drive wheel the opposite is true. The axial force is parallel to the wheel axis. The direction of the vector F_a depends on the direction of wheel rotation and the tooth line.

For determination of the radial force F_r let us write the intermediate expression

$$F_R = F_t/\cos\beta \,.$$

Then the radial force (see the section A–A in Fig. 6.29)

$$F_r = F_R \tan\alpha_w = F_t \tan\alpha_w/\cos\beta \,,$$

where T is the torque of the gear wheel (N m), d is the pitch diameter of the wheel (in mm), β is the tilt angle of the tooth, and $\alpha_w = 20°$ is the angle of action. The radial force vectors of wheels with external toothing are directed towards the axis, whereas the vectors of wheels with internal toothing are directed away from the axis of the gear wheel.

6.3.2 Contact Strength Analysis of Straight Cylindrical Gearings

The contact strength of the teeth is the main efficiency specification for most gearings. In the derivation of the calculated relation according to the contact strength condition, teeth contact is considered at the pitch point W, i. e., in the zone of one-pair contact where flaking is observed. In Fig. 6.30 $O_1O_2 = a_w$ is an axle base, N_1N_2 is a contact line (the tangent to the base circles), α_w is an angle of action, d_{b1} and d_{b2} are the diameters of the base circles, and d_{w1} and d_{w2} are the diameters of the initial circles. In gearings without shifting pitch, the initial circles coincide: $d = d_w$.

As shown previously, we have

$$a_w = (d_2 \pm d_1)/2 = d_1(u \pm 1)/2 \,.$$

Hence,

$$d_1 = 2a_w/(u \pm 1) \quad \text{and} \quad d_2 = 2a_w u/(u \pm 1) \,,$$

where $u = d_2/d_1$ is the gear ratio of the gearing. The highest contact stress in the contact zone is determined from Hertz's formula (6.1) derived for the contact of two cylinders with parallel axes (Fig. 6.6).

To develop the calculated relation, let us express the values included in Hertz's formula using the toothing parameters. The force F_n acting along the normal to the profiles (along the toothing line in the contact point) is determined according to the circumferential force F_t taking into account the load ratio K_H

$$F_n = K_H F_t/\cos\alpha_w \,.$$

The length l_Σ of the contact lines in the toothing of the gear wheels with straight teeth changes from the effective gear face b_2 of the wheel in the zone of one-pair contact to $2b_2$ in the zone of two-pair contact. The rotation angle of the gear wheel by the transference of the profile tangent point from one extreme position to another is called the *front overlap angle*. The relation of the front overlap angle to the angle spacing $2\pi/z$

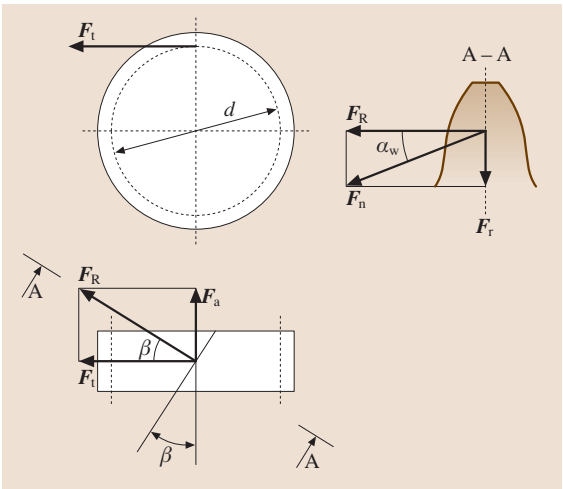

Fig. 6.29 Forces in the toothing of cylindrical gearings

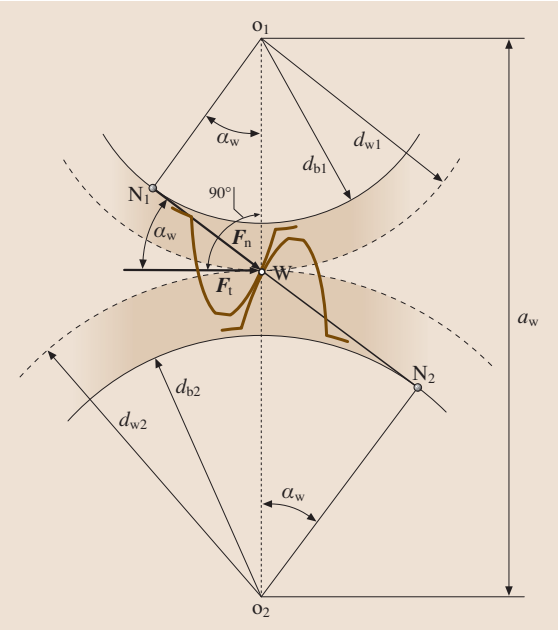

Fig. 6.30 Contact strength analysis of gearings

is called the *front contact ratio* ε_α. Here z is the teeth number of the gear wheel.

In compliance with the experimental results for the calculations the total length $b = l_\sum$ of the contact lines is determined, taking into account the front contact ratio ε_α, as

$$b = l_\sum = 3b_2/(4-\varepsilon_\alpha)\,.$$

Teeth contact is considered as the contact of two cylinders with radii equal to the curvature radii of the teeth profiles at the pitch point $\rho_1 = \mathrm{N_1W}$ and $\rho_2 = \mathrm{N_2W}$. Then

$$\sum(1/\rho_i) = 1/\rho_1 \pm 1/\rho_2 = (\rho_2 \pm \rho_1)\,/\,(\rho_1\rho_2)\,.$$

From the right triangle $\mathrm{O_1N_1W}$ we have: $\rho_1 = \mathrm{N_1W} = 0.5d_1\sin\alpha_\mathrm{w}$; and from the triangle $\mathrm{O_2N_2W}$ we have: $\rho_2 = \mathrm{N_2W} = 0.5d_2\sin\alpha_\mathrm{w} = 0.5ud_1\sin\alpha_\mathrm{w}$.

Then

$$\sum(1/\rho_i) = \frac{0.5ud_1\sin\alpha_\mathrm{w} \pm 0.5d_1\sin\alpha_\mathrm{w}}{0.5d_1\sin\alpha_\mathrm{w}0.5ud_1\sin\alpha_\mathrm{w}} = \frac{u\pm1}{0.5ud_1\sin\alpha_\mathrm{w}}\,.$$

Let us substitute the given relations into Hertz's formula

$$\sigma_\mathrm{H} = \sqrt{\frac{1}{\pi\left[\left(1-v_1^2\right)/E_1 + \left(1-v_2^2\right)/E_2\right]}} \times \sqrt{\frac{K_\mathrm{H}F_t}{\cos\alpha_\mathrm{w}}\,\frac{4-\varepsilon_\alpha}{3b_2}\,\frac{2}{d_1\sin\alpha_\mathrm{w}}\,\frac{u\pm1}{u}}\,.$$

Let us identify

$$Z_\mathrm{E} = \sqrt{1/\left[\pi[(1-v_1^2)/E_1 + (1-v_2^2)/E_2]\right]}$$

as the ratio that takes into consideration the stress–strain material properties of the mated wheels. For steel wheels $Z_\mathrm{E} = 191.6\,\mathrm{N/mm^2}$ for $E_1 = E_2 = 2.1\times10^5\,\mathrm{N/mm^2}$, and $v_1 = v_2 = 0.3$.
$Z_\mathrm{H} = \sqrt{2/\left(\cos\alpha_\mathrm{w}\sin\alpha_\mathrm{w}\right)}$ is the ratio that takes into account the form of the mated teeth surfaces at the pitch point; $Z_\mathrm{H} = 2.5$ for $\alpha_\mathrm{w} = 20°$. $Z_\varepsilon = \sqrt{(4-\varepsilon_\alpha)/3}$ is the ratio that takes into account the total length of the contact lines. $Z_\varepsilon = 0.9$ for spurs with $\varepsilon_\alpha = 1.6$.

Thus, we determine the relation in the form suggested by the standards

$$\sigma_\mathrm{H} = Z_\mathrm{E}Z_\mathrm{H}Z_\varepsilon\sqrt{\frac{K_\mathrm{H}F_\mathrm{t}\,(u\pm1)}{b_2d_1u}}\,, \qquad (6.4)$$

where u is the gear ratio; F_t is in N; d_1 and b_2 are in mm, and σ_H is in $\mathrm{N/mm^2}$.

Substituting into this formula $F_\mathrm{t} = 2\times10^3T_1/d_1$ and expressing b_2 and d_1 through a_w: $b_2 = \psi_{ba}a_\mathrm{w}$ and $d_1 = 2a_\mathrm{w}/(u\pm1)$, we then have

$$\sigma_\mathrm{H} = Z_\mathrm{E}Z_\mathrm{H}Z_\varepsilon\sqrt{\frac{K_\mathrm{H}2\times10^3T_1\,(u\pm1)}{b_2d_1^2u}} = Z_\mathrm{E}Z_\mathrm{H}Z_\varepsilon\sqrt{\frac{K_\mathrm{H}2\times10^3T_1\,(u\pm1)^3}{\psi_{ba}a_\mathrm{w}4a_\mathrm{w}^2u}}\,,$$

where T_1 is the torque of the pinion (N m).

We write the strength condition $\sigma_\mathrm{H} \le [\sigma]_\mathrm{H}$ in the form

$$\sigma_\mathrm{H} = Z_\mathrm{E}Z_\mathrm{H}Z_\varepsilon\sqrt{\frac{K_\mathrm{H}500T_1\,(u\pm1)^3}{\psi_{ba}a_\mathrm{w}^3u}} \le [\sigma]_\mathrm{H}\,. \qquad (6.5)$$

Having done this relative to a_w, we obtain

$$a_\mathrm{w} = (u\pm1)\sqrt[3]{500\,(Z_\mathrm{E}Z_\mathrm{H}Z_\varepsilon)^2}\sqrt[3]{\frac{K_\mathrm{H}T_1}{\psi_{ba}u\,[\sigma]_\mathrm{H}^2}}\,.$$

We designate

$$K_a = \sqrt[3]{500\,(Z_\mathrm{E}Z_\mathrm{H}Z_\varepsilon)^2}\,.$$

Finally the formula for the projection analysis of cylindrical gearings takes the following form

$$a_w = K_a\,(u \pm 1)\,\sqrt[3]{\frac{K_H T_1}{\psi_{ba} u\,[\sigma]_H^2}}\,,$$

where a_w is an axle base (in mm), K_H is a load ratio, T_1 is a torque on the pinion (N m), and $[\sigma]_H$ is an allowable contact stress (in units of N/mm^2).

In accordance with the standards:

- For straight gearings $K_a = 450\,(\mathrm{N/mm^2})^{1/3}$
- For helical and herring-bone gearings $K_a = 410\,(\mathrm{N/mm^2})^{1/3}$

In general, the axle base of helical cylindrical gearings is approximately 20% less than that of straight gearings.

On the analysis of cylindrical gearings the ratio value of the wheel face width $\psi_{ba} = b_2/a_w$ is set. *Depending on the pinion position relative to the bearings* it is taken as $\psi_{ba} = 0.2$–0.5.

On the basis of (6.5) we obtain the formula for the verification calculation

$$\sigma_H = \frac{Z_E Z_H Z_\varepsilon \sqrt{500}}{a_w}\sqrt{\frac{K_H T_1\,(u \pm 1)^3}{\psi_{ba} a_w u}}\,.$$

Using $Z_\sigma = Z_E Z_H Z_\varepsilon \sqrt{500}$ and substituting in $\psi_{ba} a_w = b_2$, we obtain the formula for the verification analysis of cylindrical gearings

$$\sigma_H = \frac{Z_\sigma}{a_w}\sqrt{\frac{K_H T_1\,(u \pm 1)^3}{b_2 u}} \le [\sigma]_H\,, \qquad (6.6)$$

where T_1 is in N m, a_w and b_2 are in mm, and σ_H is in N/mm^2.

The values of the ratio Z_σ for cylindrical steel gearings are:

- For straight gearings $Z_\sigma = 9600\,(\mathrm{N/mm^2})^{1/2}$
- For helical and herring-bone gearings $Z_\sigma = 8400\,(\mathrm{N/mm^2})^{1/2}$

In the projection analysis the ratio value of the rated load is set approximately as $K_H = 1.3$. In the checking analysis its adjusted value is determined from all known gearing parameters.

From the given formulas it follows that the contact strength of the wheel teeth depends on the material and gearing dimensions, and does not depend on the module and teeth number individually. With a contact strength with given a_w the module and teeth number can have different values if they meet the conditions $0.5m(z_1 + z_2) = a_w$ and $u = z_2/z_1$.

6.3.3 Bending Strength Calculation of Cylindrical Gearing Teeth

The second of the two basic efficiency criteria for gearings is the bending strength of the teeth. For the derivation of the rating relation it is supposed that (Fig. 6.31):

1. There is one pair of teeth in contact.
2. The tooth is considered as a cantilever bar loaded with a concentrated force F_n applied to the tooth point.

The force F_n acts at an angle $(90° - \alpha')$ to the symmetry axis of the tooth. The angle α' is slightly larger than the angle of action α_w. For the determination of the tooth stress state the force F_n is transferred along the contact line N_1N_2 to the intersection with the tooth axis at point C (Fig. 6.32a), decomposed into the constituents directed along the tooth axis and transversely to it.

Under the influence of the constituent directed along the axis, compressions act at the tooth root $\sigma_{com} = F_n \sin\alpha'/(bS)$, where b is the tooth length (Fig. 6.32b).

The points A and B determine the position of the weak tooth section in the case of bending. The

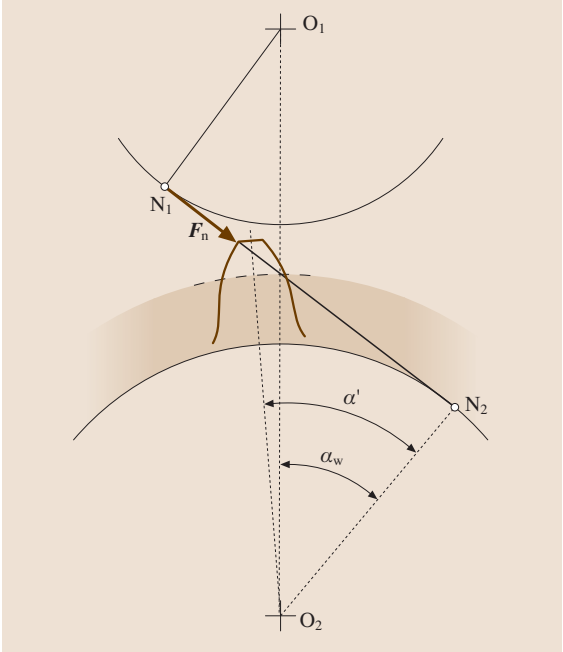

Fig. 6.31 Bending strength analysis of teeth

tooth in this section is loaded with bending moment $M = F_n h_c \cos\alpha'$, producing stress action σ_b. On the left-hand side of the axis in Fig. 6.32b there is tension; on the right-hand side there is compression.

Total stresses $\sigma_{F\,nom}$ from the side of the tension (point A) have lower values than from the side of the compression (point B). However, tensile stresses are more dangerous. From experience in the field the fatigue crack 1 that results in breaking off of the tooth arises exactly from the side of the tension at point A (Fig. 6.32). Stresses found without taking into account stress concentrators are called *nominal*.

Let us determine the nominal stresses $\sigma_{F\,nom}$ of the bending compression at point A

$$\sigma_{F\,nom} = \sigma_b - \sigma_{com} = \frac{M}{W_x} - \frac{F_n \sin\alpha'}{bS}$$
$$= \frac{F_n \cos\alpha' h_c 6}{bS^2} - \frac{F_n \sin\alpha'}{bS}$$
$$= \frac{F_n}{b}\left(\frac{\cos\alpha' h_c 6}{S^2} - \frac{\sin\alpha'}{S}\right),$$

where $W_x = bS^2/6$ is the axial modulus of the weak section AB.

Expressing the force F_n through the circumferential force F_t, and taking the load ratio K_F: $F_n = K_F F_t/\cos\alpha_w$ into account, one finds

$$\sigma_{F\,nom} = \frac{K_F F_t}{b}\frac{1}{\cos\alpha_w}\left(\frac{\cos\alpha' h_c 6}{S^2} - \frac{\sin\alpha'}{S}\right).$$

The weak section AB is positioned in the zone of stress concentration that is caused by form change on the fillet surface at the tooth root. Local stresses in this section increase nominal stresses α_T by a factor of

$$\sigma_F = \sigma_{F\,nom}\alpha_T,$$

where α_T is the theoretical stress concentration factor.

Taking into consideration the stresses in the weak section, one obtains

$$\sigma_F = \frac{K_F F_t}{b}\frac{1}{\cos\alpha_w}\left(\frac{\cos\alpha' h_c 6}{S^2} - \frac{\sin\alpha'}{S}\right)\alpha_T.$$

Value h_c and tooth thickness S are expressed through the normal module m

$$h_c = \mu m \quad \text{and} \quad S = \lambda m,$$

where μ and λ are factors taking the tooth shape into account.

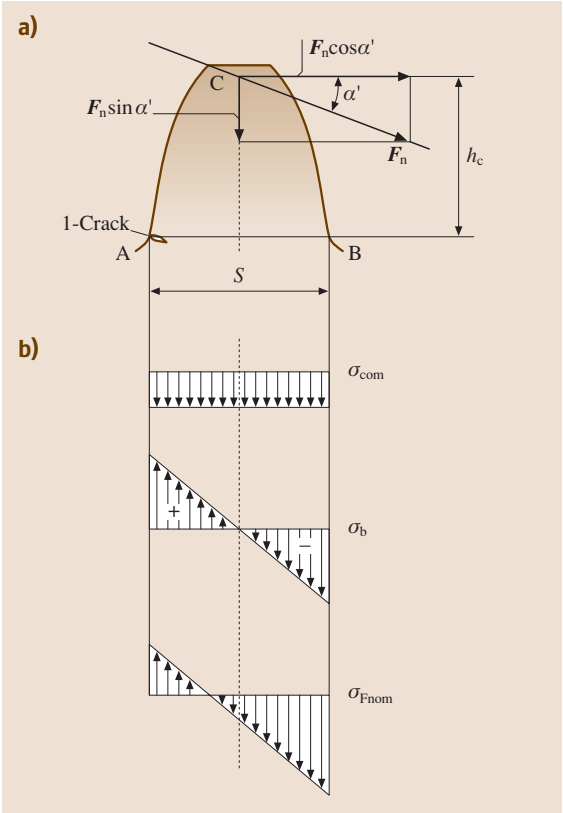

Fig. 6.32a,b Stressed state of the tooth. **(a)** Loading diagram, **(b)** stress distribution diagrams

Then

$$\sigma_F = \frac{K_F F_t}{b}\frac{1}{\cos\alpha_w}\left(\frac{\cos\alpha'\mu m 6}{\lambda^2 m^2} - \frac{\sin\alpha'}{\lambda m}\right)\alpha_T$$
$$= \frac{K_F F_t}{bm}\frac{1}{\cos\alpha_w}\left(\frac{\cos\alpha'\mu 6}{\lambda^2} - \frac{\sin\alpha'}{\lambda}\right)\alpha_T$$
$$= \frac{K_F F_t}{bm} Y_{FS},$$

where Y_{FS} is the ratio taking into consideration tooth shape and stress concentration

$$Y_{FS} = \frac{1}{\cos\alpha_w}\left(\frac{\cos\alpha'\mu 6}{\lambda^2} - \frac{\sin\alpha'}{\lambda}\right)\alpha_T.$$

The values of the ratio $Y_{FS} = 4.5–3.6$ taking tooth form and stress concentration into consideration are given in the form of tables and charts [6.35]. Lower values of the ratio Y_{FS} correspond to larger numbers of teeth and a positive shift of the tools because both result in an increase of the tooth thickness at the root.

Considering the strength condition $\sigma_F \le [\sigma]_F$, we obtain the formula for verification of the bending stress analysis of the gearings

$$\sigma_F = \frac{K_F F_t}{bm} Y_{FS} Y_\beta Y_\varepsilon \le [\sigma]_F \ , \qquad (6.7)$$

where $[\sigma]_F$ is an allowable bend stress in N/mm^2, F_t is in N, and b and m are in mm.

In the given formula, we additionally have that Y_β is the ratio that takes the tilt angle of the tooth into account, and Y_ε is the ratio that takes teeth overlap into consideration.

For spurs, $Y_\beta = 1$, $Y_\varepsilon = 1$, with an accuracy degree of 8 and 9, and $Y_\varepsilon = 0.8$, with an accuracy degree of 5–7.

Owing to the smaller number of teeth on the pinion, their roots are thinner than those on the wheel, which is reflected in a higher value of the ratio Y_{FS} (i. e., $Y_{FS1} > Y_{FS2}$). To provide an approximately equal bending strength of the pinion teeth and the wheel teeth, the pinion is manufactured from more resistant material compared with that used for the wheel.

The condition for equal bending strength for teeth on the and the wheel is

$$[\sigma]_{F1}/Y_{FS1} \approx [\sigma]_{F2}/Y_{FS2} \ .$$

Substituting into (6.7) $F_t = 2\times10^3 T_1/d_1$ and $d_1 = 2a_w/(u \pm 1)$ we obtain the formula for checking the bending stress analysis of the teeth

$$\sigma_F = \frac{K_F 10^3 T_1 \ (u \pm 1)}{bma_w} Y_{FS} Y_\beta Y_\varepsilon \le [\sigma]_F \ ,$$

where T_1 is in N m; b_2, m and a_w are in mm, and σ_F and $[\sigma]_F$ are in N/mm^2.

This inequality can be rearranged in terms of m as

$$m \ge \frac{K_F T_1 \ (u \pm 1)}{ba_w \ [\sigma]_F} 10^3 Y_{FS} Y_\beta Y_\varepsilon \ .$$

The pinion face width b_1 is 2–4 mm thicker than the wheel width b_2 to balance possible axial shifting of the gear wheels due to installation inaccuracy. This condition is important for teeth grind, when a harder pinion overlaps edgewise with a less hard wheel.

Supposing that $b = b_2$ and $K_m = 10^3 Y_{FS} Y_\beta Y_\varepsilon$ we obtain the rated relation for the determination of the minimum value of the teeth module

$$m \ge K_m K_F T_1 (u \pm 1)/(b_2 a_w [\sigma]_F) \ ,$$

where $K_m = 3.4\times10^3$ for straight gearings and $K_m = 2.8\times10^3$ for helical gearings, and T_1 is in N m, b_2, a_w are in mm, and $[\sigma]_F$ is in N/mm^2. Instead of $[\sigma]_F$ the lowest of $[\sigma]_{F1}$ and $[\sigma]_{F2}$ is substituted into this formula.

6.3.4 Geometry and Working Condition Features of Helical Gearings

The teeth of helical cylindrical wheels are cut with the same tool as is used for spurs. The hob axis forms an angle β with the end face of the wheel (Fig. 6.33). During cutting, the hob is moved in the direction of the wheel teeth. Thus, all dimensions are the same as in the straight cylindrical gearings in the plane normal to the tooth surface.

A pair of mating helical wheels with external toothing have equal angles β, but in opposite directions. In the absence of special demands, wheels are cut in the right tooth direction, and the pinions in the left direction.

The distance between the teeth of the helical wheel (Fig. 6.33) can be measured in the end, peripheral, (t–t), and standard (n–n) directions. In the first case the peripheral pitch p_t is obtained, in the second case the standard pitch p is obtained. The toothing modules are also different in these directions

$$m_t = p_t/\pi; \quad m_n = p/\pi \ ,$$

where m_t and m_n are the peripheral and normal modules of the teeth.

In compliance with Fig. 6.33

$$p_t = p/\cos\beta \ ,$$

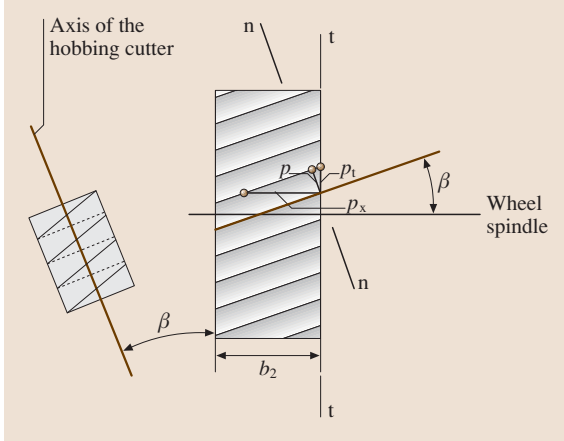

Fig. 6.33 Main parameters of a cylindrical helical wheel

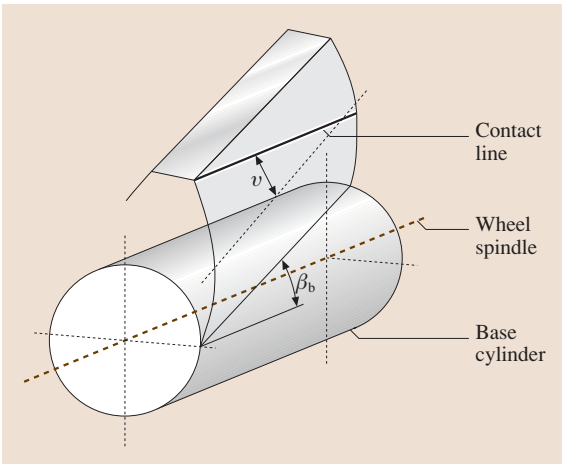

Fig. 6.34 Position of the contact line on a skew tooth of the wheel

and therefore

$$m_t = m/\cos\beta\ ,$$

where β is the tilt angle of the tooth on the pitch cylinder. The standard module conforms to the standard.

On the end face the t–t helical wheel can be considered as a spur with module value m_t, and angle of action α_T: $\tan\alpha_T = \tan\alpha/\cos\beta$.

For a wheel without a shifting pitch d and starting d_w diameters

$$d = d_w = m_t z = m_n z/\cos\beta\ .$$

In addition to front overlap there is also axial overlap in helical gearings. The axial overlap factor is

$$\varepsilon_\beta = b_2/p_x\ ,$$

where p_x is an axial spacing that equals the distance between the analogous points of two adjacent teeth, measured in the direction of the gear wheel axis (Fig. 6.33)

$$p_x = \pi m_n/\sin\beta\ .$$

Differences in the Functioning Conditions of Helical Gearings Determine Their Geometry Features

1. The contact lines on the helical wheel are positioned parallel to the axis of revolution (Fig. 6.34), at an angle of ϑ to the pitch line (on the spur this is parallel to the pitch line). Here β_b is the tilt angle of the tooth on the basic cylinder. The driven wheel tooth meshes starting from the tooth point, first increasing, then reducing the contact line length when traversing it from the tooth tip to the dedendum. As a result of the fact that the tooth does not operate along the whole length at once, it grinds better and more quickly.
2. In contrast to spur gears, in helical gearings the teeth do not mesh along the whole length at once, but rather gradually. The contact time of one teeth pair increases while new teeth pairs interlock; more contact lines transmit the load, which reduces noise and dynamic loads considerably. The greater the tilt angle β of the tooth line (Fig. 6.33), the greater the smoothness of the toothing.
3. The load along the contact line is distributed proportionally to the total teeth hardness of the pinion and the wheel (Fig. 6.35a). The contact of the mating teeth in their typical sections and their schematic sketch to determine the total rigidity are shown in Fig. 6.35b. The hardness is lower and the load is lower for the contact of one of the mating teeth at

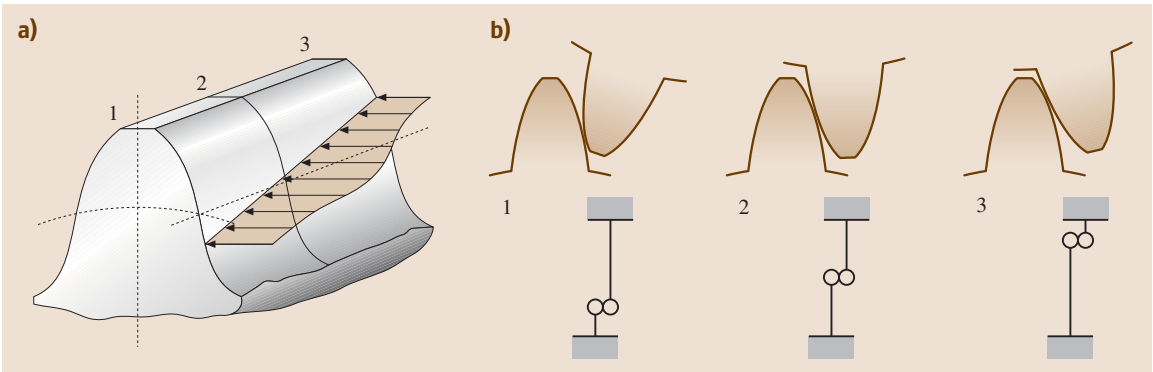

Fig. 6.35a,b Contact of conjugated teeth in the typical sections **(a)** and schematic sketch **(b)**

a point (profiles 1 and 3). Such a load distribution is positive for the gearing operation.

4. Due to axial overlap in helical gearings two or three pairs of the teeth take part in toothing simultaneously. Thus, the total length $l_{\sum \text{hel}}$ of the contact lines in the helical gearing is longer than in the spur $l_{\sum \text{spur}}$

$$l_{\sum \text{hel}} = \frac{b_2}{Z_\varepsilon^2 \cos\beta_b} \; ; \quad l_{\sum \text{spur}} = \frac{b_2}{Z_\varepsilon^2} \; .$$

In this regards, the values of the ratio Z_ε, taking into account the total length of the contact lines becomes

$$Z_\varepsilon = \sqrt{1/\varepsilon_\alpha} \quad \text{for helical gearings} \; ,$$
$$Z_\varepsilon = \sqrt{(4-\varepsilon_\alpha)/3} \quad \text{and for spur gears} \; ,$$

where ε_α is the front contact ratio.

5. The correlation between the radii of curvature of contacting teeth in the helical gearing is more favorable

$$\sum (1/\rho_i)_{\text{hel}} = \cos\beta_b \sum (1/\rho_i)_{\text{spur}} \; .$$

This is embodied in the calculation of the ratio Z_H, taking the form of the mated teeth surfaces into consideration. Contact stresses under other equal conditions in helical gearings are lower in value than in spur gearings.

6. The tooth form provides higher bend strength.

6.3.5 The Concept of the Equivalent Wheel

As has been mentioned, the profile of the oblique tooth in the standard section n–n (Fig. 6.33) coincides with the profile of the spur. The calculation for helical wheels is carried out using the parameters of the equivalent spur: the module m_n and the teeth number z_v.

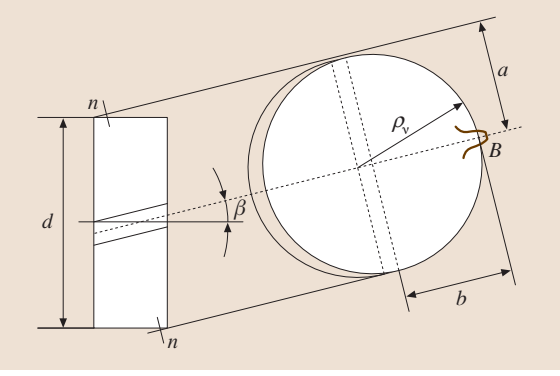

Fig. 6.36 Reduction of the helical wheel to the equivalent spur

The pitch cylinder of the helical wheel in the plane n–n normal to the tooth line (Fig. 6.36) forms an ellipse with the semi-axles: large $a = d/(2\cos\beta)$ and small $b = d/2$. The radius of curvature in the vertex B of the ellipse is

$$\rho_v = \frac{a^2}{b} = \frac{d^2}{4\cos^2\beta}\frac{2}{d} = \frac{d}{2\cos^2\beta} \; .$$

The tooth profile in this section coincides with the profile of the relative spur called the *equivalent*, the pitch diameter of which is $d_v = m_n z_v$.

Taking into consideration that $d = m_t z$ and $m_t = m_n/\cos\beta$ we have

$$d_v = 2\rho_v = d/\cos^2\beta = m_t z/\cos^2\beta = m_n z/\cos^3\beta \; .$$

From the equality

$$m_n z_v = m_n z/\cos^3\beta \; ,$$

the equivalent teeth number follows as

$$z_v = z/\cos^3\beta \; ,$$

where z is the actual teeth number of the helical wheel. With an increase in the tilt angle β of the tooth line, the equivalent parameters increase, which in turns leads to an increase in the strength of the gearings.

6.3.6 Strength Analysis Features of Helical Gearings

Strength analysis of helical gearings is carried out with calculation formulas of spur gears with insertion of correction factors that take into account their working features. These include high working smoothness (lower values of the factor of internal dynamic load K_v), longer total length of contact lines, more favorable combination of the curvature radii, and higher fatigue bend resistance (lower value of the factor Y_{FS} of the tooth form and stress concentrations as $z_v > z$). According to these strength conditions the dimensions of helical gearings are smaller than those of spur gears. In contact strength calculations the features of the geometry and work conditions of helical gearings are taken into consideration by means of the factors Z_H, Z_ε and K_H. The features of helical gearings in *bending strength testing* of the pinion teeth and wheel teeth are taken into account by the factors K_F, Y_{FS}, Y_β, and Y_ε. The factor Y_{FS} of the tooth form and stress concentrations is chosen according to the equivalent teeth number z_v. The

factor Y_β, which takes into account the tooth tilt in helical gearings, is determined from the following formula (where β is in degrees)

$$Y_\beta = 1 - \varepsilon_\beta \beta / 120 \,,$$

under the condition that $Y_\beta \geq 0.7$.

The factor Y_ε takes into consideration teeth overlap in helical gearings, where $Y_\varepsilon = 1/\varepsilon_\alpha \approx 1/1.6 \approx 0.65$.

6.3.7 The Projection Calculation of Cylindrical Gearings

The basic data for the calculation under typical loading conditions are the the turning moment T_1 (N m), the rotational frequency of the pinion rotation n_1 (min^{-1}), the gear ratio u, the working time of the gearing (lifetime) L_h (h), and the layout drawing and type of the gearing.

1. Choosing of the wheel hardness, thermal treatment and material

   For power trains the most frequently used material is steel (Table 6.1). Below the steels used for gearing production in Russia are described (Appendix 6.A Table 6.95).

   In the case of surface heat or chemicothermal teeth treatment, the previous heat refining treatment determines the mechanical data of the tooth core.

2. Allowable contact stresses $[\sigma]_{H1}$ for the pinion and $[\sigma]_{H2}$ for the wheel are determined from the total relation, but with substitution of the appropriate parameters for the pinion and the wheel

$$[\sigma]_H = \sigma_{H\,lim} Z_N Z_R Z_V / S_H \,.$$

The fatigue contact point $\sigma_{H\,lim}$ is determined from empirical formulas depending on the material and heat treatment method of the gear wheel and the average hardness (HB_m or HRC_m) of the teeth surface (Table 6.2).

The minimum value of the load factor for gear wheels with homogenous material structure (refined, volume-quenched) is $S_H = 1.1$; for gear wheels with case-hardening one has $S_H = 1.2$.

The service life ratio Z_N takes into account the influence of lifetime:

for $N_{HE} \leq N_{H\,lim}$

$$Z_N = \sqrt[6]{N_{H\,lim}/N_{HE}} \,,$$

Table 6.2 Contact fatigue points $\sigma_{H\,lim}$

under the condition that $Z_N \le Z_{N\,max}$;
for $N_{HE} > N_{H\,lim}$

$$Z_N = \sqrt[20]{N_{H\,lim}/N_{HE}}\,,$$

under the condition that $Z_N \ge 0.8$.

The number $N_{H\,lim}$ of cycles corresponding to the change of the stress-cycle diagram is determined from the average surface hardness of the teeth

$$N_{H\,lim} = 30\,HB_m^{2.4} \le 12\times10^7\,.$$

Hardness in units of HRC is transferred into units HB according to Table 6.3.

In fatigue resistance calculations the action of the short-term overload moment T_{max} is not taken into consideration, but actual varying loading conditions are changed with equivalent constant conditions with nominal torque T and equivalent number N_{HE} of the loading cycles

$$N_{HE} = \mu_H N_k\,.$$

The values of the equivalence factor μ_H for typical loading conditions are given in Table 6.4.
The lifetime N_k of the gearing in cycle numbers of stress changes with rotational frequency n (min^{-1}) and working time L_h (h) is

$$N_k = 60 n n_t L_h\,,$$

where n_t is the number of tooth matings of the calculated wheel per revolution. Generally the total working lifetime L_h (h) of the gearing is determined from

$$L_h = L365K_{year}24K_{day}\,,$$

where L is the number of working years; K_{year} and K_{day} are, respectively, ratios of annual and daily gearing applications.
If plastic strain and brittle fracture of the surface layer are prevented, $Z_{N\,max} = 2.6$ for materials with homogenous structure (refined, volume-quenched) and $Z_{N\,max} = 1.8$ for case-hardened materials (quenching by means of high-frequency current, cementing, nitrocementing, and nitriding).
The factor Z_R, which takes into account the *roughness influence* of the mated teeth surfaces, is specified for the gear wheel pair with a rougher surface depending on the parameter Ra of roughness ($Z_R = 1$–0.9). Higher values of this parameter correspond to grinding finishes and polished faces ($Ra = 0.63$–$1.25\,\mu m$).

The factor Z_V takes the circumferential velocity v influence into consideration

$$Z_V = 0.85v^{0.1} \ge 1, \qquad \text{by } H \le 350\,HB\,;$$
$$Z_V = 0.925v^{0.05} \ge 1, \qquad \text{by } H > 350\,HB\,.$$

The allowable stress $[\sigma]_H$ for cylindrical gearings with straight teeth is the lowest of the allowable stresses of the pinion $[\sigma]_{H1}$ and the wheel $[\sigma]_{H2}$.

For cylindrical gearings with indirect teeth, because the contact line is at an angle to the pitch line, allowable stresses can be increased up to the value of

$$[\sigma]_H = \sqrt{0.5\left([\sigma]_{H1}^2 + [\sigma]_{H2}^2\right)}\,,$$

under the operating condition $[\sigma]_H \le 1.2[\sigma]_{H\,min}$, where $[\sigma]_{H\,min}$ is the lowest of $[\sigma]_{H1}$ and $[\sigma]_{H2}$.

The allowable stress for bevel gearings with straight and indirect teeth is the lowest of allowable stresses of the pinion $[\sigma]_{H1}$ and the wheel $[\sigma]_{H2}$.

3. The allowable bending stress of the teeth of the pinion $[\sigma]_{F1}$ and the wheel $[\sigma]_{F2}$ is determined from the total relation, but with substitution of the appropriate parameters for the pinion and the wheel, respectively

$$[\sigma]_F = \sigma_{F\,lim} Y_N Y_R Y_A / S_F\,.$$

The fatigue point $\sigma_{F\,lim}$ with the zero-to-tension stress cycle is taken according to Table 6.5.

The minimum values of the load factors for cemented and nitrocemented gear wheels are $S_F = 1.55$ and for the rest of the gear wheels $S_F = 1.7$. The service life ratio Y_N considers the lifetime influence

$$Y_N = \sqrt[q]{N_{F\,lim}/N_{FE}}\,,$$

under the condition that $1 \le Y_N \le Y_{N\,max}$, where $Y_{N\,max} = 4$ and $q = 6$ for refined gear wheels, and $Y_{N\,max} = 2.5$ and $q = 9$ for quenched and case-hardened teeth. The cycle number corresponding to the change of the stress-cycle diagram $N_{F\,lim} = 4 \times 10^6$.

The equivalent number of loading cycles is given by

$$N_{FE} = \mu_F N_k\,.$$

The values of the equivalence factor μ_F for typical loading conditions are given in Table 6.4. The assigned life N_k is calculated just as in contact stress analysis.

The factor Y_R considers the roughness influence of the tooth space and is taken to be $Y_R = 1$ in the case of grinding, and gear milling with roughness parameter $Rz \le 40\,\mu m$; whereas $Y_R = 1.05–1.2$ in

the case of polishing (large values are obtained by refining and after quenching with heating by means of high-frequency currents).
The factor Y_A takes the influence of double-sided load application (reversing gears) into account. For one-sided load application $Y_A = 1$. For reverse loading and an equal load and number of loading cycles in the forward and backward direction (e.g., the teeth of the satellite in planetary gearing) $Y_A = 0.65$ for normalized and refined steels, $Y_A = 0.75$ for hardened and cemented steel, and $Y_A = 0.9$ for nitrided steel.

4. The tentative value of the axle base is a'_w (mm)

$$a'_w = K\,(u \pm 1)\,\sqrt[3]{T_1/u}\,,$$

where the plus sign applies for external toothing, and the minus sign applies for internal toothing. T_1 is the torque on the pinion (the highest of long-acting), in N m, and u is the gear ratio.
The factor K, which depends on the surface hardnesses H_1 and H_2 of the teeth of the pinion and the wheel, respectively, takes the following values:

Table 6.7 Coefficient K for the cylindrical gearings

Hardness H		Factor K
$H_1 \le 350$ HB	$H_2 \le 350$ HB	10
$H_1 \ge 45$ HRC	$H_2 \le 350$ HB	8
$H_1 \ge 45$ HRC	$H_2 \ge 45$ HRC	6

The circumferential velocity v (m/s) is determined from the formula

$$v = \frac{2\pi a'_w n_1}{6\times 10^4\,(u \pm 1)}\,.$$

The accuracy degree is taken from Table 6.6.
The previously determined value of the axle base is specified according to the formula

$$a_w = K_a\,(u \pm 1)\,\sqrt[3]{\frac{K_H T_1}{\psi_{ba} u [\sigma]_H^2}}\,,$$

where $K_a = 450$ applies for spurs and $K_a = 410$ applies for helical and herring-bone gears $(\mathrm{N/mm^2})^{1/3}$; and $[\sigma]_H$ is in $\mathrm{N/mm^2}$. ψ_{ba} is a width ratio taken from the sequence of standard numbers: 0.1, 0.125, 0.16, 0.2, 0.25, 0.315, 0.4, 0.5, and 0.63 depending on the wheel position relative to the bearings. Its value is as follows

$$\begin{cases} 0.315\text{–}0.5 & \text{symmetrical arrangement} \\ 0.25\text{–}0.4 & \text{unsymmetrical arrangement} \\ 0.2\text{–}0.25 & \text{console arrangement of one or both wheels} \end{cases}.$$

For herring-bone gearings $\psi_{ba} = 0.4\text{–}0.63$, for gear-boxes $\psi_{ba} = 0.1\text{–}0.2$, and for gearings of internal toothing $\psi_{ba} = 0.2(u+1)/(u-1)$. Lower values ψ_{ba} are obtained for gearings with teeth hardness $H \ge 45$ HRC.

The load factor in contact strength calculations is

$$K_H = K_{HV} K_{H\beta} K_{H\alpha}\,.$$

The factor K_{HV} takes the internal dynamics of the loading into consideration. The values K_{HV} are taken from Table 6.8 and depend on the accuracy degree of the gearing according to the smoothness standards, the circumferential velocity, and the hardness of the working surfaces.
The factor $K_{H\beta}$ takes the unevenness of the load distribution along the length of the contact lines into account. The teeth of the gear wheels can grind, and thus the unbalance factors are considered during *the initial working period* $K^0_{H\beta}$ and *after grinding* $K_{H\beta}$.
Values of the factor $K^0_{H\beta}$ are taken from Table 6.9 and depend on the coefficient $\psi_{bd} = b_2/d_1$, the gearing layout, and the teeth hardness. As the wheel width and pinion diameter have not yet been determined, the value of the coefficient ψ_{bd} is calculated approximately as

$$\psi_{bd} = 0.5\psi_{ba}(u \pm 1)\,.$$

The factor $K_{H\beta}$ is determined from the formula

$$K_{H\beta} = 1 + \left(K^0_{H\beta} - 1\right) K_{Hw}\,,$$

where K_{Hw} is the factor taking into account teeth grinding; its values are computed depending on the circumferential velocity of the gear wheel with lower hardness (Table 6.10).
The factor $K_{H\alpha}$, which takes into consideration the load distribution between the teeth, is determined from the formula

$$K_{H\alpha} = 1 + \left(K^0_{H\alpha} - 1\right) K_{Hw}\,,$$

where K_{Hw} is the factor considering teeth grinding; its values are found depending on the circumferential

velocity of the gear wheel with the lower hardness (Table 6.10).

The value of the factor $K^0_{H\alpha}$ is determined depending on the accuracy degree ($n_{ac} = 5, 6, 7, 8, 9$) according to *smoothness standards*:

- For spur gears $K^0_{H\alpha} = 1$
- For helical gearings $K^0_{H\alpha} = 1 + A(n_{ac} - 5)$

where $A = 0.12$ for gear wheels with hardness H_1 and $H_2 > 350$ HB, and $A = 0.06$ for H_1 and $H_2 \leq 350$ HB or $H_1 > 350$ HB, and $H_2 \leq 350$ HB.

In the case of large-scale manufacture of reduction gears the computed value a_w is approximated to the nearest standard value: 50, 63, 71, 80, 90, 100, 112, 125, 140, 160, 180, 200, 224, 250, 260, 280, 300, 320, 340, 360, 380, and 400 mm.

5. The preliminary basic wheel dimensions are:
   - Pitch diameter $d_2 = 2a_w u/(u \pm 1)$
   - Width $b_2 = \psi_{ba} a_w$
6. The gear module. The maximum allowed module m_{max} (mm) is determined from the condition of no teeth undercutting at the root

$$m_{max} \approx 2a_w/[17(u \pm 1)] .$$

The minimum value of the module m_{min} (mm) is determined from the strength condition

$$m_{min} = \frac{K_m K_F T_1 (u \pm 1)}{a_w b_2 [\sigma]_F} ,$$

where $K_m = 3.4 \times 10^3$ for spur gears and $K_m = 2.8 \times 10^3$ for helical gears, and instead of $[\sigma]_F$ the lowest of the values of $[\sigma]_{F2}$ and $[\sigma]_{F1}$ is substituted.

The load factor in the bending stress analysis is

$$K_F = K_{FV} K_{F\beta} K_{F\alpha} .$$

The factor K_{FV} takes the internal loading dynamics into account. The values of K_{FV} are taken from Table 6.12 and depend on the accuracy degree according to the smoothness standards, the circumferential velocity, and the hardness of the working surfaces. The coefficient $K_{F\beta}$, which considers the unevenness of the stress distribution at the teeth root along the face width, is evaluated in accordance with

$$K_{F\beta} = 0.18 + 0.82 K^0_{H\beta} .$$

The coefficient $K_{F\alpha}$, which considers the influence of manufacturing errors in the pinion and the wheel on the load distribution between the teeth, is determined in the same way as in contact strength analysis: $K_{F\alpha} = K^0_{H\alpha}$.

From the given range (m_{min}–m_{max}) of the modules the lowest value m is taken, adjusting it with stan-

7. The total teeth number and helix angle. The minimum tilt teeth angle of helical wheels amounts to

$$\beta_{\min} = \arcsin(3.45m/b_2)\,,$$

for herring-bone gears $\beta_{\min} = 25°$. The total number of the teeth becomes

$$z_\Sigma = 2a_w \cos\beta_{\min}/m\,.$$

The obtained value of z_Σ is rounded down to a whole number and the real value of the tilt tooth angle β is given by

$$\beta = \arccos[z_\Sigma m/(2a_w)]\,.$$

For helical gears $\beta = 8{-}20°$ whereas for herring-bone gears $\beta = 25{-}40°$.

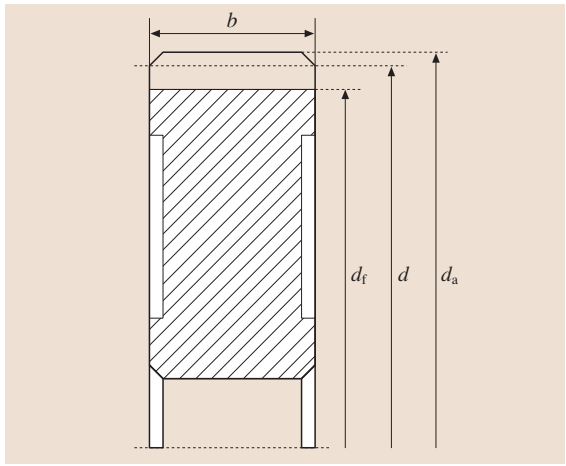

Fig. 6.38 Main diameters of the wheel

8. The teeth number of the wheel and pinion. The teeth number of the pinion is yielded as

$$z_1 = z_\Sigma/(u \pm 1) \geq z_{1\,\min}\,.$$

The value z_1 is rounded up to a whole number. For spurs $z_{1\,\min} = 17$, whereas for helical and herring-bone gears $z_{1\,\min} = 17\cos^3\beta$.
For $z_1 < 17$ the gearing is made with shifting to avoid teeth undercutting and to increase their breaking strength. The coefficient of displacement is

$$x_1 = (17 - z_1)/17 \leq 0.6\,.$$

For wheels with external toothing $x_2 = -x_1$, whereas for wheels with internal toothing $x_2 = x_1$. The teeth number of wheels with external toothing becomes $z_2 = z_\Sigma - z_1$, whereas the teeth number of wheels with internal toothing becomes $z_2 = z_\Sigma + z_1$.

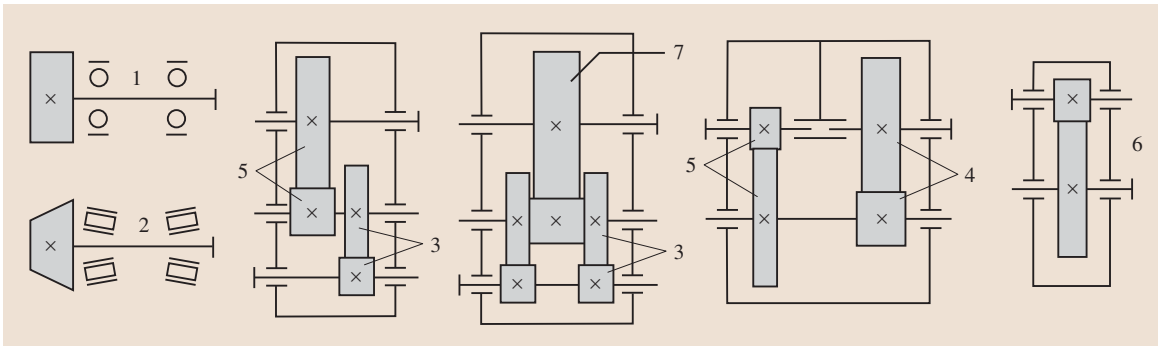

Fig. 6.37 Principal diagrams of reduction gears

9. The actual gear ratio. The actual gear ratio is $u_r = z_2/z_1$. The actual value of the gear ratio should not differ from the nominal ones by more than 3% for single-reduction units, by 4% for double-reduction units, and by 5% for multistage reduction units.
10. Wheel diameters (Fig. 6.38)
Pitch diameters d:

of the pinion $d_1 = z_1 m/\cos\beta$,
of the wheel with external toothing $d_2 = 2a_w - d_1$,
of the wheel with internal toothing $d_2 = 2a_w + d_1$.

Table 6.13 Formulas for calculation of the pitch diameters d

Wheel type	Calculating formulas
Pinion	$d_1 = z_1 m/\cos\beta$
Externally toothing wheel	$d_2 = 2a_w - d_1$
Internal toothing wheel	$d_2 = 2a_w + d_1$

The diameters d_a and d_f of the addendum circles and dedendum circles of the wheel teeth are:

– With external toothing

$$d_{a1} = d_1 + 2(1 + x_1 - y)m\ ;$$
$$d_{f1} = d_1 - 2(1.25 - x_1)m\ ;$$
$$d_{a2} = d_2 + 2(1 + x_2 - y)m\ ;$$
$$d_{f2} = d_2 - 2(1.25 - x_2)m\ ;$$

– With internal toothing

$$d_{a1} = d_1 + 2(1 + x_1)m\ ;$$
$$d_{f1} = d_1 - 2(1.25 - x_1)m\ ;$$
$$d_{a2} = d_2 - 2(1 - x_2 - 0.2)m\ ;$$
$$d_{f2} = d_2 + 2(1.25 + x_2)m\ ,$$

where x_1 and x_2 are coefficients of displacement of the pinion and the wheel, respectively, $y = -(a_w - a)/m$ is a coefficient of effective addendum modification, and a (the pitch center-to-center distance) is $a = 0.5\,m\,(z_2 \pm z_1)$.

11. Blank part dimensions
To obtain acceptable mechanical characteristics of the wheel material during heat treatment, the calculation requires that uncut dimensions of the wheels D_{blank}, C_{blank}, S_{blank} do not exceed the maximum allowable values D_{max}, S_{max} (Table 6.1)

$$D_{blank} \le D_{max}\ ;$$
$$C_{blank} \le S_{max} \quad \text{or}$$
$$S_{blank} \le S_{max}\ .$$

The values D_{blank}, C_{blank}, and S_{blank} (mm) are determined from the following formulas: for spur pinions (Fig. 6.39a) $D_{blank} = d_a + 6$ mm; for bevel pinion (Fig. 6.39b) $D_{blank} = d_{ae} + 6$ mm; for wheels with recesses (Fig. 6.39c) $C_{blank} = 0.5 b_2$ and $S_{blank} = 8$ m; and for wheels without recesses (Fig. 6.38) $S_{blank} = b_2 + 4$ mm.

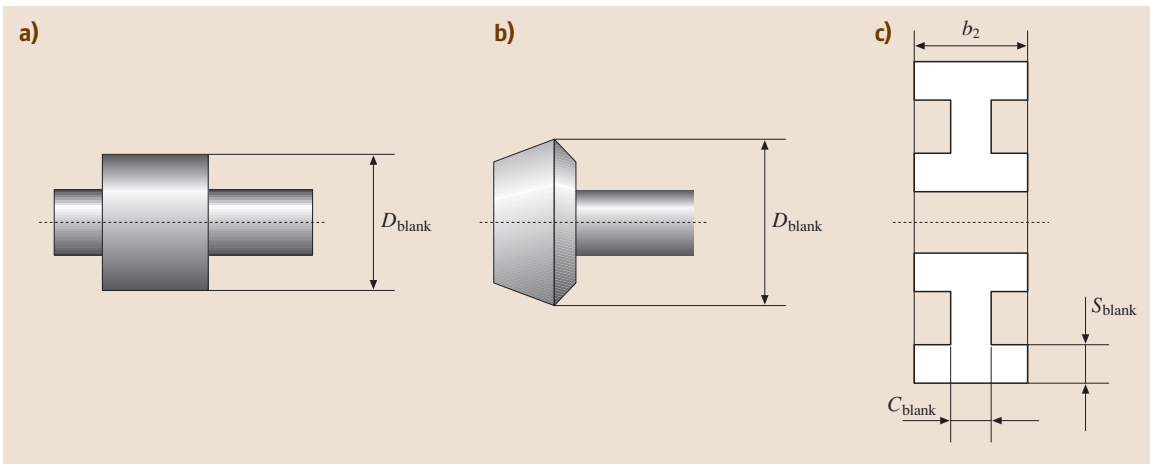

Fig. 6.39a–c Dimensions of the workpieces: (a) for a spur pinion, (b) for a bevel pinion, and (c) for a wheel with necks

Nonfulfillment of these inequalities means that the material of the details and the heat treatment method must be changed.

12. Contact stress testing of wheel teeth
The calculated value of the contact stress is determined from (6.6). If the calculated stress σ_H is lower than the allowable stress $[\sigma]_H$ by 15–20%, or if σ_H is higher than $[\sigma]_H$ by 5% or less, then the earlier accepted parameters of the gearing are taken as final. Otherwise recalculation is required.
13. Forces in toothing (Fig. 6.29) are given by

$$\textit{peripheral } F_t = 2\times 10^3 T_1/d_1 \ ;$$
$$\textit{radial } F_r = F_t \tan\alpha/\cos\beta \ ,$$
$$(\text{for the standard angle } \alpha = 20^\circ \ \tan\alpha = 0.364) \ ;$$
$$\textit{axial } F_a = F_t \tan\beta \ .$$

14. Bending stress testing of wheel teeth
The calculated bending stress in the wheel teeth is

$$\sigma_{F2} = \frac{K_F F_t}{b_2 m} Y_{FS2} Y_\beta Y_\varepsilon \le [\sigma]_{F2} \ ,$$

and in the pinion teeth

$$\sigma_{F1} = \sigma_{F2} Y_{FS1}/Y_{FS2} \le [\sigma]_{F1} \ .$$

The value of the coefficient Y_{FS} takes into account the form of the tooth and stress concentration depending on the reduced number $z_v = z/\cos^3\beta$ of the teeth. The coefficient x of the displacement for external toothing is taken according to Table 6.14.

For internal toothing it is as follows:

Table 6.15 Coefficient Y_{FS} for internally toothing

z	Y_{FS}
40	4.02
50	3.88
63	3.80
71	3.75

The value of the coefficient Y_β, which considers the tilt angle of the tooth in *helical* gearings, is determined from (β in degrees)

$$Y_\beta = 1 - \varepsilon_\beta \beta/120 \ ,$$

under the condition that $Y_\beta \ge 0.7$. Y_ε is a coefficient that takes teeth overlap into account.
For spur gears $Y_\beta = 1$; $Y_\varepsilon = 1$ in the case of accuracy degrees 8 or 9; $Y_\varepsilon = 0.8$ applies for accuracy degrees 5–7. For helical gearings one has $Y_\varepsilon = 0.65$.

15. Checking strength calculation of teeth under peak load
The aim of this calculation is prevention of residual strains or brittle fracture of the surface layer or the teeth under the action of the maximum torque T_{max}.
The action of peak loads is evaluated by means of the overload factor $K_{load} = T_{max}/T$, where T is the nominal torque.
For prevention of residual strains or brittle fracture of the surface layer the contact stress $\sigma_{H\,max}$ must not exceed the allowable stress $[\sigma]_{H\,max}$

$$\sigma_{H\,max} = \sigma_H \sqrt{K_{load}} \le [\sigma]_{H\,max} \ ,$$

where σ_H is the contact stress under the action of the nominal torque T.

The allowable stress $[\sigma]_{\mathrm{H\,max}}$ for refining or through quenching is taken to be $[\sigma]_{\mathrm{H\,max}} = 2.8\sigma_y$, for cementing or induction hardening current it is $[\sigma]_{\mathrm{H\,max}} = 44\,\mathrm{HRC_m}$, and for nitriding it is $[\sigma]_{\mathrm{H\,max}} \approx 35\,\mathrm{HRC_m} \leq 2000\,\mathrm{N/mm^2}$.
For the prevention of residual strains and brittle fracture of the teeth the bending stress $\sigma_{\mathrm{F\,max}}$ under the action of the maximum torque must not exceed the allowable value of $[\sigma]_{\mathrm{F\,max}}$, i.e.,

$$\sigma_{\mathrm{F\,max}} = \sigma_{\mathrm{F}} K_{\mathrm{load}} \leq [\sigma]_{\mathrm{F\,max}} ,$$

where σ_{F} is the bending stress determined from the fatigue strength calculations. Testing is carried out separately for the pinion and the wheel. The allowable limit stress of the bending is computed depending on the heat treatment method applied and the potential application frequency of the peak load

$$[\sigma]_{\mathrm{F\,max}} = \sigma_{\mathrm{F\,lim}} Y_{\mathrm{N\,max}} k_{\mathrm{st}} / S_{\mathrm{st}} ,$$

where $\sigma_{\mathrm{F\,lim}}$ is the fatigue bending point. $Y_{\mathrm{N\,max}} = 4$ for steel with volume heat treatment (normalization, refining, and volume quenching). $Y_{\mathrm{N\,max}} = 2.5$ for steel with surface treatment (quenching with heating by means of high-frequency currents, cementing, nitrocementing, and nitriding). k_{st} is a coefficient that captures the influence of the frequency of the peak load application; in the case of single overloads ($\leq 10^3$) $k_{\mathrm{st}} = 1.2$–1.3 are high values for volume heat treatment; under repeated ($> 10^3$) overload action $k_{\mathrm{st}} = 1$. S_{st} is a load factor; usually $S_{\mathrm{st}} = 1.75$.

6.4 Bevel Gearings

6.4.1 Basic Considerations

Bevel gearings are used for the transmission of mechanical energy between shafts with intersecting axes. *Right-angle gears* (with angle $\Sigma = 90°$) are the most common (Fig. 6.40). As has been noted bevel wheels can have *straight* or *circular* teeth.

The tooth lines in bevel wheels with circular teeth are circular arcs. Gearings with straight teeth have initial *linear contact*, and those with circular teeth have *point contact* in the toothing. The tilt angle β_n of the tooth line is determined in the average section along the face width. For gearings with straight teeth $\beta_n = 0$; for those with circular teeth $\beta_n = 35°$. The tilt of the tooth line increases the operating smoothness, and the contact and bending strengths, but also increases the load on the bearings and shafts. Bevel wheels with circular teeth as compared with spurs have a higher load-carrying ability, and operate smoothly and with less noise. When, the total contact ratio $\varepsilon_\gamma = \sqrt{\varepsilon_\alpha^2 + \varepsilon_\beta^2}$, is more than two, not less than two tooth pairs of teeth are constantly operating.

In order to increase the wear and sliding strength of teeth, specific slips in the boundary points of the toothing are adjusted by means of shifting of the initial contour. The pinion is made with positive shifting, and the wheel with negative shifting of the same absolute value.

The analog of the pitch cylinder of cylindrical gearings for bevel gearings are pitch cones that are coincident with the initial cones. When the wheels rotate, pitch cones move against one another without slip. Bevel gearings should be adjusted to achieve coincidence of the pitch cone points of the wheels. The angle Σ between the axes of the gearings equals the angular sum of the pitch cones $\Sigma = \delta_1 + \delta_2$ (Fig. 6.40).

The advantage of bevel gearings is their ability to transmit mechanical power between shafts with inter-

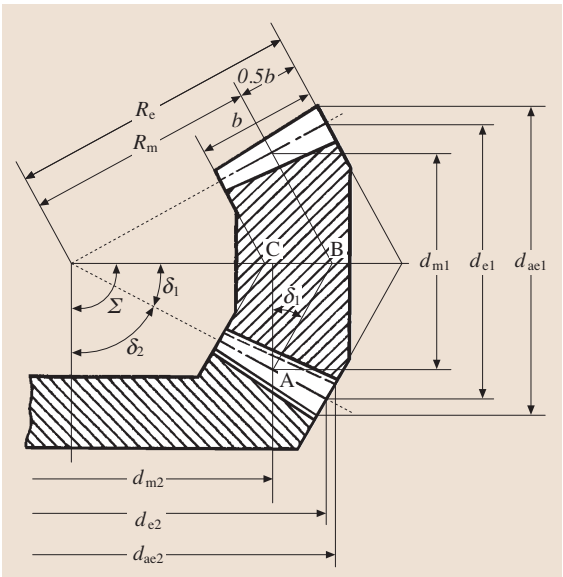

Fig. 6.40 Geometry of a bevel wheel

secting axes. Their disadvantages are the necessity for adjustment of the gearing (the pitch cone points must coincide), as well as their lower load-carrying capacity and greater manufacture complexity as compared with cylindrical gearings.

The external and internal ends of bevel wheels form external and internal *extra cones*, of which the generating lines are perpendicular to the generating line of the pitch cone. The mean extra cone is positioned an equal distance from the external and internal extra cones. The face width b of the gear wheel is limited by two extra cones – external and internal. The length of the generating line from its point to its external end is called the *external cone distance* R_e, and the length to the middle of the face width is called the *average cone distance* R_m (Fig. 6.40). The intersections of the pitch cone with extra cones determine the diameters of the pitch circles of the bevel wheel, and distinguish the external d_e, internal d_i, and mean d_m pitch diameters.

According to Fig. 6.40 the gear ratio becomes

$$u = d_{e2}/d_{e1} = d_{m2}/d_{m1} = \tan\delta_2 = 1/\tan\delta_1 = z_2/z_1 ,$$

where d_{e1}, d_{e2}, d_{m1}, d_{m2}, and δ_1, δ_2 are, respectively, the external and mean pitch diameters, and pitch cone angles, of the pinion (subscript "1") and the wheel (subscript "2"). For bevel spur gears $u = 2–3$ is recommended, whereas for wheels where the circular teeth u has a value as high as 6.3.

6.4.2 The Axial Tooth Form

The teeth of bevel wheels depend on dimensional changes of their normal sections along their length and are made of three axial forms (Fig. 6.41)

Axial Form I – Normally Reducing Teeth (Fig. 6.41a)

In this form, the pitch cone and dedendum cone points coincide, and the root is proportionate to the cone radius. This is used for straight teeth as well as in restricted cases for circular teeth with $m \geq 2$ mm and $\sqrt{z_1^2 + z_2^2} = 20–100$.

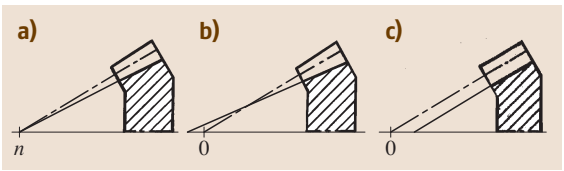

Fig. 6.41a–c Axial tooth form of the bevel wheel: **(a)** normally lowered (I), **(b)** normally narrowed (II), and **(c)** uniformly high (III)

Axial Form II – Normally Convergent Teeth (Fig. 6.41b)

In this form, the dedendum cone point is positioned so that the bottom land width is constant and the tooth thickness along the pitch cone is proportionate to the cone radius. This form provides the optimal bending strength in all sections, allows both surfaces of the gear wheels to be treated with one tool at once, and thus increases productivity in the gear cutting. This form is the basic one used for wheels with circular teeth and is used in mass production.

Axial Form III – Teeth of Equal Depth (Fig. 6.41c)

In this form, the generating lines of the pitch cone, the dedendum cone, and the addendum cone are parallel. The teeth depth is constant along the whole length. This is used for nonorthogonal gearings with axis angle $\Sigma < 40°$ and circular teeth with $\sqrt{z_1^2 + z_2^2} \geq 60$.

6.4.3 Basic Geometric Proportions

In bevel wheels with axial forms I and II the tooth depth and therefore the toothing module increase from the internal cone to the external extra cone (Figs. 6.40 and 6.41). For measurement convenience it is customary to define the dimensions of bevel wheels according to the external tooth end. The maximum teeth module – the exterior peripheral module m_{te} – is received on the external wheel end. The basic geometric proportions for bevel gearings are listed below (Fig. 6.40).

The outer pitch diameters of the pinion and the wheel are

$$d_{e1} = m_{te} z_1; \quad d_{e2} = m_{te} z_2 .$$

The outer cone radius is

$$R_e = \sqrt{(0.5 d_{e1})^2 + (0.5 d_{e2})^2} = 0.5 d_{e1}\sqrt{1+u^2} .$$

The face width is $b = K_{be} R_e$. For most bevel gearings the face width coefficient is $K_{be} = 0.285$. Then

$$b = 0.285 \times 0.5 d_{e1}\sqrt{1+u^2} = 0.143 d_{e1}\sqrt{1+u^2} .$$

The average cone radius then becomes

$$R_m = R_e - 0.5b = R_e - 0.5 \times 0.285 R_e = 0.857 R_e .$$

From the similarity condition (Fig. 6.40) it follows that $d_{e1}/R_e = d_{m1}/R_m$. Then the mean pitch diameter of the

pinion becomes

$$d_{m1} = d_{e1} R_m / R_e = 0.857 d_{e1} .$$

The peripheral module in the mean section $m_{tm} = 0.857 m_{te}$. The normal module in the mean section for the circular tooth ($\beta_n = 35°$) is

$$m_n = m_{tm} \cos \beta_n \approx 0.702 m_{te} .$$

The pitch cone angles are

$$\tan \delta_1 = z_1 / z_2 = 1/u; \quad \delta_2 = 90° - \delta_1 .$$

The external peripheral module m_{te} is taken as a rated module for bevel wheels with straight teeth; the mean normal module m_n is taken for bevel wheels with circular teeth in the middle of the gear ring.

The teeth of the bevel wheels with modules that change over a certain continuous range can be cut with the same gear-shaping cutter head. Thus, rogue values of the module can be used.

6.4.4 Equivalent Cylindrical Wheels

For the spur, the gear teeth profiles of the bevel wheel on the middle extra cone (Fig. 6.42) are similar to the teeth

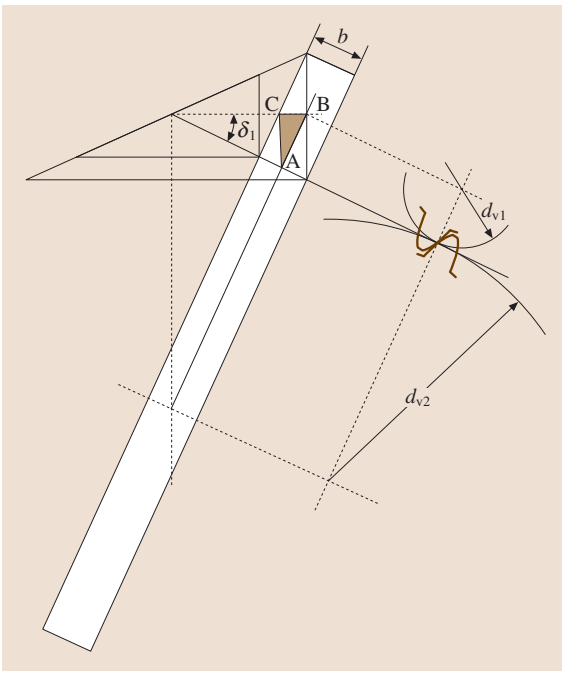

Fig. 6.42 Reduction of the bevel wheel to the equivalent spur

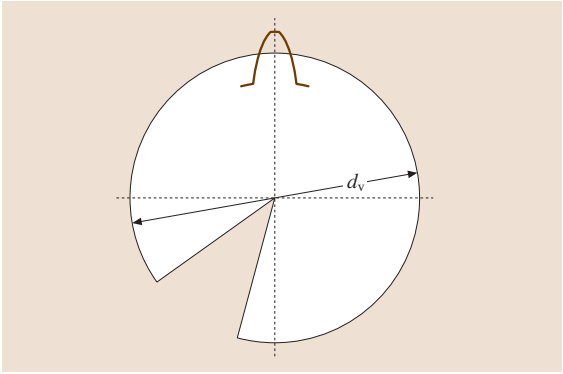

Fig. 6.43 Development of the middle additional cone on the plane

profiles of a spur gear with pitch diameter d_v. By adding an extra middle cone on the plane (Fig. 6.43) up to the whole cycle, we obtain an equivalent cylindrical wheel with teeth number z_v and pitch diameter $d_v = m_n z_v$. After consideration of the triangle ABC (Fig. 6.42) we can obtain a relation between the pitch diameters d_v and d_m

$$d_v = d_m / \cos \delta = m_n z / \cos \delta .$$

From the equality $m_n z_v = m_n z / \cos \delta$ a relation for the determination of the *equivalent teeth number* follows as

$$z_v = z / \cos \delta ,$$

i. e., the actual straight bevel gear with teeth number z in the strength analysis can be replaced with a cylindrical one with teeth number z_v.

For gearings with circular teeth, the teeth profiles of the bevel wheel in the normal section are similar to those of the equivalent spur gear. The equivalent teeth number z_{vn} is obtained by means of double reduction: of the bevel wheel to the cylindrical one, and of the circular tooth to the straight tooth, as follows

$$z_{vn} = z / \left(\cos \delta \cos^3 \beta_n \right) .$$

6.4.5 Toothing Forces

In the bevel gearing, the site of the force application F_n, which acts normal on the tooth surface, is considered to be the section in the middle of the face width.

For calculation for the shafts and bearings it is convenient for the force F_n to be represented in the form of its constituents F_t, F_r, and F_a.

The peripheral force F_t (N) on the pinion becomes

$$F_t = 2 \times 10^3 T_1 / d_{m1} ,$$

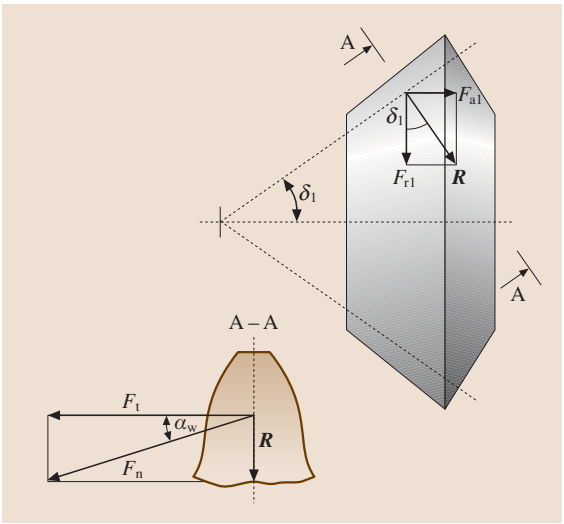

Fig. 6.44 Forces loading the bevel pinion

where T_1 is the torque (N m) and d_{m1} is the mean pitch diameter (in mm).

To determine the constituents for spur gears (Fig. 6.44), let us write the intermediate expression (where $\alpha_w = 20°$, the angle of action)

$$R = F_t \tan \alpha_w \, .$$

The radial force on the pinion is then

$$F_{r1} = R \cos \delta_1 = F_t \tan \alpha_w \cos \delta_1 \, .$$

The axial force on the pinion becomes

$$F_{a1} = R \sin \delta_1 = F_t \tan \alpha_w \sin \delta_1 \, .$$

The corresponding forces on the wheel equal (Fig. 6.45) are then $F_{r2} = F_{a1}$ and $F_{a2} = F_{r1}$. In gearings with circular teeth it is necessary to ensure that the axial force F_{a1} on the drive pinion is directed towards the base of the pitch cone. This, in order to avoid teeth seizing, caused by considerable gaps in the bearings. The rotation of the drive pinion (as seen from the direction of the vertex of the pitch cone) and the direction of the teeth helix angle must coincide. In Fig. 6.46 the pinion is rotating counterclockwise, i. e., to the left, and the tooth of the pinion is left tooth.

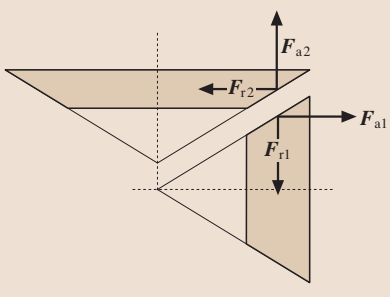

Fig. 6.45 Forces in the toothing of a bevel gearing

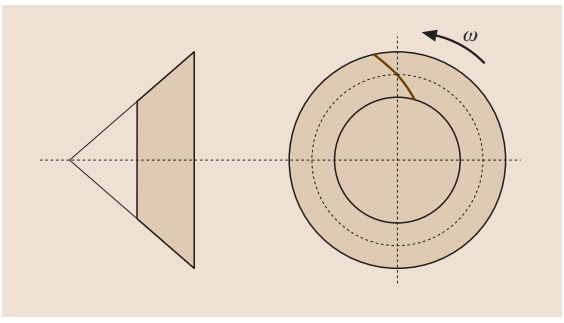

Fig. 6.46 Recommended direction of tooth dip for the drive pinion

If this condition is met, in gearings with circular teeth the radial force of the pinion is

$$F_{r1} = F_t(\tan \alpha_w \cos \delta_1 - \sin \beta_n \sin \delta_1)/\cos \beta_n \, .$$

The axial force on the pinion is

$$F_{a1} = F_t(\tan \alpha_w \sin \delta_1 + \sin \beta_n \cos \delta_1)/\cos \beta_n \, .$$

The signs in the formulas will be the same in the case of clockwise rotation of the drive pinion with the tooth on the right. The forces on the wheel equal, respectively, $F_{r2} = F_{a1}$ and $F_{a2} = F_{r1}$.

6.4.6 Contact Strength Analysis of Bevel Gearings

Strength analysis of bevel gearings is based on the assumption that the load-carrying capacity of the teeth of bevel wheels is the same as that of the equivalent cylindrical wheels with the same tooth length b and a profile corresponding to the middle extra cone (the mean tooth section).

Checking Analysis

Equation (6.6), expressed using the parameters of the equivalent cylindrical spur gear according to the mean extra cone (Fig. 6.40), is

$$\sigma_H = Z_E Z_H Z_\varepsilon \sqrt{\frac{K_H F_t}{b d_{v1}} \frac{(u_v + 1)}{u_v} \frac{1}{\vartheta_H}} \, , \qquad (6.8)$$

where ϑ_H is the ratio taking into consideration the influence of the gearing of the bevel wheel type (i.e., straight or circular teeth) on the load-carrying capacity.

The gear ratio of the equivalent cylindrical gearing is then

$$u_v = \frac{d_{v2}}{d_{v1}} = \frac{d_{m2}}{\cos\delta_2}\frac{\cos\delta_1}{d_{m1}} = \frac{u\cos\delta_1}{\cos\delta_2} .$$

Considering that $\cos\delta_1 = \sin\delta_2$ (Fig. 6.40) and $\tan\delta_2 = u$, we have

$$u_v = u\sin\delta_2/\cos\delta_2 = u^2 .$$

The diameter of the equivalent spur pinion is $d_{v1} = d_{m1}/\cos\delta_1$. Substituting the cosine function for the tangent function we obtain

$$\cos\delta_1 = 1/\sqrt{1+\tan^2\delta_1} .$$

Bearing in mind that $\tan\delta_1 = 1/u$ and $d_{m1} = 0.857d_{e1}$ we can write

$$d_{v1} = d_{m1}/\cos\delta_1 = d_{m1}\sqrt{1+\tan^2\delta_1}$$
$$= d_{m1}\sqrt{\left(u^2+1\right)/u^2} = 0.857d_{e1}\sqrt{1+u^2}/u .$$

Substituting the values u_v and d_{v1} into (6.8) and replacing $F_t = 2\times10^3 T_1/(0.857d_{e1})$, $b = 0.143d_{e1}\sqrt{1+u^2}$, subject to the strength condition $\sigma_H \le [\sigma]_H$ we obtain the formula for checking analysis of steel bevel gearings

$$\sigma_H = 6.7\times10^4\sqrt{\frac{K_H T_1}{d_{e1}^3 u\vartheta_H}} \le [\sigma]_H , \qquad (6.9)$$

where T_1 is in N m, d_{e1} is in mm, and σ_H and $[\sigma]_H$ are in N/mm^2. The load factor K_H for bevel gearings is $K_H = K_A K_{H\beta} K_{HV}$. The values of the ratio K_A are set in the same way as for cylindrical gearings. The factor $K_{H\beta}$ takes the unevenness of load distribution along the contact lines into account. K_{HV} considers internal dynamic load.

Checking Analysis

Having solved (6.9) relative to d_{e1} we obtain the checking analysis formula for steel bevel gearings as

$$d_{e1} = 1650\sqrt[3]{\frac{K_H T_1}{u[\sigma]_H^2\vartheta_H}} ,$$

where d_{e1} is an outer pitch diameter of the pinion (mm), T_1 is in N m, and $[\sigma]_H$ is in N/mm^2.

6.4.7 Calculation of the Bending Strength of Bevel Gearing Teeth

Similarly as for straight cylindrical gearings, the bending strength condition is checked for the teeth of the pinion and the wheel

$$\sigma_{F1} = \frac{K_F F_t Y_{FS1}}{b m_n \vartheta_F} \le [\sigma]_{F1} ;$$
$$\sigma_{F2} = \frac{Y_{FS2}}{Y_{FS1}}\sigma_{F1} \le [\sigma]_{F2} ,$$

where K_F is the load factor, m_n is the normal module in the mean section of the bevel wheel, Y_{FS} is the ratio of the tooth form and stress concentration of the equivalent wheel [Y_{FS} is chosen according to z_v (z_{vn})], and ϑ_F is the ratio that takes into account the influence of the bevel-wheel gearing on the load-carrying capacity.

The load factor K_F for bevel gearings is

$$K_F = K_A K_{F\beta} K_{FV} .$$

The values of the coefficient K_A are obtained in the same way as for the cylindrical gearings. $K_{F\beta}$ is the ratio that considers the unevenness of the stress distribution at the teeth root along the face width, and K_{FV} is a coefficient for the internal dynamic load. The choice of the allowable stresses $[\sigma]_{F1}$ and $[\sigma]_{F2}$ was explained above.

6.4.8 Projection Calculation for Bevel Gearings

The following basic data are considered: T_1 (the torque on the pinion measured in N m), typical loading conditions, n_1 (the rotational frequency of the pinion measured in min^{-1}), u (the gear ratio), L_h (the operation time of the gearing, i.e., the lifetime, measured in hours), and the gearing layout, and gear wheel type. The choice of materials, heat treatment method, and the determination of the allowable stresses are given in Sect. 6.3.7.

Diameter of the Outer Pitch Circle of the Pinion

The tentative value of the outer pitch circle diameter of the pinion (mm) is

$$d'_{e1} = K\sqrt[3]{\frac{T_1}{u\vartheta_H}} ,$$

where T_1 is the torque on the pinion (N m) and u is the gear ratio. The factor K, which depends on the surface hardnesses H_1 and H_2 of the teeth of the pinion and the wheel, have the following values, respectively:

Table 6.16 Coefficient K for the bevel gearings

Hardness H		Factor K
$H_1 \le 350$ HB	$H_2 \le 350$ HB	30
$H_1 \ge 45$ HRC	$H_2 \le 350$ HB	25
$H_1 \ge 45$ HRC	$H_2 \ge 45$ HRC	22

The values of the factor ϑ_H are taken as:

- For straight bevel gearings $\vartheta_H = 0.85$
- For gearings with circular teeth, according to Table 6.17

The circumferential velocity v_m (m/s) at the mean pitch diameter is determined from (with $K_{be} = 0.285$)

$$v_m = \pi 0.857 d'_{e1} n_1 / (6 \times 10^4) .$$

The accuracy degree is specified depending on circumferential velocity. Straight bevel gears are used with circumferential velocities up to 5 m/s; the accuracy degree is not lower than 7. Bevel wheels with circular teeth with a circumferential velocity of up to 5 m/s are made with an accuracy degree of not lower than 8; with $v_m = 5$–10 m/s it is not lower than 7.

The previously determined diameter value of the outer pitch circle of the pinion is made more precise (in mm) using

$$d_{e1} = 1650 \sqrt[3]{\frac{K_{HV} K_{H\beta} T_1}{u \vartheta_H [\sigma]_H^2}} .$$

The factor K_{HV} of the internal dynamic load for *straight* bevel wheels is chosen from Table 6.8, conditionally taking their accuracy lower than actual the by one degree; i. e., instead of the actual accuracy degree 7 an accuracy degree of 8 is used for the factor K_{HV}. For bevel wheels with *circular teeth* the value of K_{HV} is taken from Table 6.8 as for helical wheels. The factor $K_{H\beta}$ considers the unevenness of the load distribution along the contact lines. In bevel gearings *the pinion is set as a cantilever*. In order to increase the rigidity of the bearing, the shafts are mounted *on tapered roller bearings*.

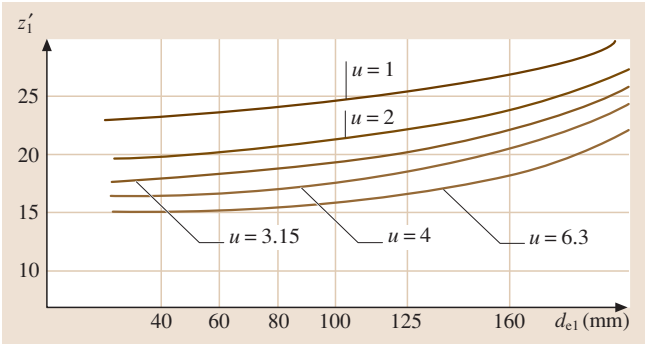

Fig. 6.47 Determination of the tooth number of a bevel pinion with straight teeth

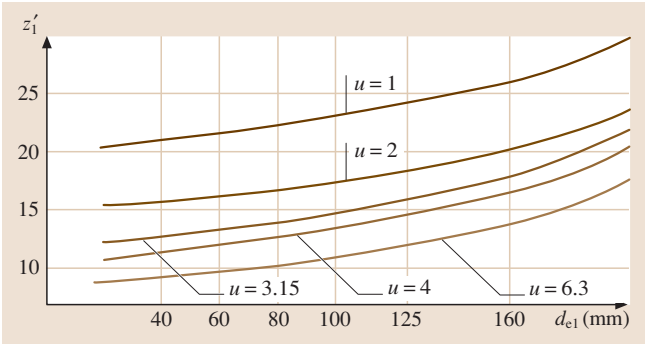

Fig. 6.48 Determination of the tooth number of a bevel pinion with circular teeth

For bevel wheels

with circular teeth $K_{H\beta} = \sqrt{K^0_{H\beta}}$,

on condition that $K_{H\beta} \ge 1.2$,

with straight teeth $K_{H\beta} = K^0_{H\beta}$.

The factor $K^0_{H\beta}$ is taken from Table 6.9 for cylindrical gearings, depending on the ratio $\psi_{bd} = b/d_{e1}$, the hardness of the gear wheels, and the gearing position relative to the bearings. As the face width and pinion diameter have not yet been determined, the value of the factor

Table 6.17 Coefficients ϑ_H and ϑ_F for bevel gearings with circular teeth

Hardness of the gear wheels		Values	
		ϑ_H	ϑ_F
$H_1 \le 350$ HB	$H_2 \le 350$ HB	$1.22 + 0.21u$	$0.94 + 0.08u$
$H_1 \ge 45$ HRC	$H_2 \le 350$ HB	$1.13 + 0.13u$	$0.85 + 0.04u$
$H_1 \ge 45$ HRC	$H_2 \ge 45$ HRC	$0.81 + 0.15u$	$0.65 + 0.11u$

ψ_{bd} is computed approximately from

$$\psi_{bd} = 0.166\sqrt{u^2+1}\,.$$

Cone Radius and Face Width

The angle of the pitch pinion cone is

$$\delta_1 = \arctan(1/u)\,.$$

The external cone distance is $R_e = d_{e1}/(2\sin\delta_1)$ and the face width is $b = 0.285R_e$.

The Gearing Module

The exterior end module of the gearing (m_e for bevel wheels with straight teeth, m_{te} for wheels with circular teeth) is

$$m_e\,(m_{te}) \geq \frac{14K_{FV}K_{F\beta}T_1}{d_{e1}b\vartheta_F[\sigma]_F}\,.$$

The value of the internal dynamic load factor K_{FV} for straight bevel wheels is chosen from Table 6.12, conditionally taking their accuracy as one degree rougher than the actual degree. For bevel wheels with circular teeth the value of K_{FV} is taken from Table 6.12, as for helical wheels.

The factor $K_{F\beta}$ takes the unevenness of the stress distribution at the teeth root along the face width into account. For bevel gearings with straight teeth one has $K_{F\beta} = K'_{F\beta}$; for wheels with circular teeth one uses

$$K_{F\beta} = \sqrt{K'_{F\beta}}\,,$$

on the condition that $K_{F\beta} \geq 1.15$, where $K'_{F\beta} = 0.18 + 0.82K^0_{H\beta}$. For spurs the coefficient ϑ_F is taken equal to 0.85 and for wheels with circular teeth it is taken from Table 6.17. Instead of $[\sigma]_F$ the lesser of $[\sigma]_{F1}$ and $[\sigma]_{F2}$ is substituted into the design formula. Rounding off of the computed module value to the standard value can be ignored.

Teeth Number of the Pinion and the Wheel

For the pinion with straight teeth one has $z_1 = d_{e1}/m_e$, whereas with circular teeth one has $z_1 = d_{e1}/m_{te}$.

The teeth number of the wheel is $z_2 = z_1u$. The given values are rounded to the whole number.

In practice, there is another method to determine the teeth number and wheel module. The tentative value of the teeth number of the pinion (z'_1) is chosen depending on its diameter d_{e1} and gear ratio u in accordance with one of the diagrams graphed for straight bevel wheels (Fig. 6.47) or wheels with circular teeth (Fig. 6.48), with the teeth hardness of the wheel and the pinion ≥ 45 HRC. z_1 is specified, taking into account the teeth hardness of the pinion and the wheel by:

Table 6.19 Correction of the pinion tooth number z_1

Hardness H		Teeth number z_1
$H_1 \leq 350$ HB	$H_2 \leq 350$ HB	$1.6z'_1$
$H_1 \geq 45$ HRC	$H_2 \leq 350$ HB	$1.3z'_1$
$H_1 \geq 45$ HRC	$H_2 \geq 45$ HRC	z'_1

The teeth number of the wheel is $z_2 = z_1u$. Calculated values of the teeth number of the pinion and the wheel are rounded to whole numbers. The exterior end module of the gearing is calculated (m_e for bevel wheels with straight teeth, m_{te} for wheels with circular teeth) by using

$$m_e(m_{te}) = d_{e1}/z_1\,.$$

The Actual Gear Ratio $u_r = z_2/z_1$

The calculated value of u_r must not differ from the target value by more than 3% for bevel reduction gears, 4% for bevel-cylindrical double-reduction gears, and 5% for three-stage (or greater) bevel-cylindrical reduction gears.

Final Values of Wheel Dimensions

The pitch cone angles of the pinion and the wheel are

$$\delta_1 = \arctan(1/u_r); \quad \delta_2 = 90^\circ - \delta_1 .$$

The pitch diameters of the wheels are

with straight teeth $d_{e1} = m_e z_1$, $d_{e2} = m_e z_2$;

with circular teeth $d_{e1} = m_{te} z_1$, $d_{e2} = m_{te} z_2$.

The outer diameters of the wheels are

with straight teeth

$$d_{ae1} = d_{e1} + 2(1 + x_{e1}) m_e \cos\delta_1 ,$$

$$d_{ae2} = d_{e2} + 2(1 + x_{e2}) m_e \cos\delta_2 ;$$

with circular teeth

$$d_{ae1} = d_{e1} + 1.64(1 + x_{n1}) m_{te} \cos\delta_1 ,$$

$$d_{ae2} = d_{e2} + 1.64(1 + x_{n2}) m_{te} \cos\delta_2 .$$

The coefficients x_{e1} and x_{n1} for straight and helical *pinions* are taken from Tables 6.18 and 6.20. For gearings with z_1 and u that differ from those given in Tables 6.18 and 6.20, the values x_{e1} and x_{n1} are rounded up. The coefficient of tool displacement for the wheel is

$$x_{e2} = -x_{e1} ; \quad x_{n2} = -x_{n1} .$$

Uncut Wheel Dimensions

The dimensions of the billets are computed for the bevel pinion and the wheel (mm) (Fig. 6.39b) as

$$D_{blank} = d_{e1} + 2m_e(m_{te}) + 6\,\text{mm} ,$$

$$S_{blank} = 8m_e(m_{te}) .$$

The values of D_{blank} and S_{blank} determined from calculations are then compared with the limit dimensions D_{max} and S_{max} detailed in Table 6.1.

The conditions for suitability of the billets are

$$D_{blank} \le D_{max} ;$$

$$S_{blank} \le S_{max} .$$

Toothing Forces (Fig. 6.44)

The circumferential force on the mean diameter d_{m1} of the pinion is

$$F_t = 2 \times 10^3 T_1 / d_{m1} , \quad \text{where} \quad d_{m1} = 0.857 d_{e1} .$$

The axial force on the pinion is

with straight teeth $F_{a1} = F_t \tan\alpha_w \sin\delta_1$,

with circular teeth $F_{a1} = \gamma_a F_t$.

The radial force on the pinion is

with straight teeth $F_{r1} = F_t \tan\alpha_w \cos\delta_1$,

with circular teeth $F_{r1} = \gamma_r F_t$.

The axial force on the wheel is $F_{a2} = F_{r1}$, and the radial force on the wheel is $F_{r2} = F_{a1}$.

The coefficients γ_a and γ_r for the angle $\beta_n = 35°$ are determined from the formulas

$$\gamma_a = 0.44 \sin \delta_1 + 0.7 \cos \delta_1 ,$$

$$\gamma_r = 0.44 \cos \delta_1 - 0.7 \sin \delta_1 .$$

The calculated coefficients γ_a and γ_r are substituted into the formulas with their corresponding signs. Teeth seizing will not occur if the force F_{a1} is directed towards the base of the pitch cone of the drive pinion. Thus the rotating sense of the pinion (seen from the direction of the pitch cone point) and the dip direction of the teeth are chosen to be identical; e.g., for the drive pinion with a left tooth dip the sense of rotation is counterclockwise.

Contact Stress Analysis of Wheel Teeth

The rated contact stress is

$$\sigma_H = 6.7 \times 10^4 \sqrt{\frac{K_{HV} K_{H\beta} T_1}{u_r d_{e1}^3 \vartheta_H}} \le [\sigma]_H .$$

Bending Stress Analysis of Wheel Teeth

The bending stress in the teeth of the spur is

$$\sigma_{F2} = \frac{2.72 \times 10^3 K_{FV} K_{F\beta} T_1 Y_{FS2}}{b d_{e1} m_e \, (m_{te}) \, \vartheta_F} \le [\sigma]_{F2} .$$

For gearings with circular teeth the module m_e is substituted for the module m_{te} in this formula. The bending stresses in the teeth of the pinion are

$$\sigma_{F1} = \sigma_{F2} Y_{FS1} / Y_{FS2} \le [\sigma]_{F1} .$$

The values of the factors Y_{FS1} and Y_{FS2}, considering tooth form and stress concentration, are taken from Table 6.14 and depend on the coefficient of displacement and the given number of teeth

$$z_{v2} = z_2 / \left(\cos^3 \beta_n \cos \delta_2 \right) ,$$

$$z_{v1} = z_1 / \left(\cos^3 \beta_n \cos \delta_1 \right) .$$

For the checking strength analysis of teeth under the action of peak loads see Sect. 6.3.7.

6.5 Worm Gearings

6.5.1 Background

Worm gearings are used for transmission of rotational motion between shafts, the axes of which intersect in space. In most cases, the intersection angle is 90° (Fig. 6.49). The drive is worm 1, representing a gear wheel with a small number ($z_1 = 1–4$) of teeth (coils), which is similar to an acme screw or an approximate thread. To increase the contact line length in the toothing with the worm, the teeth of worm wheel 2 have the form of an arc in axial section. The worm gearing is a tooth-screw gear, the motion of which is transformed according to the principle of the screw pair with its inherent increased slip [6.38–47].

Depending on the form of the external worm surface gearings can have a cylindrical worm (Fig. 6.49a) or a globoidal worm (Fig. 6.49b). The quality of globoidal gears is higher, but they are complicated to manufacture and assemble, and are sensitive to the axial displacement caused by, e.g., wear of the bearings. In practice, gearings with cylindrical worms are most often applied.

The advantages of worm gearings are:

1. The availability of a high gear ratio u in one stage (up to 80).
2. Compactness and moderate mass of the structure.
3. Operation smoothness and silence.
4. The availability of self-stopping gearings, i. e., permitting motion only from the worm to the wheel. This self-stopping of the worm gearing allows a mechanism without a braking device, preventing reverse rotation of the wheels (e.g., under the action of a lifted load gravity).
5. The availability of exact and slight displacements.

Their disadvantages are:

1. A relatively low efficiency factor because of increased slip of the worm coils on the wheel teeth, and as a result considerable heat release in the toothing zone
2. The need for expensive antifriction materials for the ring of the worm wheels
3. Increased wear and tendency to seizing
4. The necessity for adjustment of the mesh (the mean plane of the worm wheel ring must coincide with the axis of the worm)

Worm gearings are widely used in vehicles, lifting-and-shifting machines with low and mean capacity (the lifting mechanism of elevators, winch, power hoist;

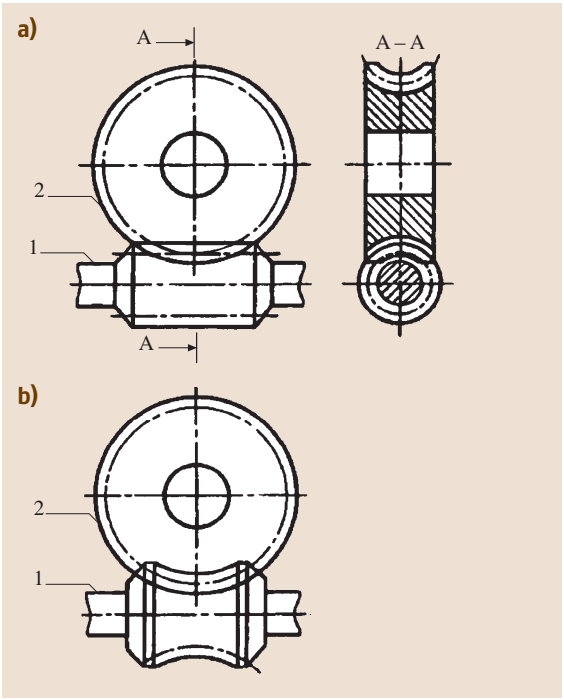

Fig. 6.49a,b Worm gear with a cylindrical **(a)** and a globoidal **(b)** worm

drives of underground escalators, transmissions of vehicles, etc.), as well as those vehicles having the purpose of slight and exact displacements (dividing devices of the machines, tuning and adjusting mechanisms, etc.).

Owing to the disadvantages mentioned above it is impractical to use worm gearings in environments of continuous action with power of more than 30 kW. By operating in intermittent cycles they can be effective also with higher power.

6.5.2 Geometry of Worm Gearings

The quality and efficiency of worm gearings depend on the form, hardness, roughness, and manufacturing accuracy of the screw surface of the worm coil. There are linear and nonlinear worms, depending on whether screw surfaces of the worm coils can or cannot be produced by a straight line. Cutting of the linear screw surfaces is carried out with universal screw-cutting lathes, in which the linear cutting edge reproduces evolvent, convolute, or Archimedean surfaces. A nonlinear screw surface is obtained by using milling cutters of bevel or toroidal form. In accordance with this fact there are involute, Archimedean, convolute, and nonlinear worms. The kind of screw surface of the worm coils obtained depends on the cutting method.

The involute worm (ZI – designation according to [6.44]) is obtained in the case of installation of the linear cutting edge in the plane tangential to the base cylinder with diameter d_b (Fig. 6.50). The left and right coil sides are cut, respectively, with cutters 1 and 2 mounted above and below the axis of the worm (see also sections C–C and B–B). In the face section (perpendicular to the axis of the worm) the coil profile of the worm is outlined with an involute surface; in axial section (A–A) it is curvilinear (convex). The involute worm represents a helical wheel of involute profile with a teeth number equal to the turn number of the worm and with a large tilt angle of the teeth. In this regard more efficient methods are involute worm cutters with worm milling and hob cutters assigned for the production of involute oblique teeth of cylindrical gearings.

To obtain high surface hardness of the turns, and thus increase the quality characteristics of the gearings, heat treatment with subsequent grinding of the work coil surfaces is used. Involute worms can be ground with high accuracy with a flat surface of the grinding wheel. Efficient cutting methods and ease of grinding determine high fabricability of the involute worms.

The Archimedean worm (ZA) is obtained by arranging that the position of the cutting edges in the plane passes through the axis of the worm. Archimedean worms have a linear profile with an angle of 2α, which equals the profile angle of the cutter, in axial section. In the face section the coil profile is outlined with an Archimedean spiral. The lateral coil surfaces of Archimedean worms can be ground only with special shapes along the compound curve grinding wheel. Strengthening heat treatment and subsequent grinding are not carried out, and Archimedean worms with low hardness are used in slow-speed gearings with low demands for load-carrying ability and lifetime.

The convolute worm (ZN) is obtained by placement of the cutting edges in the plane tangential to the cylinder with diameter d_x ($0 < d_x < d_b$) and normal to the symmetry axis of the valley. Convolute worms have convex profile in axial section; in the face section the coil section is outlined with an elongated evolvent.

The disadvantages of gearings with convolute worms are the irregular shape of the polishing tools for the worms and the impossibility of precision milling cutters for teeth cutting of the worm wheels. Like Archimedean worms, gearings with convolute worms have limited application, in general in the short-run environment.

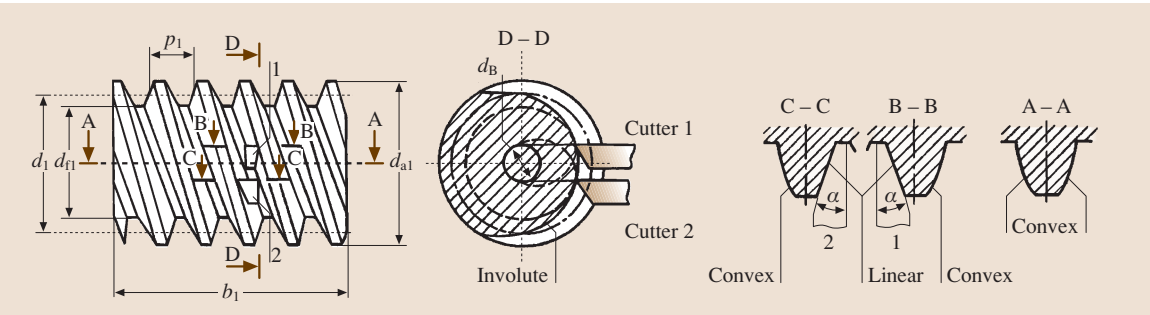

Fig. 6.50 Principal geometry of the worm

Nonlinear worms are cut with milling cutters of conical or toroidal form. The coils of such worms have a curvilinear profile in every section; in the section normal to the symmetry axis of the valley they are convex; in the axial section they are concave.

The work coil surfaces of nonlinear worms are ground with high accuracy with conical or toroidal wheels. Gearings with nonlinear worms are characterized by increased load-carrying capacity. Nonlinear worms formed by the cone (ZK) or the torus (ZT) are considered promising. Involute and nonlinear worms are used in power trains.

The geometry of the worm and the wheel is determined from formulas similar to those for gear wheels. In worm gearings the axial module m of the worm is rated and equals the face module of worm wheels. The values for m (in mm) are chosen from the series: ...4, 5, 6.3, 8, etc. The basic geometry of the worm consists of the following (Fig. 6.50):

- A pitch diameter, i. e., the diameter of the cylinder of the worm, where the coil thickness equals the width of the valley

  $$d_1 = mq \,,$$

  where q is a module number in the pitch diameter of the worm or a coefficient of the worm diameter. To reduce the number of gear cutting tools required the values of q are standardized to 8, 10, 12.5, 16, and 20.
- The rated pitch of the worm: $p_1 = \pi m$;
- Coil move: $p_{z1} = p_1 z_1$, where z_1 is the coil number of the worm, taking values of 1–4;
- The angle α of thread for involute, Archimedean, and convolute worms is $\alpha = 20°$, for worms formed by the torus it is $\alpha = 22°$;
- A pitch helix angle of the coil line (see Fig. 6.51)

  $$\tan\gamma_1 = p_{z1}/(\pi d_1) = \pi m z_1/(\pi m q) = z_1/q \,.$$

For the worm in gearings with displacement it is computed separately as follows:

- The diameter of the pitch cylinder (starting diameter)

  $$d_{w1} = m(q + 2x) \,,$$

- The helix angle of the coil line on the pitch cylinder

  $$\tan\gamma_{w1} = z_1/(q + 2x) \,,$$

where x is the coefficient of displacement.

The teeth of the worm wheel are mostly cut with a hob that represents a clone of the worm with which the worm wheel will be meshed. Only the milling cutter has cutting edges and a somewhat greater (by the double rim clearance dimension in the toothing) outer diameter. During cutting the work piece of the wheel and the milling cutter both move the same way as the worm wheel and the worm will during operation.

The basic geometry of worm-wheel rings is determined by its mean section. The pitch d_2, and hence also the starting d_{w2} diameter of the wheel, with teeth number z_2 (Fig. 6.52) is given by

$$d_2 = d_{w2} = m z_2 \,.$$

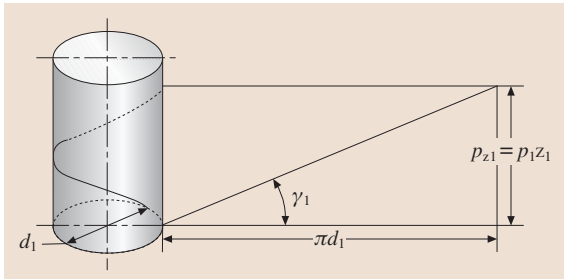

Fig. 6.51 Determination of the pitch helix angle of the coil line

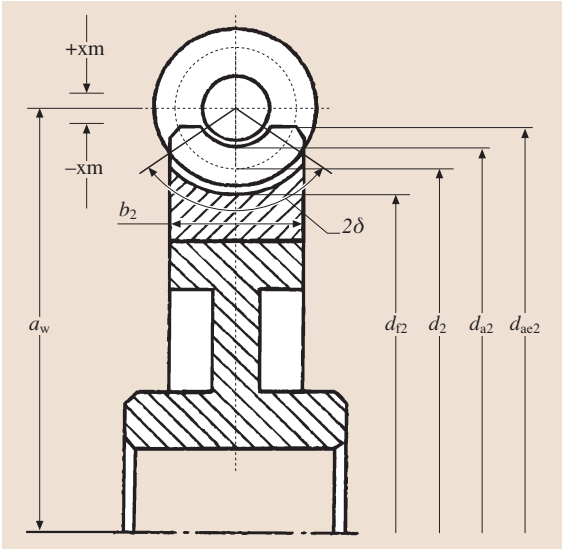

Fig. 6.52 Principal geometry of the worm wheel

The axle base of the worm gearing is

$$a = 0.5(d_1 + d_2) = 0.5(mq + mz_2) = 0.5m(q + z_2) \, .$$

Worm gearings with displacement are made in order to achieve a standard or given axle base. This is achieved in the same way as in gearings by means of a displacement by xm of the milling cutter relative to the work piece in teeth cutting of the wheel (Fig. 6.52)

$$a_w = a + xm = 0.5m(q + z_2 + 2x) \, .$$

For standard reduction gears a_w takes the values 80, 100, 125, 140, 160, etc. For teeth cutting of the wheels in gearings with and without displacement, the same tool is used. Thus, cutting with displacement is carried out only for the wheel.

With the set center distance the coefficient of tool displacement is

$$x = (a_w/m) - 0.5(q + z_2) \, .$$

The values of the tool displacement coefficient x are chosen from the data for noninterference and nonthinning of the teeth. The following is recommended for gears with worms:

- Involute: $-1 \le x \le 0$
- Formed by a torus: $0.5 \le x \le 1.5$

The worm wheel is helical, with an angle γ_w of tooth dip.

The relative angle 2δ of contact for strength analysis is determined according to the crossing points of the circle with diameter $(d_{a1} - 0.5m)$ and the end lines of the worm-wheel face.

To ensure correct toothing of worms with the wheel in a single-part environment, mean plane position control of the wheel ring relative to the worm axis is required; in a mass-manufacturing environment deliberate low surface distortion (retraction) of the wheel tooth along the depth in the direction of its point and root (profile modification), or along the length towards its ends (longitudinal modification), is resorted to.

6.5.3 The Kinematics of Worm Gearings

The gear ratio u of worm gearings is determined by the observation that, for each worm revolution, the wheel turns by an angle corresponding to the teeth number of the wheel, which equals the coil number of the worm.

The wheel turns completely during z_2/z_1 worm revolutions, so

$$u = n_1/n_2 = d_2 \operatorname{cotan} \gamma_1/d_1 = z_2/z_1 \, ,$$

where n_1 and n_2 are the rotational frequencies of the worm and the wheel, d_1 and d_2 are the pitch diameters of the worm and the wheel, γ_1 is the pitch helix angle of the coil line, and z_1 and z_2 are the coil number of the worm and the teeth number of the wheel, respectively.

To avoid interference of the tooth root $z_2 \ge 26$ is allowed in teeth cutting. $z_2 = 32$–63 is optimal. For worm gearings of standard reduction gears the gear ratios are chosen from the series: ... 31.5, 40, 50, 63, and 80.

6.5.4 Slip in Worm Gearings

In operation, the worm coils in worm gearings slip on the teeth of the worm wheel. The slip velocity v_{sl} (Fig. 6.53) is directed at a tangent to the coil line of the worm and can be determined from the parallelogram of velocities (v_1 and v_2 are circumferential velocities of

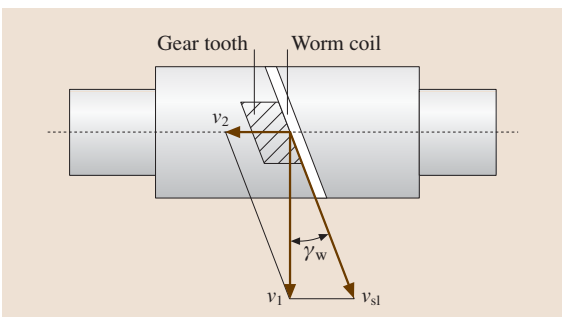

Fig. 6.53 Determination of the slip velocity in worm gears

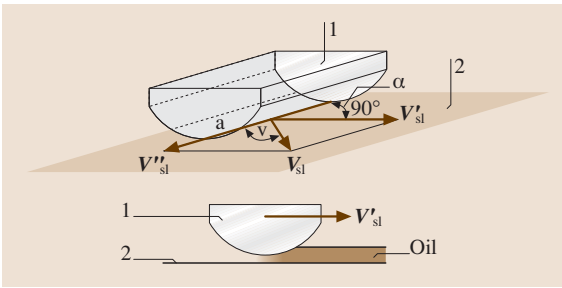

Fig. 6.54 Formation of the base oil layer in contact

the worm and the wheel, m/s) as

$$v_{sl} = v_1 / \cos\gamma_w = \pi d_{w1} n_1 / (60\,000 \cos\gamma_w) .$$

Obviously $v_{sl} > v_1$. Slip in worm gearings causes considerable losses in toothing, gearing heat, and wear of the worm-wheel teeth, and increases the seizing inclination.

The load-carrying capacity of movement on lubricated surfaces is considerably higher if wedge clearance is ensured in the direction of velocity. For surfaces with line contact, e.g., bodies 1 and planes 2 (Fig. 6.54) this corresponds to the condition that the velocity vector v_{sl} is perpendicular to the line contact a–a, or that it has the constituent v'_{sl}, which is perpendicular to that line. At the same time, oil sucked into the wedge clearance separates the mated surfaces and transfers the active load. If slip increases along the contact line a–a, the oil layer in the contact zone cannot be formed and conditions for seizing occur.

In worm gearings the contact line configuration depends on the form of the worm surface. In Fig. 6.55 the layout of the worm-wheel tooth has the contact line a–a embossed on it; the series of subsequent positions is

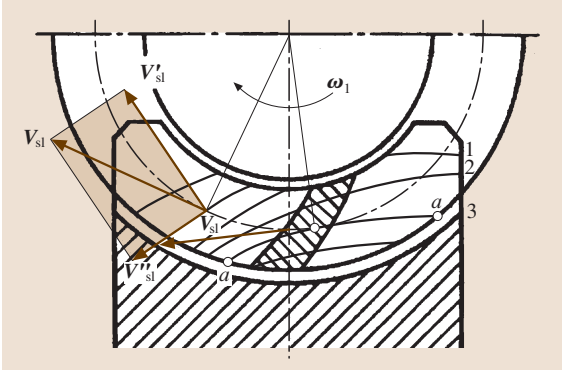

Fig. 6.55 Position of the contact lines on the tooth of the worm wheel

marked with the numbers 1, 2, and 3 in the toothing process of wheels with Archimedean worms. Obviously, in position 3 the slip velocity vector v_{sl} is directed at a tangent to the contact line. The area where the direction v_{sl} almost coincides with the direction of the contact lines is shaded. An unfavorable direction of the slip velocity is the cause of increased losses, and wear and seizing starting exactly in this area and are then distributed throughout the work surface of the wheel teeth.

The most favorable contact zone is the part of the wheel tooth from the side of the worm lead-out of the toothing. Here the vector v_{sl} has a considerable constituent v'_{sl}, which is perpendicular to the contact line, and therefore there are favorable conditions for the formation of the base oil layer.

In worm gearings with nonlinear worms the contact lines are located so that in all positions a considerable constituent v'_{sl} of the slip velocity vector takes place in the toothing process. This provides increased load-carrying capacity for the gearing.

Twelve accuracy degrees are determined for worm gearings. Kinematic accuracy standards, smoothness standards, and contact standards of the teeth and the coils are provided for all of these. In power trains the seventh ($v_{sl} \le 10$ m/s), eighth ($v_{sl} \le 5$ m/s), and ninth ($v_{sl} \le 2$ m/s) accuracy degrees are mostly used.

6.5.5 The Efficiency Factor of Worm Gearings

Lubrication in worm gearing is more important than in toothed gears because coil slipping of the worm occurs along the contact lines of the worm-wheel teeth in toothing. The worm gearing is a tooth-screw and has losses that are inherent to the toothed gear as well as to the screw-nut gear. Generally the efficiency factor of the worm gearing is

$$\eta = \eta_b \eta_t \eta_{st} ,$$

where η_b, η_t and η_{st} are efficiency factors that take into account losses in bearings, toothing, and in oil stir and splatter, respectively.

The efficiency factor of the worm meshing is determined from the formula

$$\eta_t = \tan\gamma_w / \tan(\gamma_w + \rho) ,$$

where γ_w is the helix angle of the screw line and ρ is the modified angle of friction.

The values of the friction angle ρ, depending on the slip velocity, are obtained experimentally for worm

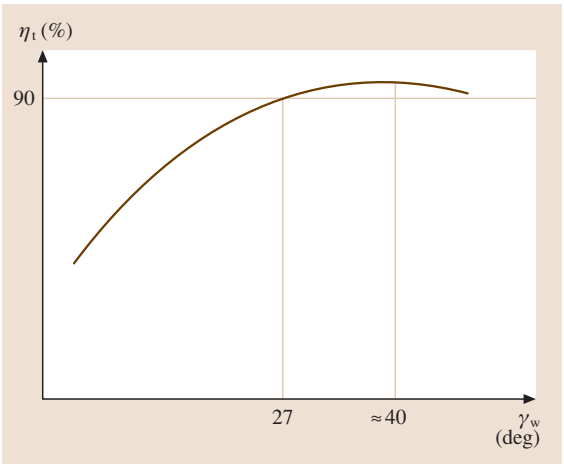

Fig. 6.56 Dependence of the efficiency factor η_t on the helix angle γ_w of the coil for the pitch cylinder of the worm

gearings on supports with frictionless bearings; i. e., capacity losses in frictionless bearings, in toothing, and in oil stir and splatter are considered in these values. The value r reduces if v_{sl} increases, because with high slip velocities in the contact area favorable conditions for oil layer formation occur, which separates the worm coils and wheel teeth and reduces losses in the toothing.

The numerical value of η_t increases with the helix angle γ_w increasing the screw line on the pitch cylinder up to $\gamma_w \approx 40°$ (Fig. 6.56). Usually, in worm gearings one has $\gamma_w \leq 27°$. Large helix angles are applied in gearings with four-thread worms and small gear ratios. Worm gearings have a relatively low efficiency factor, which limits their application field to $\eta_t = 0.75–0.92$.

6.5.6 Toothing Forces

The interaction force between the worm and the wheel is taken to be concentrated and is applied at the pitch point along the normal line to the work surface of the coil. It is described by three mutually perpendicular constituents: F_t, F_a, and F_r. For clarity of the force representation, the worm and worm wheel in Fig. 6.57a have been disengaged.

The peripheral force F_{t2} on the worm wheel is

$$F_{t2} = 2\times10^3 T_2/d_2 \,,$$

where T_2 is the torque on the worm wheel (N m) and d_2 is the pitch diameter of the wheel (mm).

The axial force F_{a1} on the worm numerically is F_{t2}, i.e., $F_{a1} = F_{t2}$.

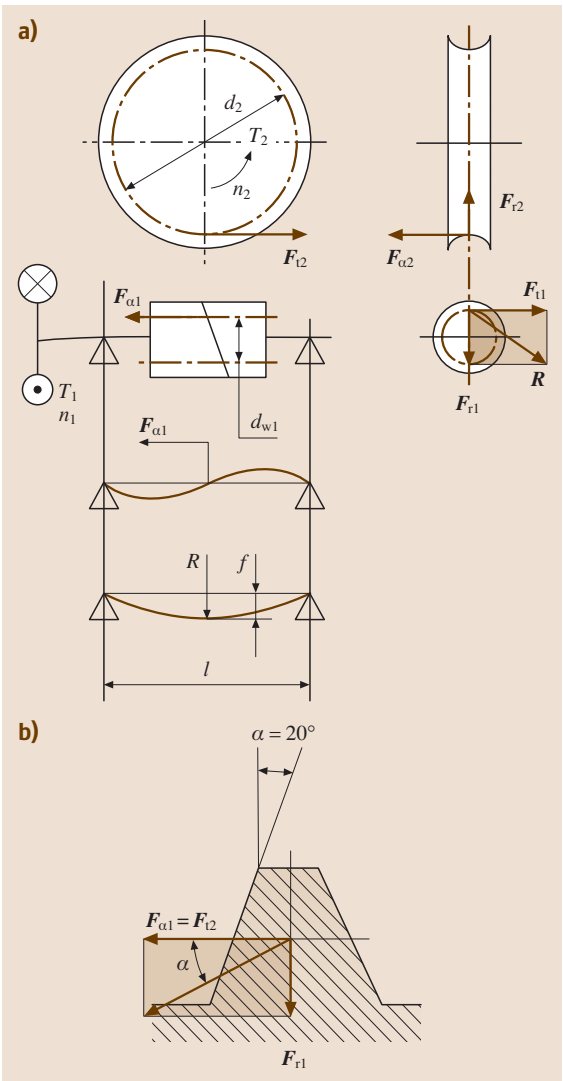

Fig. 6.57a,b Forces in the toothing of worm gears (a), layout to determine F_{r1} (b)

The peripheral force F_{t1} on the worm is

$$F_{t1} = 2\times10^3 T_1/d_{w1} = 2\times10^3 T_2/(u\eta_t d_{w1}) \,,$$

where T_1 is the torque on the worm (N m), η_t is the efficiency factor of the gearing, and d_{w1} is in mm.

The axial force F_{a2} on the worm wheel numerically equals F_{t1}, i.e., $F_{a2} = F_{t1}$. The radial force F_{r1} on the worm (the radial force F_{r2} on the wheel numerically equals F_{r1}) is (Fig. 6.57b)

$$F_{r1} = F_{r2} = F_{t2} \tan\alpha / \cos\gamma_w \,.$$

The direction of the force F_{t2} always coincides with the sense of rotation of the wheel, and the force F_{t1} is directed towards the side opposite the worm rotation.

6.5.7 Stiffness Testing of Worms

Hardness analysis of the worm body under the action of the forces in the toothing is carried out in order to prevent excessive load concentration in the contact area.

Flexing due to the constituents F_{t1} and F_{r1} in the worm bearing section, where the most important toothing area is located, have maximum values. Flexing in this section due to the torque produced by the axial force F_{a1} is zero (Fig. 6.57a).

Flexing f of the worm due to the resultant radial force R leads to an increase of the axle base and an increase of the pitch cylinder radius of the worm. The angle of the coil dip on the deformed worm does not equal the angle of the teeth dip of the worm wheel; toothing precision is broken, which causes load concentration in the toothing.

Thus, worm flexing f (mm), in the mean section is limited to the allowed values $[f] = (0.005–0.008)m$ (where m is the toothing module, mm)

$$f = \frac{\sqrt{F_{t1}^2 + F_{r1}^2} \times l^3}{48 E J_e} \leq [f] \ ,$$

where l is the distance between the worm bearings (mm) (in predesigns, $l \approx 0.9 d_2$ can be used), E is the coefficient of elasticity of the worm material (N/mm^2), J_e (mm^4) is the equivalent moment of inertia (the moment of inertia of the cylindrical bar, which is distortion equivalent to the worm),

$$J_e = \frac{\pi d_{f1}^4}{64} \left(0.36 + 0.64 \frac{d_{a1}}{d_{f1}}\right) \ .$$

6.5.8 Materials for Worms and Worm-Wheel Rings

Worms and wheels must have sufficient strength and form a well-ground antifriction pair in view of the considerable slip velocities in the toothing. Worms are manufactured from medium-carbon steels of grades C 46, C 45 (EN), C 53, and C 50 E (EN) or alloy steels of grades 37 Cr 4, 41 Cr 4 (EN), and 40 NiCr 6 (DIN) with surface hardening or volume quenching up to hardnesses of 45–54 HRC and subsequent grinding of work coil surfaces. Worms from cemented steels of grades 20 MnCr 5 G (DIN) and 20 CrS 4 (DIN) with hardness after quenching of 56–63 HRC ensure good operation (Appendix 6.A Table 6.95).

Materials for worm-wheel rings can be classified into three groups according to decreasing score-resistance and antifriction behavior, as recommended for application slip velocities (Appendices 6.A Table 6.95, Table 6.97).

Group I

Tin bronze is applied for high slip velocities ($v_{sl} = 5–25$ m/s). This material has good score resistance, but low strength.

Group II

Tinless bronze and brass are used with intermediate slip velocities ($v_{sl} = 2–5$ m/s). Most often aluminum bronze is applied. This bronze has high mechanical strength, but low score resistance, so it is used together with quenched (> 45 HRC) ground and polished worms.

Group III

Grey iron of grades ISO 150 and ISO 200 are applied for low slip velocities ($v_{sl} < 2$ m/s) in hand-driven devices.

6.5.9 The Nature and Causes of Failure of Worm Gearings

In gearings with wheels made of tin bronze (a soft material) fatigue spalling of the work surfaces of the wheel teeth is the most dangerous failure mode, because of the increasing contact stress and increasing fatigue limit of metal for the given loading cycle number.

Seizing is also possible as a result of the considerable slip velocities of the contact surfaces in combination with the boundary lubrication rate (lack of a separating oil layer). Seizing of soft materials is shown as a *smearing* (diffusion transfer) of bronze on the worm; the teeth section decreases gradually, but the gearing continues to operate for some time, determined by the wear rate.

Seizing in gear rings made of tinless bronze, brass, and iron (a hard material) results in the formation and subsequent fracture of a microwelded bridge with a jump of the friction coefficient and catastrophic wear, which results in wheel teeth damage with scales after microwelding onto the worm coils. To prevent seizing it is recommended that surfaces of the coils and teeth be thoroughly treated, and that materials with high antifriction behavior and oils with load-carrying and antiscoring additives be used.

Wear of the wheel teeth of worm gearings is mostly caused by work surface seizing of the worm/worm-wheel pair. It can also occur as a result of insufficient coil smoothness of considerably harder worms or insufficient oil purity. Higher wear leads to the formation of inadmissible clearance in the toothing. Fracture of the worm-wheel teeth occurs mostly after wear. Tooth stripping occurs very rarely.

6.5.10 Contact Strength Analysis and Seizing Prevention

For worm gearings, similarly to tooth gearings, contact strength and bending strength analysis of the worm-wheel teeth are carried out. In worm gearings, besides flaking of the work tooth surfaces, there is a risk of seizing, which also depends on the values of contact stresses σ_H. Thus, for all worm gearings contact stress analysis is the most important, determining the dimensions of the gearings, while seizure-prevention calculations and bending strength analysis are used for verification.

Contact stress analysis is carried out for the toothing in the pitch point, as applied to gearings with Archimedean worms, taking into account that the toothing conditions and the load-carrying capacity of gearings with linear-base-type worms are very similar.

To obtain the rated relation, let us express the values in Hertz's formula in terms of the parameters of the worm meshing. The force F_n acting along the normal line at the contact point of the worm-wheel tooth and the worm coil is determined according to the peripheral force F_{t2} considering the dip angle γ_w of the wheel tooth and the load factor K according to

$$F_n = KF_{t2}/(\cos\alpha\cos\gamma_w) .$$

Here the load factor $K = K_{H\beta}K_{HV}$ takes into account the unevenness of the load distribution in the contact area ($K_{H\beta}$) due to distortion of the worm and wheel shaft, the bearings, and the case, as well as the internal gearing dynamics (K_{HV}) caused by manufacturing errors.

b in Hertz's formula is understood as $l_\sum$, the total length of the contact lines in the toothing of the worm gearing. The tooth width b' of the wheel along the circular arc with diameter d_{w1} can be written in terms of the starting diameter of the worm d_{w1} and the relative contact angle 2δ (Fig. 6.52) as

$$b' = \pi d_{w1} 2\delta/360^\circ .$$

To take into consideration that, with an increase of the helix coil angle γ_w, the length of the contact line rises inversely with $\cos\gamma_w$, with the front contact ratio ε_α in the mean plane of the worm wheel and the coefficient ξ of the full-length mode of the contact line we have

$$l_\sum = b'\xi\varepsilon_\alpha/\cos\gamma_w = \frac{\pi d_{w1}}{\cos\gamma_w}\frac{2\delta}{360^\circ}\xi\varepsilon_\alpha .$$

where the mean values of the coefficient is $\xi = 0.75$, the angle of contact is $2\delta \approx 100^\circ$, and the coefficient $\varepsilon_\alpha = 2$, so the total length of the contact lines equals $l_\sum \approx 1.3 d_{w1}/\cos\gamma_w$.

The coils of Archimedean worms have a straight-sided profile ($\rho_1 = \infty$) in axial section, and the teeth of the worm wheel have an involute profile (Fig. 6.58). The radius of profile curvature of the worm-wheel tooth in the pitch point as a function of the dip angle γ_w of the tooth is

$$\rho_2 = 0.5 d_2 \sin\alpha/\cos^2\gamma_w .$$

Then

$$\sum(1/\rho_i) = 1/\rho_1 + 1/\rho_2 = \frac{1}{\rho_2} = \cos^2\gamma_w/(0.5 d_2 \sin\alpha) .$$

For the combination steel–bronze or steel–iron we have: $E_1 = 2.1\times10^5$ N/mm^2, $E_2 = 0.9–1.0\times10^5$ N/mm^2, $\nu_1 = 0.3$, and $\nu_2 = 0.25–0.33$. We assume $\alpha = 20^\circ$ and $\gamma_w = 10^\circ$.

Substituting the above parameters into the basic relation for σ_H and at the same time replacing the

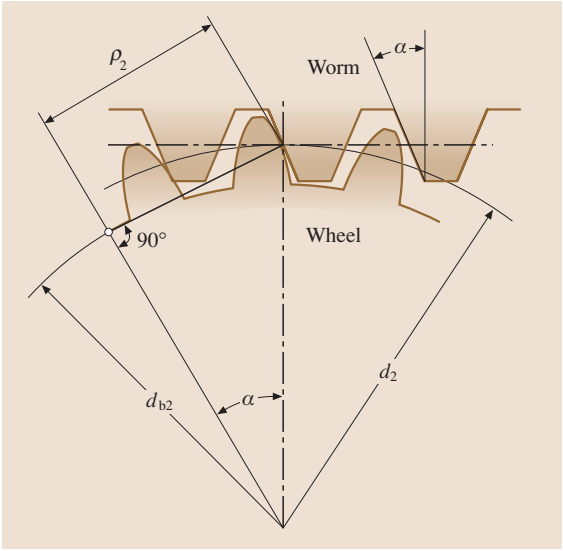

Fig. 6.58 Diagram for the contact strength analysis of the worm gear

values $F_{t2} = 2\times10^3 T_2/d_2$; $d_{w1} = m(q+2x)$; $d_2 = mz_2$; $m = 2a_w/(z_2+q+2x)$, and also using a strength condition $\sigma_H \le [\sigma]_H$, we obtain

$$\sigma_H = \frac{5350\,(q+2x)}{z_2} \times\sqrt{\left[\frac{z_2+q+2x}{a_w\,(q+2x)}\right]^3 KT_2} \le [\sigma]_H\ , \qquad (6.10)$$

where σ_H is the rated contact stress in the toothing area (N/mm^2), a_w is the axle base (mm), T_2 is the torque on the wheel (N m), and $[\sigma]_H$ is the allowable contact stress (N/mm^2).

Worm gearings with nonlinear worms are characterized by a more favorable ratio of curvature radii of the worm and the wheel, as well as a greater total length of the contact lines, which leads to increased load-carrying capacity. Contact stresses in gearings with nonlinear worms can be determined approximately from (6.10) with substitution of the numerical coefficient of 5350 for the value 4340.

Assuming the worm to be rigid, one obtains $q = 0.25z_2$ and $x = 0$. Solving (6.10) for a_w we obtain the verification analysis formula for worm gearings

$$a_w \ge K_a\sqrt[3]{KT_2/[\sigma]_H^2}\ ,$$

where $K_a = 610$ for linear worms and $K_a = 530$ for nonlinear ones, a_w is in mm, $[\sigma]_H$ is in N/mm^2, and T_2 is in N m. Substituting the parameters of worm gearings into the initial dependence for σ_H, we obtain a formula for the verification analysis

$$\sigma_H = \frac{98Z_E\cos\gamma_w}{d_2}\sqrt{\frac{KT_2}{d_{w1}\xi}} \le [\sigma]_H\ , \qquad (6.11)$$

where σ_H is a rated contact stress (N/mm^2), $Z_E = \sqrt{1/\left\{\pi[(1-\nu_1^2)/E_1 + (1-\nu_2^2)/E_2]\right\}}$ is a coefficient taking into account the stress–strain properties of the worm and worm wheel, (N/mm^2)$^{0.5}$; T_2 is the torque on the wheel (N m), d_2 and d_{w1} are the pitch diameter and the initial diameter, respectively, of the wheel and the worm (mm). ξ is a coefficient that takes into account the influence of the worm gear class on the load-carrying capacity; for linear worms one uses $\xi = 1$, whereas for nonlinear worms $\xi = 1.06 + 0.057\nu_{sl}$ on the condition that $\xi \le 1.65$, and $[\sigma]_H$ is the allowable contact stress (N/mm^2).

In short-cut calculations seizing prevention is provided in contact stress analysis by the choice of the allowable stress. In more precise calculations the worst case is supposed, i. e., when the load-carrying capacity reduction of the oil film results in immediate surface seizing. The critical temperature ϑ_{cr} of oil film breakdown has been determined experimentally for the main oil grades ($\vartheta_{cr} = 100$–$350\,^\circ$C).

The criterion for lack of seizing is represented in the form

$$\vartheta_\sum = (\vartheta + \vartheta_{mom}) < \vartheta_{cr}\ ,$$

where ϑ is the temperature of the friction surface before the contact (the oil temperature in the reduction gear), ϑ_{mom} is the instantaneous temperature on contact (*temperature flash*), which can be determined from a special calculation by solving the differential thermal conductivity equation while taking into account the specific characteristics of the behavior of the thermal process during the contact. To achieve the total temperature $\vartheta_\sum$ the critical value ϑ_{cr} can be determined experimentally.

6.5.11 Bending Strength Calculation for Wheel Teeth

This calculation is carried out for the teeth of the worm wheel, because the coils of the worm are considerably tougher. A bending calculation is performed according to the formulas for helical wheels, writing included values in terms of the parameters of the worm gearing and taking into consideration the greater teeth bending strength of worm wheels due to their arched form (Fig. 6.52).

Taking into account these features, we obtain the formula for checking the bending stress analysis of worm-wheel teeth

$$\sigma_F = \frac{KF_{t2}Y_{F2}\cos\gamma_w}{1.3\text{m}^2\,(q+2x)} \le [\sigma]_F\ , \qquad (6.12)$$

where σ_F is the design bending stress in the weakest section of the tooth (N/mm^2), Y_{F2} is the form factor of the wheel tooth, chosen depending on the equivalent tooth number z_{v2} (where greater values correspond to lower values of the tooth number), and $[\sigma]_F$ is the allowable bending stress for the wheel teeth (N/mm^2).

The *equivalent tooth number* z_{v2}, similarly to a helical wheel with dip angle γ_w, of the tooth becomes

$$z_{v2} = z_2/\cos^3\gamma_w\ .$$

6.5.12 Choice of Permissible Stresses

Permissible stresses are determined from empirical formulas depending on the material of the wheel teeth, the

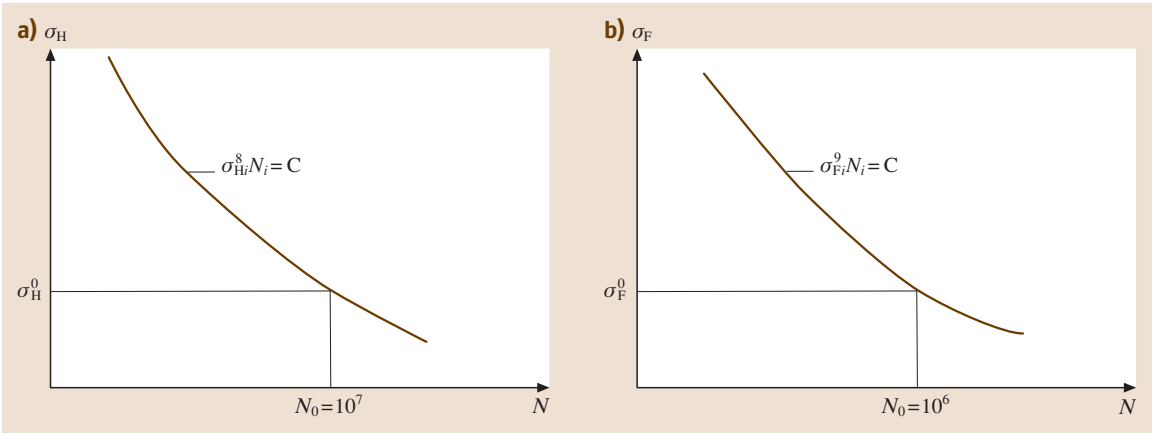

Fig. 6.59a,b Stress-cycle diagrams for (a) contact stresses and and (b) bending stresses

hardness of the worm coils, the slip velocity, and the required lifetime.

Stress-cycle diagrams for contact stresses (Fig. 6.59a) and bending stresses (Fig. 6.59b) of bronze specimens have very long inclined areas: up to 25×10^7 loading cycles. In connection with low rotational frequencies the equivalent loading cycle number of the worm-wheel teeth is small. Thus, the initial stresses are σ^0_H and σ^0_F, which equal the fatigue strength at for 10^7 and 10^6 loading cycles, respectively. For tinless bronze and iron the inclined areas of the stress-cycle diagrams are short, which allows stresses to be chosen irrespective of the cycle number. More details on the choice of permissible stresses are given in Sect. 6.5.14.

6.5.13 Thermal Design

Worm gearings operate with high levels of heat generation as a consequence of their low efficiency factor. Oil heats up to a temperature exceeding the permissible value $[t]_{oi}$, which results in a reduction of its protective ability, a breakdown of the oil film, and the possibility of seizing in the gearing.

The power $(1-\eta)P_1$ that is wasted in the toothing and due to bearing friction, as well as due to oil stir and splatter, is converted into heat, which warms the oil, the gearing units, and the walls of the case, through which it is exported to the environment.

The thermal design of worm gearings under a set operating mode (Fig. 6.60) is performed on the basis of heat balance, i. e., the equality of heat generation Q_{fr} and heat exchange Q_{sn}.

The heat flow (heat power) W of the gearing per second is

$$Q_{fr} = 10^3(1-\eta)P_1 \,,$$

where η is the efficiency factor of the worm gearing and P_1 is the power passing through the worm (in kW)

$$P_1 = T_2 n_2/(9550\eta) \,,$$

where T_2 is in (N m) and n_2 is in min^{-1}.

The heat flow (heat exchange power) W of the outer surface of the reduction gear case per second is

$$Q_{sn} = K_t(t_{oi} - t_0)A(1+\psi) \,,$$

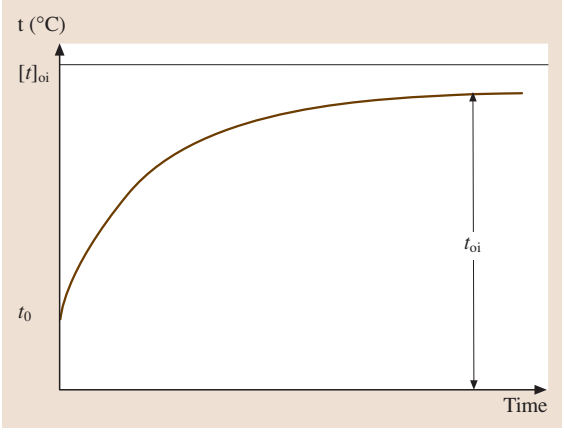

Fig. 6.60 Change in the oil temperature t_{oi} in the steady operating mode

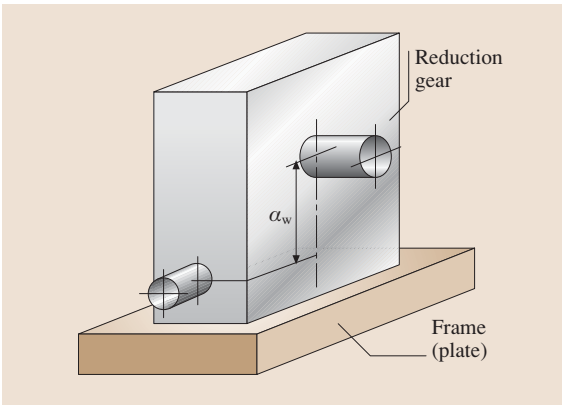

Fig. 6.61 Installation of the reduction gear on the frame (plate)

where A is the case surface area covered inside by oil or its splatter and outside by air (m^2). The bottom surface of the case is not taken into account, because air cannot freely circulate outside this area. The surface area of the cooling case A can be approximately assumed as depending on the axle base a_w (m) according to

$$A = 12a_w^{1.71} .$$

ψ is the coefficient of heat rejection from the bottom of the reduction gear to the base of the case. When mounting the reduction gear onto a metal plate or frame (Fig. 6.61), $\psi = 0–0.3$, depending on the fit of the case to the plate or frame, t_0 is the air temperature out of the case (in workshop conditions usually $t_0 = 20\,°C$), t_{oi} is the oil temperature in the case of the gearing, (°C), and K_t is the heat transfer factor defining heat flow, i.e., the heat that is transferred per second through a surface area of $1\,m^2$ for a temperature difference of 1 °C, which depends on the material of the reduction

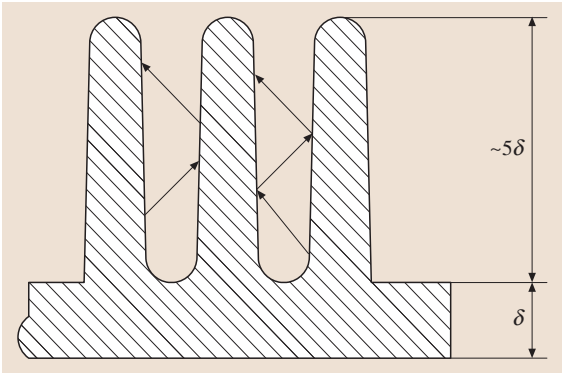

Fig. 6.62 Heat exchange between adjacent fins

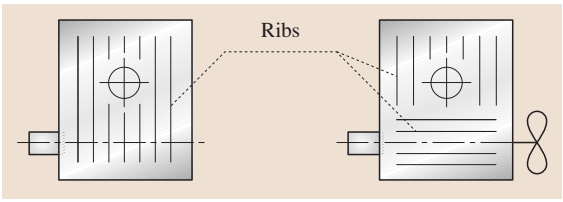

Fig. 6.63 Position of the cooling fins

gear case and the air circulation rate, i. e., the ventilation rate of the room. In the case of self-cooled cast iron one has $K_t = 12–18\,W/(m^2\,°C)$. Higher values are assumed in the case of slight roughness and clean surfaces of the exterior walls, good air circulation around the case, and intensive oil stir (due to a lower worm position).

According to heat balance condition: $Q_{fr} = Q_{sn}$, i. e.,

$$10^3(1-\eta)P_1 = K_t(t_{oi} - t_0)A(1+\psi) ,$$

hence the oil temperature t_{oi} in the case of worm gearings operated continuously without artificial cooling is

$$t_{oi} = t_0 + 10^3(1-\eta)P_1/[K_t A(1+\psi)] \le [t]_{oi} . \quad (6.13)$$

The value $[t]_{oi}$ depends on the oil grade $[t]_{oi} = 95–110\,°C$. If calculation results in $t_{oi} > [t]_{oi}$, it is necessary to increase the cooling surface A by providing cooling fins (Fig. 6.62). The fins are located upright (Fig. 6.63a), in the line of free circulated air. In calculations only 50% of the fin surface is taken into account because of the heat exchange between adjacent fins (Fig. 6.62). Artificial cooling can also be applied, e.g., using air blown onto the case with the help of a fan mounted on the worm shaft (Fig. 6.63b). The fins are positioned horizontally along the air flow direction from the fan. In this case

$$t_{oi} = t_0 + \frac{10^3(1-\eta)P_1}{[(0.65(1+\psi)K_t + 0.35K_{tv})\,A]} \le [t]_{oi} , \quad (6.14)$$

where K_{tv} is the heat transfer factor due to the air from the fan; with rotational frequencies of the worm shaft of $1000–3000\,min^{-1}$ its value falls in the range $K_{tv} = 21–40\,W/(m^2\,°C)$. In worm gearings with strong heat generation, cooling of oil with water going through the worm pipe is applied or a circulation lubrication system with a special refrigerator is used.

6.5.14 Projection Calculation for Worm Gearings

The basic data for this calculation is as follows: T_2 is the torque on the wheel (N m), n_2 is the rotational frequency of the wheel (min^{-1}), u is the gear ratio, and L_h is the service lifetime of the gearing (h).

Worm and Wheel Materials

For worms, the same steel grades are applied as for gear wheels (Table 6.1). Quenching up to hardness ≥ 45 HRC, and grinding and polishing of the worm coils are used to obtain high-quality gearings. The most practically feasible are involute worms (ZI), and promising options are nonlinear worms formed with a cone (ZK) or a torus (ZT).

Heat refining treatment with hardness ≤ 350 HB is applied for low-power (up to 1 kW) short-term gearings. The field of application of these gearings with Archimedean worms (ZA) is reduced. For power trains, involute and nonlinear worms should be used.

Materials of worm-wheel gear rings can be classified into three groups, depending on their score-resistance and antifriction behavior and whether they can be recommended for application slip velocities (Table 6.21) (Appendices 6.A Table 6.95, Table 6.97):

Group I: Tin bronze is applied for slip velocities $v_{sl} > 5$ m/s .

Group II: Tinless bronze and brass are used for slip velocity $v_{sl} = 2–5m/s$.

Group III: Soft grey iron is applied with slip velocity $v_{sl} < 2$ m/s in hand-driven devices .

As the choice of material is concerned with slip velocity, its expected value is determined previously (in m/s) as

$$v_{sl} = 0.45 \times 10^{-3} n_2 u \sqrt[3]{T_2} .$$

Permissible Contact Stresses for Material Groups

Group I – Permissible Contact Stresses.

$$[\sigma]_H = K_{HL} C_v \sigma_H^0 .$$

Here σ_H^0 is the fatigue contact point for 10^7 stress change cycles

$$\sigma_H^0 = (0.75 \text{ to } 0.9)\sigma_t .$$

Table 6.21 Mechanical characteristics of materials used for manufacture of rings of worm wheels. Casting methods are as follows: sc – spin casting, cs – chill casting, s – sand casting (in single-part production). σ_t and σ_y are, respectively, the tensile stress and the tensile yield strength for bronze (N/mm^2), and σ_{bs} is the bending strength of iron (N/mm^2)

The factor 0.9 is used for worms with hard ($H \geq 45$ HRC), ground and polished coils. The factor 0.75 is used for worms with hardness ≤ 350 HB, and σ_t is taken from Table 6.21.

The service life ratio is $K_{HL} = \sqrt[8]{10^7/N_{HE}}$, under the condition that $K_{HL} \leq 1.15$. Here $N_{HE} = K_{HE}N_k$ is an equivalent loading cycle number for the worm-wheel teeth for the whole lifetime of the gearing. If $N_{HE} > 25\times10^7$, it is assumed that $N_{HE} = 25\times10^7$.

The total cycle number of stress change is

$$N_k = 60n_2L_h\ ,$$

where L_h is the service lifetime of the gearing (h).

The values of the equivalence factors K_{HE} for typical loading conditions are given in Table 6.23.

The coefficient C_v takes the material wear rate of the wheel into account. It is assumed to depend on the slip velocity v_{sl}:

or in accordance with the formula $C_v = 1.66v_{sl}^{-0.352}$ on the condition that $C_v \geq 0.8$.

Group II – Permissible Contact Stresses.

$$[\sigma]_H = \sigma_H^0 - 25v_{sl}\ .$$

Here $\sigma_H^0 = 300\,N/mm^2$ for worms with hardness on the coil surface ≥ 45 HRC, whereas $\sigma_H^0 = 250\,N/mm^2$ for worms with hardness ≤ 350 HB.

Group III – Permissible Contact Stresses.

$$[\sigma]_H = \sigma_H^0 - 35v_{sl}\ .$$

Here $\sigma_H^0 = 200\,N/mm^2$ for worms with hardness on the coil surface ≥ 45 HRC, whereas $\sigma_H^0 = 175\,N/mm^2$ for worms with hardness ≤ 350 HB.

Allowable Bending Stresses

Allowable bending stresses are calculated for the teeth material of the worm wheel according to

$$[\sigma]_F = K_{FL}\sigma_F^0\ ,$$

Table 6.23 Coefficients of equivalence for the typical loading conditions of worm gearings

Typical condition	Equivalence factors	
	K_{HE}	K_{FE}
0	1.0	1.0
I	0.416	0.2
II	0.2	0.1
III	0.121	0.04
IV	0.081	0.016

where σ_F^0 is a fatigue bending point for 10^6 stress change cycles. For materials of groups I and II

$$\sigma_F^0 = 0.25\sigma_y + 0.08\sigma_t\ ,$$

whereas for materials of group III

$$\sigma_F^0 = 0.22\sigma_{bs}\ .$$

The service life ratio is

$$K_{FL} = \sqrt[9]{10^6/N_{FE}}\ .$$

Here $N_{FE} = K_{FE}N_k$ is an equivalent loading cycle number for the worm-wheel teeth, and N_k is the total number of stress change cycles for the whole lifetime of the gearing. If $N_{FE} < 10^6$, it is assumed that $N_{FE} = 10^6$. If $N_{FE} > 25\times10^7$, it is assumed that $N_{FE} = 25\times10^7$.

The values of the equivalence factors K_{FE} for typical loading conditions are given in Table 6.23.

Overload Stress Capacity

The overload stress capacity on the maximum static or unit peak load for materials is

Group I: $[\sigma]_{H\,max} = 4\sigma_y$; $[\sigma]_{F\,max} = 0.8\sigma_y$.
Group II: $[\sigma]_{H\,max} = 2\sigma_y$; $[\sigma]_{F\,max} = 0.8\sigma_y$.
Group III: $[\sigma]_{H\,max} = 1.65\sigma_{bs}$; $[\sigma]_{F\,max} = 0.75\sigma_{bs}$.

The Axle Base

The axle base (mm) is

$$a_w \geq K_a\sqrt[3]{K_{HV}K_{H\beta}T_2/[\sigma]_H^2}\ ,$$

where $K_a = 610$ for involute, Archimedean, and convolute worms; $K_a = 530$ for nonlinear worms. K_{HV} is a coefficient of internal dynamics, taking the value $K_{HV} = 1$ for $v_2 \leq 3$ m/s, and $K_{HV} = 1–1.3$ for $v_2 > 3$ m/s, where v_2 is the circumferential velocity of

the worm-wheel. $K_{H\beta}$ is a load concentration coefficient: under constant loading conditions $K_{H\beta} = 1$, wile under varying conditions

$$K_{H\beta} = 0.5\left(K^0_{H\beta} + 1\right) .$$

The initial load concentration coefficient $K_{H\beta}$ is found from the diagram shown in Fig. 6.64, for which the number z_1 of worm coils is determined depending on the gear-ratio u:

Main Parameters of Worm Gearings

The number of wheel teeth is $z_2 = z_1 u$, rounded to the nearest whole number. The tentative values are

For the module of the gearing

$m = (1.4–1.7)a_w/z_2$,

For the coefficient of the worm diameter

$q = 2a_w/m - z_2$.

The nearest standard value m to the calculated one is substituted into the formula for q (Table 6.26).

Series 1 should be preferred to series 2. The series 3 modules may be used for standardized reduction gears in machine-building applications.

The calculated value q is rounded to the nearest standard value (series 1 should be preferred to series 2) according to:

Table 6.27 Standard values of q

Series 1	Series 2
8.0	7.1
10.0	9.0
12.5	11.2
16.0	14.0
20.0	18.0

The minimum permissible value q from the rigidity condition of the worm is $q_{min} = 0.212 z_2$. The coefficient of displacement is

$$x = a_w/m - 0.5(z_2 + q) ,$$

which is recommended for gearings with the following worms

Involute (ZI)	$-1 \le x \le 0$,
Formed by a torus (ZT)	$0.5 \le x \le 1.5$,
Archimedean (ZA), convolute (ZN) ,	
Formed by a cone(ZK)	$0 \le x \le 1.0$.

For the helix angle of the coil worm line on the cylinder

The pitch angle	$\gamma = \arctan(z_1/q)$,
The starting angle	$\gamma_w = \arctan[z_1/(q+2x)]$,
The base angle	
(for the wormZI)	$\gamma_b = \arccos(0.940 \cos \gamma)$.

With the exception of those cases caused by drive kinematics, the worms of gearings have a coil line of the right direction. The actual gear ratio is $u_r = z_2/z_1$. The calculated value u_r must not differ from the target value by more than 4%; for standardized reduction gears for machine-building applications the tolerances are 6.3% for single gearing and 8% for double gearing .

Dimensions of the Worm and the Wheel

The dimensions of the worm and the wheel are as follows (Figs. 6.51 and 6.52):
The pitch diameter of the worm

$$d_1 = qm \ .$$

The diameter of the coil crests

$$d_{a1} = d_1 + 2m \ .$$

The diameter of the roots

$$d_{f1} = d_1 - 2.4m \ .$$

The pitch diameter of the wheel

$$d_2 = z_2 m \ .$$

The diameter of the tooth tops

$$d_{a2} = d_2 + 2m(1+x) \ .$$

The socket diameter for gearings with ZI worms

$$d_{f2} = d_2 - 2m(1 + 0.2 \cos \gamma - x) \ .$$

The socket diameter for gearings with ZN, ZA, ZK, and ZT worms:

$$d_{f2} = d_2 - 2m(1.2 - x) \ .$$

The largest diameter of the wheel

$$d_{ae2} \le d_{a2} + 6m/(z_1 + k) \ ,$$

where $k = 2$ for gearings with ZI, ZA, ZN, and ZK worms; and $k = 4$ for gearings with ZT worms.

The length b_1 of the cut worm part is

$$b_1 = 2\sqrt{(0.5d_{ae2})^2 - (a_w - 0.5d_{a1})^2} + 0.5\pi m \ .$$

The face width b_2 of the worm wheel for the gearings is:

- for ZI, ZA, ZN, and ZK worms

$$b_2 = 0.75 d_{a1} \quad \text{for } z_1 \le 3 \ ,$$
$$b_2 = 0.67 d_{a1} \quad \text{for } z_1 = 4$$

- and for ZT worms

$$b_2 = (0.7 - 0.1x) d_{a1}$$

Checking Strength Analysis of Gearings

The slip velocity in the toothing is

$$v_{sl} = v_{w1} / \cos \gamma_w \ ,$$

where $v_{w1} = \pi n_1 m(q + 2x)/60\,000$.

Here v_{w1} is the circumferential velocity on the starting diameter of the worm (m/s), $n_1 = n_2 u_r$, (min^{-1}), m is in mm, and γ_w is the initial helix coil angle. The allowable stress $[\sigma]_H$ is specified according to the rated value v_{sl}.

The design stress is determined from (6.11) by specifying the load factor as the value of $K = K_{HV} K_{H\beta}$. The circumferential velocity of the worm wheel (m/s) is $v_2 = \pi n_2 d_2/60\,000$. In the case of common manufacturing accuracy and under the condition of worm rigidity it is assumed that $K_{HV} = 1$ for $v_2 \le 3$ m/s. For $v_2 > 3$ m/s the value of K_{HV} is assumed to be equal to the coefficient K_{HV} (Table 6.8) for helical gearings with a hardness of the working tooth area ≤ 350 HB and the same accuracy degree.

The load concentration coefficient $K_{H\beta}$ is $K_{H\beta} = 1 + (z_2/\theta)^3(1 - X)$, where θ is the coefficient of worm strain (Table 6.29); X is a coefficient that takes into account the influence of the operating gearing mode on the grind of the worm-wheel teeth and the worm coils.

The values of X for typical loading conditions and cases, when the rotational frequency of the worm-wheel shaft does not change with load modification, are detailed in in Table 6.30.

The Efficiency Factor of Gearings

The efficiency factor for worm gearings is

$$\eta = \tan\gamma_w / \tan(\gamma_w + \rho) ,$$

where γ_w is a helix angle of the coil line on the pitch cylinder, and ρ is a modified friction angle determined experimentally, taking into account the relative capacity loss in the toothing, in the bearings, and due to oil stirring. The value of the friction angle ρ between a steel worm and a bronze (brass, iron) wheel depends on the slip velocity v_{sl}:

Table 6.31 Angle friction values ρ depending on the slip velocity v_{sl}

v_{sl} (m/s)	ρ	
0.5	3°10′	3°40′
1.0	2°30′	3°10′

7.0	1°00′	1°30′
10	0°55′	1°20′
15	0°50′	1°10′

The lower value of ρ is for tin bronze and the higher one is for tinless bronze, brass, and iron.

Toothing Forces (Fig. 6.57)

The peripheral force on the wheel, which is equal to the axial force on the worm, is

$$F_{t2} = F_{a1} = 2\times10^3 T_2/d_2 .$$

The peripheral force on the worm, which is equals to the axial force on the wheel, is

$$F_{t1} = F_{a2} = 2\times10^3 T_2/(d_{w1}u_2\eta) .$$

The radial force is

$$F_r = F_{t2}\tan\alpha/\cos\gamma_w .$$

For the standard angle $\alpha = 20°$, $F_r = 0.364F_{t2}/\cos\gamma_w$.

Bending Stress Analysis of Wheel Teeth

The calculated bending stress is determined from (6.12), where K is a load factor, the values of which are computed in the paragraph *Checking Strength Analysis of Gearing*, and Y_{F2} is the form factor of the wheel tooth, which is chosen depending on the equivalent tooth number $z_{v2} = z_2/\cos^3\gamma_w$:

Checking Strength Analysis of Worm-Wheel Teeth under the Action of Peak Load

The action of the peak load is estimated by the overload factor $K_{load} = T_{max}/T$, where T is the nominal torque. The contact strength analysis under the short-term action of the maximum torque is

$$\sigma_{H\,max} = \sigma_H\sqrt{K_{load}} \le [\sigma]_{H\,max} \ .$$

The bending stress analysis of the worm-wheel teeth under the action of the maximum torque is

$$\sigma_{F\,max} = \sigma_F K_{load} \le [\sigma]_{F\,max} \ .$$

The allowable stresses $[\sigma]_{H\,max}$ and $[\sigma]_{F\,max}$ are taken from paragraph *Overload Stress Capacity*.

Thermal Design

The worm-and-wheel gearbox is checked on heating in connection with the low efficiency factor and high heat release. The power (W) on the worm is $P_1 = 0.1T_2n_2/\eta$.

The reheating temperature of oil (in the casing) under set thermal conditions without artificial cooling is determined from (6.13); with fan cooling it is determined from (6.14).

6.6 Design of Gear Wheels, Worm Wheels, and Worms

6.6.1 Spur Gears with External Toothing

The form of a gear wheel can be flat (Fig. 6.65a,b) or with a salient hub (Fig. 6.65c). Rarely (in single-reduction units), the wheel is made with a hub, which is salient on both sides [6.12, 48–56].

In Fig. 6.65 elementary forms of the wheels that are produced in *single-part small-quantity production* are shown. Wheels with small diameters are manufactured from a bar; in the case of large diameters the workpieces are produced in open forging with a subsequent turning process. To replace the requirements for precise machining with cutting, recesses are made on the wheel disks (Fig. 6.65b,c). As a rule, for diameters $d_a < 80$ mm, these recesses are not made (Fig. 6.65a).

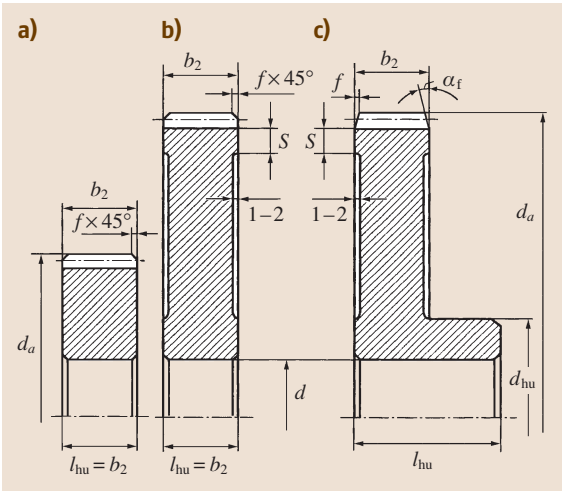

Fig. 6.65a–c Structural forms of the wheels produced in small-lot production. **(a,b)** Plane, **(a)** with a salient hub

It is advisable to assume that the length l_{hu} of the wheel slot is equal to or longer than the face width b_2 ($l_{hu} \ge b_2$). The standard hub length is adjusted by using that obtained as a result of calculation of the spline connection, with a tightness or key joint, which was chosen for torque transfer from the wheel to the shaft, and (with slot diameter d)

$$l_{hu} = (0.8–1.5)d \ , \quad \text{usually} \quad l_{hu} = (1.0–1.2)d \ ,$$

where $l_{hu} > b_2$, the projection of the hub, is positioned in the axial force direction F_a of the toothing.

The diameter d_{hu} is set depending on the material of the hub: for steel $d_{hu} = (1.5–1.55)d$, for iron $d_{hu} = (1.55–1.6)d$, and for light alloys $d_{hu} = (1.6–1.7)d$; lower values are used a spline connection of a wheel with a shaft, whereas higher values are used for a key joint and pressure coupling joint.

The cutting width S of the gear ring is assumed to be

$$S = 2.2m + 0.05b_2 \ ,$$

where m is the toothing modulus (mm).

The bevels are made on the ring ends (teeth and crown angle): $f = (0.5 - 0.6)m$, which are rounded to a standard value (see below).

On the spurs the bevel is made on-the-miter $\alpha_f = 45°$; on helical and herring-bone wheels with a working surface hardness of less than 350 HB it is made on-the-miter $\alpha_f = 45°$ (Fig. 6.65a,b), and with higher hardness $\alpha_f = 15–20°$ (Fig. 6.65c).

Pointed edges on the hub ends are also blunted with the bevels, the dimensions of which are assumed to be:

Table 6.32 Facet size f depending on d

d (mm)	f (mm)
20–30	1.0
30–40	1.2
40–50	1.6
50–80	2.0
80–120	2.5
120–150	3.0
150–250	4.0
250–500	5.0

In the case of *lot production* the workpieces of the wheels are obtained from a bar through open forging as well as through forging in dies. Yearly output of wheels of more than 50 pieces forged in elementary one-sided pad dies is economically feasible. In this case, the form of the gear wheels is designed according to the type shown in Fig. 6.66a,b.

With a yearly output of more than 100 items, double-sided dies are used. In this case, the form of the wheel is designed according to Fig. 6.67a,b. The wheel billet after die forming is shown by a fine line. For easy removal of the billet from the die, the forming gradients are assumed to obey $\gamma \geq 7°$ and the rounded radii to obey $R \geq 6$ mm. The disk thickness is

$$C \approx 0.5(S + S_{hu}) \geq 0.25 b_2 \,, \quad \text{where}$$

$$S_{hu} = 0.5(d_{hu} - d) \,.$$

For reduction of the influence of heat treatment on geometric accuracy the gear wheels are made to be massive: $C = (0.35–0.4)b_2$.

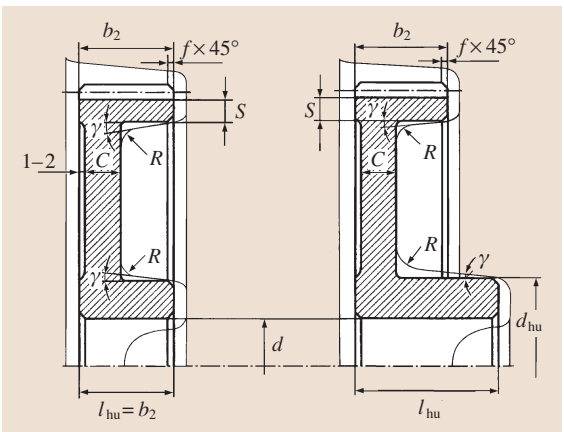

Fig. 6.66a,b Structural forms of wheels where workpieces are made through open forging or in one-sided dies. **(a)** With a nonsalient hub, **(b)** with a salient hub

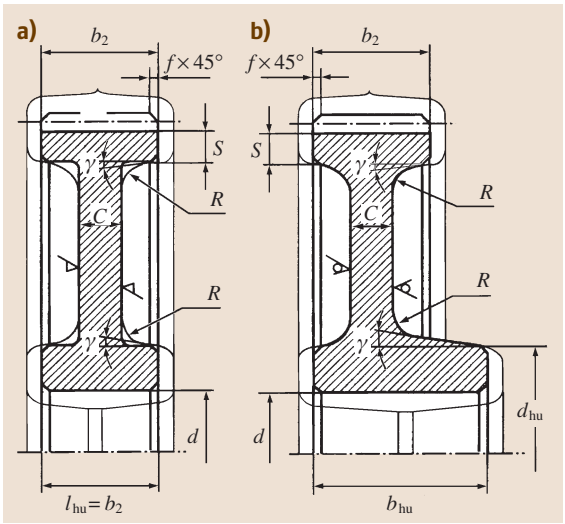

Fig. 6.67a,b Structural forms of wheels where workpieces are made in double-sided dies. **(a)** With a nonsalient hub, **(b)** with a salient hub

Plastic forming conditions of metal are improved if the grooves in the wheel disks are made as illustrated in Fig. 6.68. The rounded radii are assumed to be $R \geq 20$ mm, and the forming gradients are $\gamma \geq 12°$.

Depending on the ratio of the wheel dimensions, the grooves in the disks are shaped with one radius arc R (Fig. 6.68a) or with two arcs and a straight line segment (Fig. 6.68b). In this case, the disk thickness is $C \approx 0.5 b_2$.

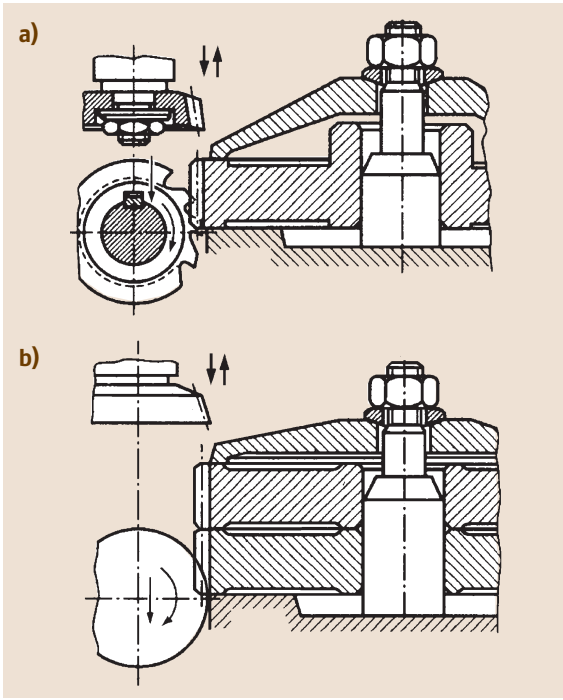

Fig. 6.69a,b Position of the workpiece for teeth cutting of one wheel (a) of the *package* of two and more wheels (b)

In automobile and aircraft construction, wheels are manufactured with a thinner disk ($C = 0.25b_2$); four to six holes of major diameter are made in the disk,

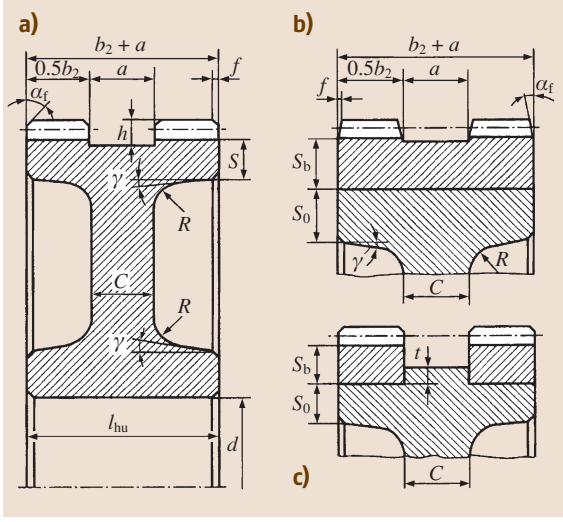

Fig. 6.70a–c Structural forms of the chevron gear. (a) One-piece, (b) and (c) composite

and the rounded radii are assumed to be minimum. Gear wheels rotating with a relatively high frequency ($n \geq 1000\,\mathrm{min}^{-1}$) are treated over their entire surface (Fig. 6.67a) and balanced.

The base surfaces in tooth *cutting* are the surface of the central bore and of the gear-ring ends. A tooth cutting layout chart for a wheel is shown in Fig. 6.69a. Output capacity increases during tooth cutting of a set of two or more wheels (Fig. 6.69b). To provide a juxtaposition of the gear-ring ends it should be mentioned in the specification that the hub end must not project beyond the gear-ring end.

Herring-bone gears (Fig. 6.70a–c) are distinguished from other cylindrical gears by their increased width. Most often herring-bone gears are manufactured with a flute in the middle, which is used for the runout of the worm hob that cuts the teeth. The width a of the flute is determined according to the diameter of the cutter depending on the module m:

Table 6.33 The dimension a of the flute for the herring-bone gears

3	42
3.5	48
4	53
5	60
6	67
7	75
8	85
10	100

The dimensions (mm) of other structural components of herring-bone gears are

$$l_{hu} = b_2 + a\,;$$
$$C = (0.3\text{–}0.35)(b_2 + a)\,;$$
$$S = 2.2m + 0.05(b_2 + a)\,;$$
$$h = 2.5m\,;$$
$$S_b \approx 6m\,;$$
$$S_0 = (1.0\text{–}1.1)S_b\,;$$
$$t = 0.35S_b \geq 3\,\mathrm{mm}\,.$$

To decrease consumption of high-quality steel, wheels are sometimes produced to be stackable. Gear rings from alloy steel are pressed on a center made of carbon structural steel (Fig. 6.70b). The structure of a composite wheel with two gear rings is shown in Fig. 6.70c.

6.6.2 Spur Gears with Internal Toothing

The dimensions d_{hu}, l_{hu}, S, and f of the main structural components (Fig. 6.71) of a wheel with internal toothing are taken according to the ratios for wheels with external toothing. The embodiment of wheels with internal toothing can be achieved according to one of the choices shown in Fig. 6.71a,b. They differ in the hub position relative to the gear ring: in Fig. 6.71a the hub is positioned inside the wheel, which provides better operating conditions of the toothing as compared with the choice illustrated in Fig. 6.71b, in which the hub is outside the gear ring. The version shown in Fig. 6.71a can be used when the distance from the outer surface of the hub to the internal surface of the gear ring is greater than the external diameter D_e of the shaping cutter with which the teeth are produced. Moreover, it is required that the pinion which will mesh with the wheel can be easily positioned between the gear ring and the hub. The diameter D_e of the shaping cutter, the dimension a of the flute for the outlet of the shaping cutter and the chip disposability that form in tooth slotting, for the spurs take values depending on the module:

Table 6.34 The diameter D_e of the shaping cutter and the dimension a of the flute depending on the module m

3.5	56	
4	112	7
5	110

The flute dimension a of helical wheels with internal toothing is increased by 30–40%. The depth of the flute in every case is assumed to be $h = 2.5\,m$, and the disk thickness C is $(0.3–0.35)b_2$.

6.6.3 Gear Clusters

Gear wheels with two, three, or four gear rings are applied in gearboxes of cars, tractors, and metal-cutting machine tools. These structures are called *gear clusters*. They are produced according to the form shown in Fig. 6.72a–d. Between the single gear rings flutes for the runout of the cutting tool (shaping cutter) are in-

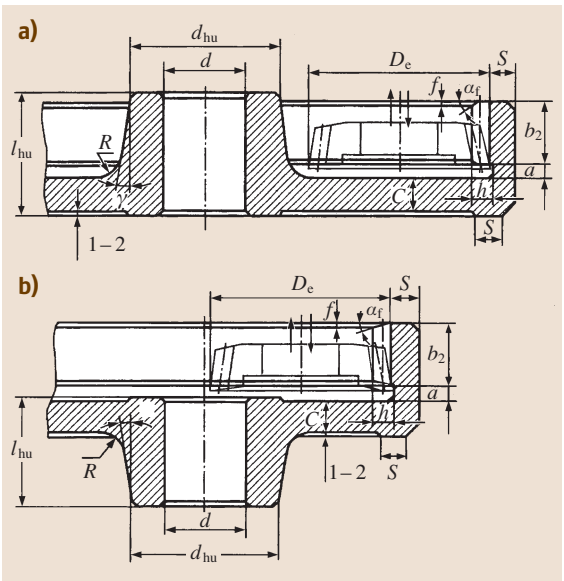

Fig. 6.71a,b Structural forms of the wheel of the internal toothing with hub position: **(a)** inside the wheel, **(b)** out of the contour of the gear ring

cluded. The flute width a is calculated depending on the diameter D_e of the shaping cutter (Sect. 6.6.2). The flute depth is $h = 2.5m$.

For the location of transferable lever or forks between the gear rings of the wheels circular grooves are made with a width that is more than a and with tolerance range H11, which is provided by grinding of the groove side walls in the case of wheel quenching. The teeth of the gear cluster rings from the entry side in the toothing are beveled $f = 0.6–0.7m$ on-the-miter $\approx 15°$ (Fig. 6.72a) and rounded (section A–A). Skewing is carried out along the curvilinear profile (remote element B, Fig. 6.72b). The gear ring teeth of mating gear wheels are also beveled and rounded from the entry side of the toothing.

The tooth work surfaces of high-accuracy gears (fifth and sixth accuracy degrees) are ground. For the exit of the grinding wheel a wide groove is needed, and therefore large axial dimensions of the gear clusters are used. To reduce these dimensions clusters are manufactured to be *stackable* through the use of key joints (Fig. 6.73a) or adhesive joints (Fig. 6.73b). In the latter case, helical grooves with mutually antithetical direction (remote element A) are cut on the mated surfaces for better toothing.

For a large cluster length ($l > 1.5d$) multispline (keyway) broaching is complicated, so the length of the opening is reduced with a recess in the middle part (Figs. 6.72b,d and 6.73b).

6.6.4 Bevel Wheels

The structural configurations of bevel wheels with an outer diameter of tooth tops of $d_{ae} \leq 120$ mm are shown in Fig. 6.74. With a pitch cone angle of $\delta \leq 30°$ the wheels are manufactured according to Fig. 6.74a. With an angle of $\delta \geq 45°$ they are manufactured according to Fig. 6.74b. If the pitch cone angle is 30–45°, both bevel wheel configurations are allowed. The hub dimensions d_{hu} and l_{hu} are determined from the ratios for cylindrical wheels. It is recommended to assume $l_{hu} = (1.2–1.4)d$.

Figure 6.75 shows bevel wheel configurations with an outer diameter of the tooth tops of $d_{ae} > 120$ mm.

For the approach illustrated in Fig. 6.75a the wheels are designed by *single-part* and *small-lot production*. Wheels with smaller diameters are produced from plain bars; wheels with greater diameters are manu-

factured by open forging with subsequent turning. For the approach illustrated in Fig. 6.75b bevel wheels are designed for *high-volume applications*. The fine lines show a billet that results from forging in double-sided dies. The thickness C is determined from the ratios for cylindrical wheels.

With any wheel configuration the external tooth angles are blunted by a bevel of $f \approx 0.5 m_{te}$, when manufactured along the outer diameter d_{ae} parallel to the axis of the fit opening. The width S (mm) is assumed to be $S = 2.5 m_{te} + 2$ mm. A gear-ring end with width $b_1 \approx S$ is used for billet mounting for teeth cutting. Recesses with a depth of 1–2 mm are made to reduce the requirements for precise machining.

With an outer diameter of $d_{ae} > 180$ mm the wheels are sometimes manufactured to be stackable in order to save expensive steel. Depending on the wheel dimensions, the gear ring is fastened to the center by bolts, which are installed without clearance *for reaming* (Fig. 6.76a) or to the shaft flange by rivets (Fig. 6.76b). The gear ring is positioned so that the axial force acting in the toothing is directed towards the bearing flange. Centering of the gear ring is mostly carried out according to the diameter D (Fig. 6.76), but not D_0; here the centering accuracy is higher (for the same fit, the tolerance on the dimension D of the gear ring and the center, as well as the possible fit clearance, are lower). According to the technology used it is easier to obtain a precisely fitting ring opening, which is smooth, without a ledge, with a lower timetable for surface processing of a smaller diameter. Composite bevel wheels of the main gears in many cars have centering of the gear rings according to the diameter D.

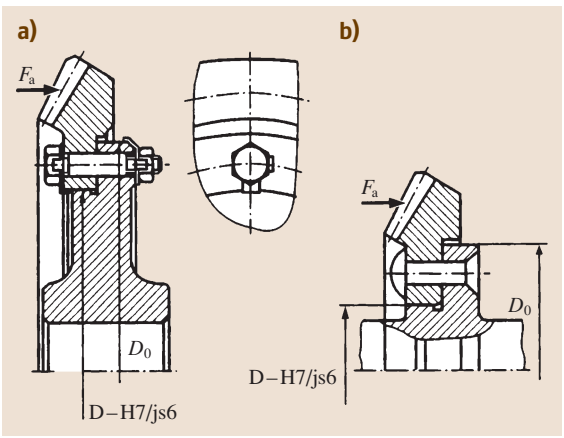

Fig. 6.76a,b Structural forms of composite conical gears using (a) a bolted connection and (b) a rivet joint

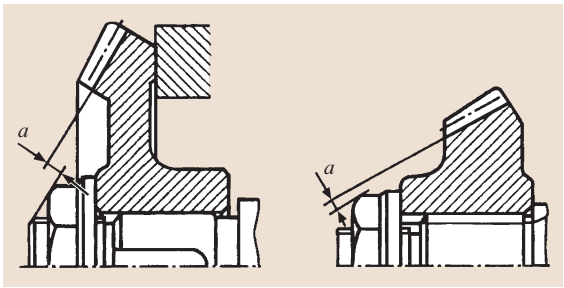

Fig. 6.77 Ensuring free outlet of the tool by cutting of circular teeth with a cutter head

However, centering according to D_0 results in higher joint rigidity, so as well as centering according to D such structures are applied where the centering of the gear ring is carried out in accordance with D_0.

Bevel wheels with circular teeth, which are cut with cutter heads by fastening the billet into the work holder, have wide application. It is necessary to include easy runout for the tool, with dimension of $a \geq 0.5 m_{te}$ (Fig. 6.77), where m_{te} is the external peripheral module.

6.6.5 Gear Shafts

There are two pinion embodiments of gearings: a single whole version with the shaft (*gear shaft*) and separately from it (*shell pinion*). The quality (rigidity, accuracy, etc.) of the gear shaft is higher, but production cost is lower than that of the shaft and shell pinion, so all the pinions of reduction gears are manufactured as a single whole with the shaft. Shell pinions are applied, for ex-

ample, in cases in which, under operating conditions, the pinion must be mobile along the shaft axis.

Figure 6.78 shows the structures of the gear shaft: (a) for high speed (with a small gear ratio) and (b) for low speed (countershaft) of the steps of the double-reduction gear. Both structures provide tooth cutting with easy exit of the tool.

With high gear ratios the outer pinion diameter, as a rule, differs only slightly from the shaft diameter, and the gear shafts are designed as illustrated in Fig. 6.79a,b. In this case, the teeth are cut on the surface of the shaft. The exit of the milling cutter is determined graphically according to its outer diameter D_f, assumed to be dependent on the module m:

Table 6.35 The outer diameter D_f on the milling cutter depending on the module m

m (mm)	D_f (mm) with accuracy degree	
	7	8–10
2–2.25	90	70
2.5–2.75	100	80
3–3.75	112	90
4–4.5	125	100
5–5.5	140	112
6–7	160	125

It is advisable to avoid cutting-in pinions, because in this case gear milling and tooth grinding are difficult. If possible, entry of the tool from the side of the shaft shoulder should be incorporated (Fig. 6.79b). A version of the tapered gear shaft is shown in Fig. 6.80.

6.6.6 Worm Wheels

Most often worm wheels are manufactured to be stackable: the center is made of gray iron or steel, the gear ring is made of bronze. The junction of the ring with the center must provide the transmission of high torque and relatively low axial force.

The design of the worm wheel and the technique used to bond the ring to the center depend on the numbers required. In single-part and small-lot production, when the annual numbers are less than 50 items, and with small wheel dimensions ($d_{ae2} < 300$ mm), the gear rings are joined to the center with an interference fit. For constant rotating sense of the worm wheel a collar is included where the axial force is directed (Fig. 6.81a). The junction of the gear ring with the center does not need a collar (Fig. 6.81b). In joints with relatively small interference the screws (usually three along the circle) are mounted in the butt of the gear ring and the center.

In the case of large wheel dimensions ($d_{ae2} \geq 300$ mm) mounting of the gear ring to the center can be carried out with bolts installed without clearance (Fig. 6.81c). In this case, the gear ring is previously centered according to the diameter D; mating of the centering surfaces is done according to the transition fit. Finally, the location of the gear ring is determined by mating of its opening with bolt bodies mounted without clearance. In this construction it is necessary to include reliable nut fastening; *retaining and spring-lock washers are not recommended*.

The rotational frequency of worm wheels is, as a rule, not high, and balancing is not carried out. Thus, inactive areas of the rim, disk, and hub of the wheel are left unprocessed and beveled with large rounded radii. Sharp edges on the ring ends are blunted with a bevel of $f \approx 0.5$ m with rounding to a standard value, where m is a module of the toothing. The dimensions of other structural components are

$$S \approx 2m + 0.05b_2\,; \quad S_0 \approx 1.25S\,;$$
$$C = (1.2\text{–}1.3)S_0\,; \quad h \approx 0.15b_2; \quad t \approx 0.8h\,.$$

Other structural components of worm wheels should be assumed to be the same as for cylindrical wheels (Sect. 6.6.1).

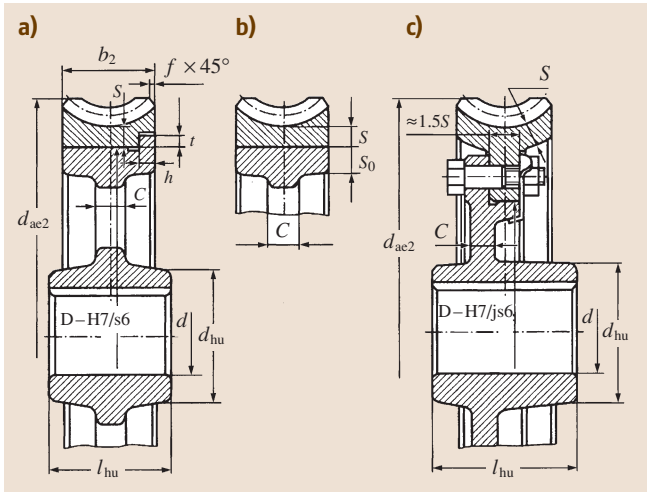

Fig. 6.81a–c Embodiments of the composite worm wheel using a joint with interference **(a,b)** and bolted connection **(c)** ▶

In the case of lot production (annual numbers of more than 100 items) it is economically sound to apply a build-up ring, as the working accuracy requirements of the mated surfaces of the ring and the center reduce, presses are not needed for joining, and screw fixing is not required.

An iron or steel center heated to 700–800 °C is put into the die, warmed to 150–200 °C and coated with molten bronze. Upon cooling there is interference between the center and the ring, caused by shrinkage of the freezing of the molten metal of the ring. Six to eight hollows of different forms are included on the rim of the center; after building-up, lugs form that additionally transfer both the peripheral force as well as the axial force. The thickness of the build-up ring is assumed to be $S \approx 2m$. The outer surface of the center is obtained by cutting or chill casting.

Figure 6.82 shows configurations of worm wheels where the centers are obtained by cutting. A concave surface of the center (Fig. 6.82a,b) is obtained by turning. The difference between these two versions lies in the form of the transverse grooves obtained by means of radial infeed of the milling cutter: (a) a disk cutter (the rotation axis of the cutter is perpendicular to the rotation axis of the wheel), and (b) a circular cutter (the rotation axis of the cutter is parallel to the rotation axis of the wheel). The dimensions of the grooves are $b \approx (0.3–0.5)b_2$ and $h = (0.3–0.4)b$. Both variants are equivalent in fabricability and labor output ratio. According to Fig. 6.82c the hollows on the rim of the center are drilled.

Figure 6.83 shows wheel configurations where the centers are obtained by chill casting. Machining of the outer surface is not carried out. Before the bronze is poured the center is cleaned of oil and oxide films by using chemical treatment. The variant shown in Fig. 6.83a, the chill mold design, is simpler, consisting of two parts only. In the variants shown in Fig. 6.83b and c the chill mold includes single segments, the number of which corresponds to the number of grooves. This elaborate

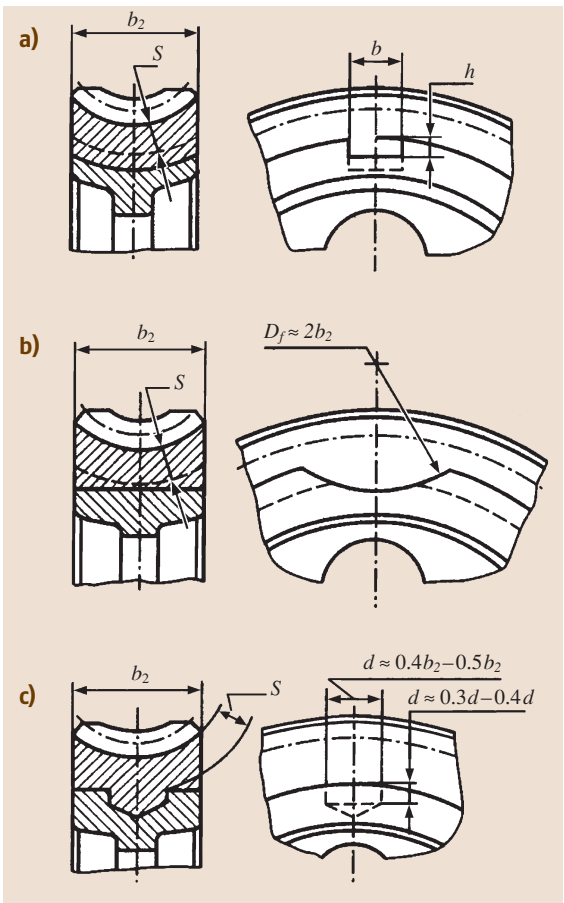

Fig. 6.82a–c Embodiments of the joints of surfaced gear rings with a center on whose rim there are valleys that are received through machining with **(a)** a disk cutter and **(b)** a circular cutter, **(c)** through drilling ▶

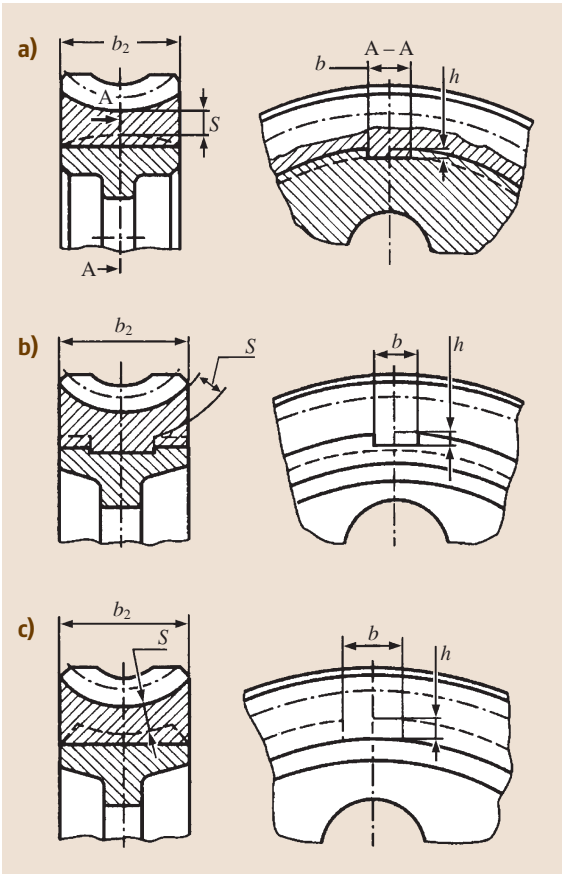

Fig. 6.83a–c Embodiments of the joints of the surface rings with a center received **(a)** by means of chill casting consisting of two parts segments **(b,c)** corresponding to the number of the grooves

design of the chill mold is due to the necessity to extract the billet after metal solidification. The dimensions b and h of the center grooves are assumed to be the same as in cutting.

The teeth of worm wheels have a concave form. This is why such a form of the outer center surface that follows the form of the teeth is optimal, as shown in Fig. 6.82a,b or in Fig. 6.83b,c. However, in practice other configurations are equally widely applied. With any configuration of the gear ring, machining and tooth cutting are carried out after joining of the ring with the center. The dimensions of other structural components are assumed to be given according to the relations given in Sect. 6.6.1

6.6.7 Worms

Worms are manufactured from steel, and mostly as a part of the shaft. The geometry of the worm including the length b_1 of the cut part and approximate distance l between the bearings is known from calculations and the layout diagram of reduction gears.

The dimensions of the salient from the reduction gear end of the worm shaft are adjusted using the appropriate dimensions of the motor shaft and joint sleeve. Then the shaft diameter is determined at the bearing seat.

Figure 6.84 shows possible structures of cylindrical worms. One of the main requirements is the provision of high worm rigidity. Toward this end the distance between the bearings is made as small as possible.

The diameter of the worm shaft in the uncut part is assigned to be of such kind to provide, as far as pos-

sible, easy exit of the tool during coil processing and the necessary value of the thrust collar for the bearing. In Fig. 6.84a,b the diameter of the worm shaft before the cut part meets the condition of easy exit of the tool during coil processing. In Fig. 6.84a the collar height is both sufficient for the bearing thrust, and according to Fig. 6.84b, is low. Thus, for the bearing thrust a special collar is included.

Worms with a smaller diameter must be produced in accordance with Fig. 6.84c. In this case, the thrust collars are made at the bearing seats according to Fig. 6.84b as well as Fig. 6.84c.

Globoidal worms (Fig. 6.85) differ structurally from cylindrical ones in the form of the cutting area and the diameters of the bearing journals, which are comparable to the worm diameter. The other elements of this kind of worm are designed in the same way as for cylindrical worms.

6.6.8 Design Drawings of Gear and Worm Wheels: The Worm

The overall data for the design drawing development is given in Sect. 6.9.7. The design drawing shows an image component with the required dimensions, maximum dimensional deviations, form and position tolerances, roughness parameters, and specifications. In the right upper corner of the design drawings there is a table for the parameters of gear rings and worm coils. Figures 6.86–6.89 show drawings for cylindrical and bevel wheels, and worms and worm wheels, respectively.

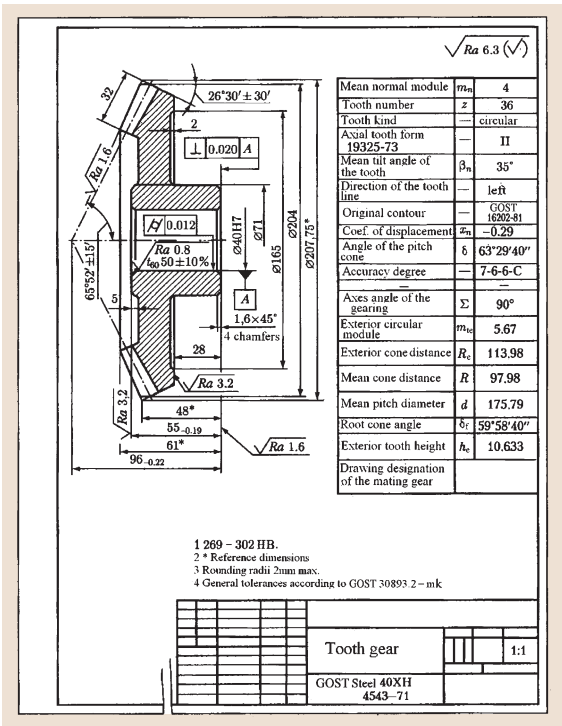

Fig. 6.87 Execution example of the working drawing of a conical gear

6.6.9 Lubrication of Tooth and Worm Gears

For lubrication of gearings the *oil bath system* is widely used. Oil is poured into the case of the reduction gear or the gearbox in such a way that the wheel rings are sunk into it. During rotation the wheels carry the oil and spray it inside the case. The oil falls on the inner walls of the case, from where it trickles down to the bottom again. A suspension of oil particles forms in the air inside the case and covers the surface of the details located inside the case.

Oil bath lubrication is applied when using a circumferential velocity of gear wheels and worms of 0.3–12.5 m/s. At higher velocities centrifugal forces throw oil off the teeth, and insufficient lubrication remains for toothing operation. Furthermore, under these conditions, the power power associated with oil stirring and temperature rises increases considerably. With circumferential velocities greater than 12.5 m/s circulating spray lubrication is used, where the toothing is lubricated by an oil jet created by a pipe nozzle under the pressure produced by a pump. The choice of lubricant is based on the operating experience of the corresponding machines.

Oils are mainly used for this application. The principle for the choice of the oil grade is as follows: the higher the circumferential velocity of the wheel, the lower the oil body; the higher the contact pressures in the toothing, the higher the body of the oil. Thus the required oil body is determined based on the contact stress and circumferential velocity of the wheels (Table 6.36). In Russia the oil grade for lubrication of tooth and worm gears is chosen according to Table 6.37.

In Russia the designation of machine oils consists of four groups of symbols, which indicates: (1) industrial (И), (2) according to purpose (Л, easily loaded units; Г, hydraulic systems; И, plain slideways; Т, heavily loaded units), (3) according to operating abilities (A, untreated oil; B, oil with antioxidant additives and stabilizers; C, oil with antioxidant and load-carrying additives and stabilizers; D, oil with antioxidant, load-carrying, and antiscoring additives and stabilizers; E, oil with antioxidant, load-carrying, antiscoring, and anti-"stick-slip" additives and stabilizers), and (4) the numerical kinematic viscosity class.

6.7 Planetary Gears

6.7.1 Introduction

Planetary gears are gears that have gear wheels with moving axes. The most commonly used *ordinary single-row planetary gear* (Fig. 6.90) consists of a central wheel a with external teeth, a stationary central wheel b with internal teeth, planetary pinions g, wheels with external teeth interlocking simultaneously with a and b (here the planetary pinion number $n_w = 3$), and carriers h, to which the axes of the planetary pinions are fixed. The carrier is joined to the low-speed shaft. In planetary gearing *one wheel is locked* (connected to the case) [6.57–69].

With the stationary wheel b rotation of the wheel a causes rotation of the planetary pinion g relative to its own axis, and running of the planetary pinion along the wheel b moves the pinion axis and turns the carrier h. Thus the planetary pinion rotates relative to the carrier and rotates with the carrier around the central axis, i. e., it performs a motion similar to that of the planets, hence the name.

With wheel b stationary the movement is mostly transmitted from wheel a to the carrier h; transmission of the motion from the carrier h to the wheel a is possible.

Master links are links that are loaded with the external torque. For the gearing shown in Fig. 6.90 the master links are a, b, and h, i. e., two central wheels ($2K$) and a carrier (h). Such gearings are conventionally designated $2K$–h. The external torques on the links are denoted by T_a, T_b, and T_h. In planetary gears not only cylindrical wheels but also bevel wheels with a straight or oblique tooth can be applied.

If all the links in the planetary gear are mobile, i. e., both wheels and carrier, the gearing is called *differential*. With the help of the differential mechanism the

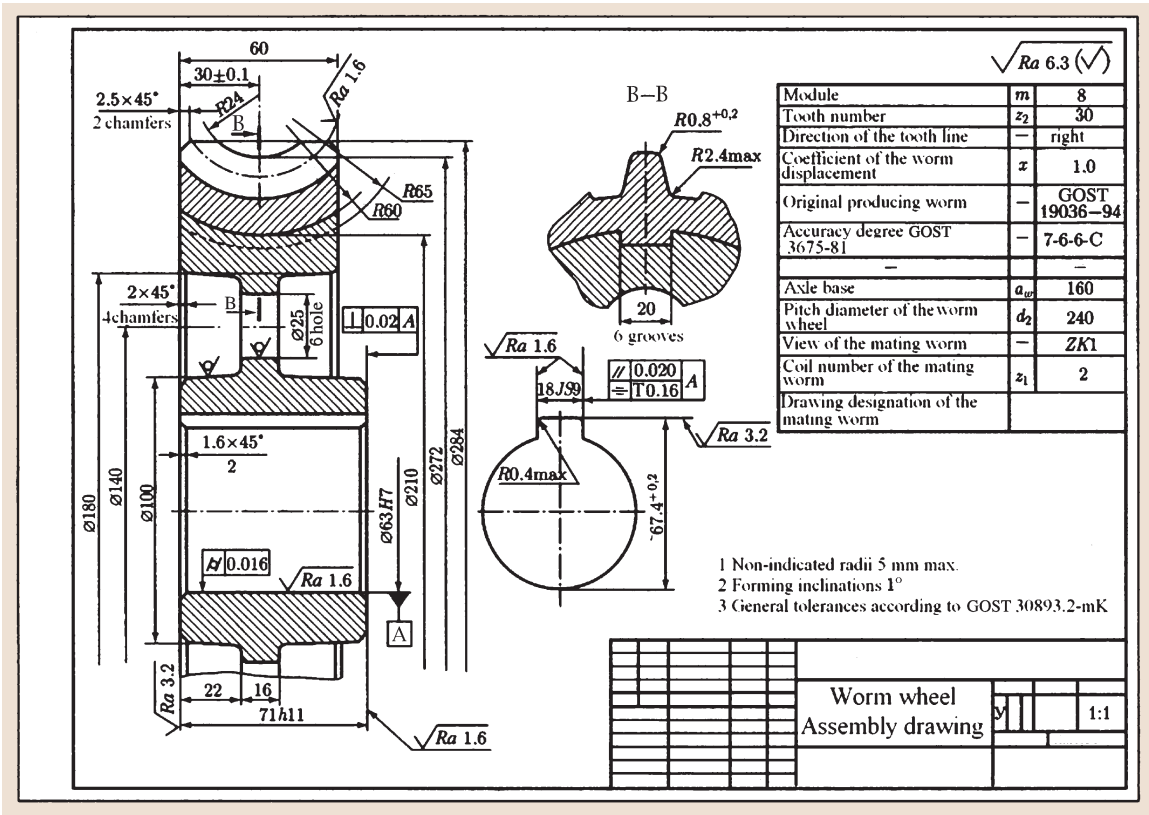

Fig. 6.89 Execution example of the working drawing of a worm wheel

motion of two links can be summed to one, or the motion of one link can be distributed between two links. For example, in the differential of the back axle of an automobile, the motion from the carrier h is transmitted simultaneously to wheels a and b, which allows one wheel to rotate more quickly than the other during turning.

The advantages of planetary gears are as follows:

1. Small dimensions and weight as a result of power transmission in several flows that are numerically equal to the number of planetary pinions. The load in each toothing is reduced by several times.
2. Convenience of assembly in machines due to the coaxiality of the drive shaft and the driven shaft.
3. Operation with less noise than standard gearings, due to the small wheel dimensions and force locking in the mechanism. In the case of symmetrical arrangement of the planetary pinions, the forces in the gear are mutually balanced.
4. Small loads on the shafts and bearings, which simplifies bearing construction and reduces losses.
5. Availability of high gear ratios with a small number of gear wheels and small dimensions.

The disadvantages are as follows:

1. Greater requirements of accuracy of manufacture and gearing mounting.
2. Greater number of details (bearings), with more complicated assembly.
3. To cut wheels with internal teeth, shaping cutters and gear shapers are needed, the base of which is smaller than for gear hobbers.

The planetary gear is applied as a reduction gear in power trains and devices, gearboxes where the gear ratio is changed by means of alternate braking of the different links (e.g., of the carrier or one of the wheels), and in differential gears in cars, tractors, machines, and devices. Planetary gears that are integrated with electric

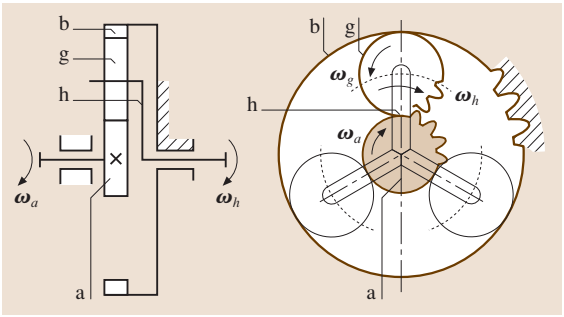

Fig. 6.90 Construction diagram of a one-row planetary gear

motors (e.g., reduction gear motors, hub motors) are often used.

6.7.2 Gear Ratio

For determination of the planetary gear transmission ratio the *method of the carrier stop* (Villis's method) is used. According to this method an additional rotation with angular carrier velocity ω_h is mentally imposed on the whole planetary gear, but in the reverse direction. Then the carrier acts as if stopped and the fixed wheel is released. There is also a so-called *reversed mechanism* representing a common nonplanetary gear, where the geometrical axes of all the wheels are stationary. Here the planetary pinions become intermediate wheels, which do not influence the transmission ratio of the mechanism. The transmission ratio in the reversed mechanism is determined as in case of a double-reduction gear with one external and one internal toothing.

The gear ratio relator has an essential value here. The transmission ratio u is assumed to be *positive* if the driven units and the drive units rotate in the same direction in the reversed mechanism, and *negative* if they rotate in different directions. Thus, for the reversed mechanism of the gear shown in Fig. 6.90 we have

$$u = u_1 u_2 = \left(-\frac{\omega_a}{\omega_g}\right)\left(\frac{-\omega_g}{-\omega_b}\right) = \left(-z_g/z_a\right)\left(z_b/z_g\right) = -z_b/z_a \,, \qquad (6.15)$$

where the tooth numbers of the appropriate wheels are indicated by z. In the reversed mechanism *the minus sign shows that wheels g and b rotate in the reverse direction with respect to wheel a*.

On the other hand, the imaginary stopping of the carrier in the motion transmission from a to b is equal to the subtraction of its angular velocity ω_h from the angular velocities of the wheels. Then for the reversed mechanism of this gear we have

$$u^h_{ab} = (\omega_a - \omega_h) \,/\, (\omega_b - \omega_h) = -z_b/z_a \,,$$

where $(\omega_a - \omega_h)$ and $(\omega_b - \omega_h)$ are, respectively, the angular velocities of the wheels a and b relative to the carrier h, and z_a and z_b are the tooth numbers of wheels a and b. The superscript "h" in the designation of the transmission ratio corresponds to the designation of the nonrotating unit, and the subscripts "a" and "b" correspond, respectively, to the drive element and the driven element. In this way the transmission ratio is determined from (6.15) for the planetary gear, which has a stationary carrier h ($\omega_h = 0$), a drive wheel a, and a driven wheel b. In the planetary gear any main element can be stopped.

For the planetary gear where the wheel b is fixed to be stationary in the case ($\omega_b = 0$), the wheel a is the drive, and the carrier h is driven. Thus from (6.15) we have

$$(\omega_a - \omega_h)/(0 - \omega_h) = -z_b/z_a \quad \text{or} \quad (-\omega_a/\omega_h) + 1 = -z_b/z_a \,.$$

It then follows that

$$u^b_{\mathrm{ha}} = \omega_a/\omega_h = 1 + z_b/z_a \,. \qquad (6.16)$$

For the planetary gear where the wheel b is fixed to be stationary in the case ($\omega_b = 0$), the carrier h is the drive, and the wheel a is driven. We then have

$$u^b_{ah} = \omega_h/\omega_a = 1/(\omega_a/\omega_h) = 1/(1 + z_b/z_a) \,.$$

Thus, depending on the stopped link, the planetary gear transmission ratio can take on different values, a characteristic of planetary gears that is used in gearboxes.

6.7.3 Planetary Gear Layouts

There are many different kinds of planetary gears. The *single-row gear* (Fig. 6.90) is most widely applied. This gear ($2K$–h) is physically simple and has small dimensions. It is applied in power and auxiliary drives. The efficiency factor of the gear is $\eta = 0.96$–0.98 with $u^b_{ah} = 3$–8.

To obtain higher transmission ratios *multiple* planetary gears are used in power drives. Figure 6.91a shows a planetary gearing consists of *two concatenated single-row planetary gears* with transmission ratios u_1 and u_2. The total transmission ratio u and the efficiency factor η in this case are

$$u = u_1 u_2 \le 64 \,; \quad \eta = \eta_1 \times \eta_2 = 0.92\text{–}0.96 \,.$$

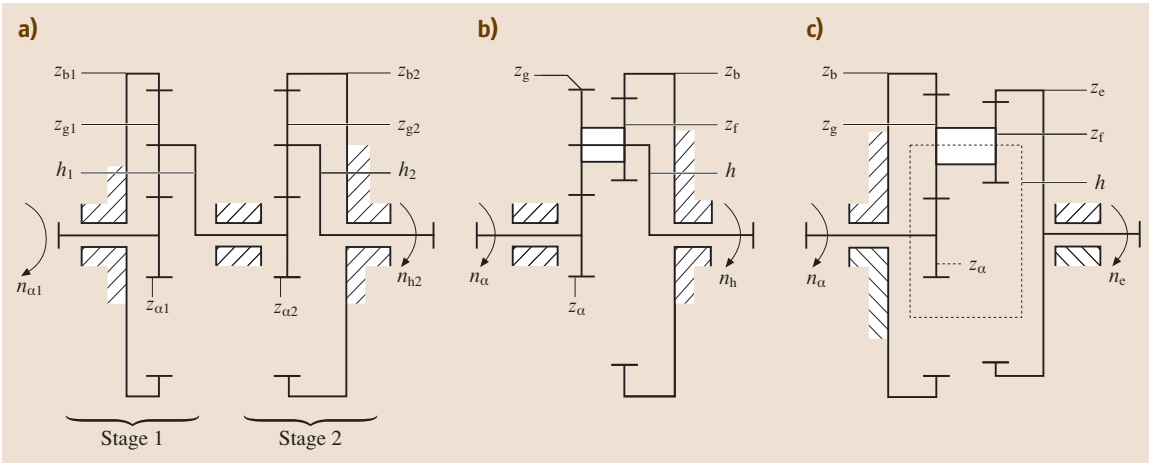

Fig. 6.91a–c Diagrams of planetary gears. (a) Double, (b,c) with double-row planetary pinion

Figure 6.91b shows the layout of a planetary gear with a double-row (two-ring) planetary pinion. The main units a and b are two central wheels, and the carrier h, and the gear $2K$–h. The transmission ratio for motion transmission from wheel a to carrier h and the fixed wheel b ($\omega_b = 0$) is

$$u^b_{ah} = \omega_a/\omega_h = n_a/n_h = 1 + z_b z_g/\left(z_f z_a\right) .$$

In this gear $u^b_{ah} = 3$–19 with $\eta = 0.95$–0.97.

In Fig. 6.91c the layout of the planetary gear $3K$ is shown. The main elements a, b, and e are three central wheels. The carrier h serves only to hold the planetary pinions. The transmission ratio for motion transmission from wheel a to wheel e and the fixed wheel b ($\omega_b = 0$) is

$$u^b_{ae} = \frac{\omega_a}{\omega_e} = \frac{n_a}{n_e} = \frac{(1 + z_b/z_a)}{\left[1 - z_b z_g/\left(z_f z_e\right)\right]} .$$

In this gear $u^b_{ae} = 16$–200 (up to 1600) with $\eta = 0.9$–0.7 (0.4).

6.7.4 Torques of the Main Units

For strength analysis of the toothing and force calculation in the toothing and for the following computation of the bearings it is necessary to know the torques on the main units. Further reasoning is provided for the planetary gear in Fig. 6.90. The torque T_a, (N m) on the main unit can be determined from the known power P_a (kW) and the rotational frequency $n_a(\mathrm{min}^{-1})$ according to

$$T_a = 9550 P_a/n_a .$$

From the balance condition we have

$$T_a + T_b + T_h = 0 .$$

From the condition of energy conservation with steady movement it follows that

$$T_a\omega_a + T_b\omega_b + T_h\omega_h = 0 .$$

With $\omega_b = 0$ we have

$$T_a\omega_a + T_h\omega_h = 0 \quad \text{and}$$
$$T_h = -T_a\omega_a/\omega_h = -T_a \times u^b_{ah} ,$$

or, taking into account losses η^b_{ah} due to movement of transmission from a to h,

$$T_h = -T_a u^b_{ah}\eta^b_{ah} .$$

The balance condition is written in the form

$$T_a + T_b + \left(-T_a u^b_{ah}\eta^b_{ah}\right) = 0 .$$

From this $T_b = T_a\,(u^b_{ah}\eta^b_{ah} - 1)$. In this way we obtain

$$T_b = -T_h\left[1 - 1/\left(u^b_{ah}\eta^b_{ah}\right)\right] .$$

Because u^b_{ah} is usually high, the torque on the central wheel b does not differ greatly from the torque on the output shaft: $T_b \approx -T_h$.

6.7.5 Toothing Forces

Peripheral forces in the toothing are determined from the torques (N m) and pitch diameters d_a, d_b, d_g (mm)

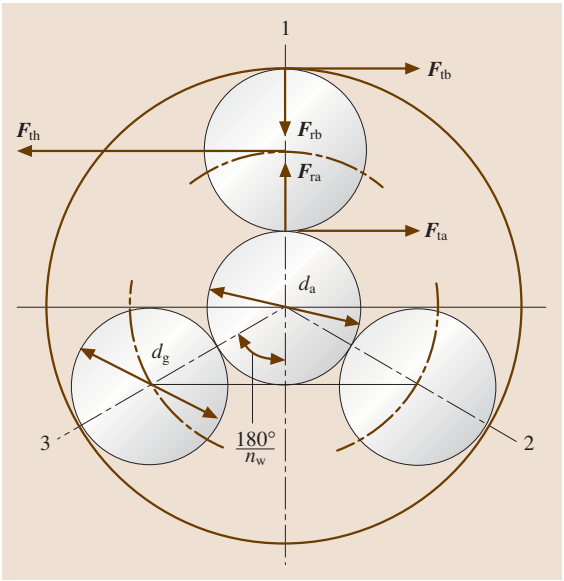

Fig. 6.92 Forces acting on one of the planetary pinions

of the gear wheels (for the gears without displacement)

$$F_{ta} = 2\times10^3 T_a k_w/(d_a n_w)\,,$$
$$F_{tb} = 2\times10^3 T_b k_w/(d_b n_w)\,,$$
$$F_{th} = 2\times10^3 T_h k_w/[(d_a + d_g) n_w]\,,$$

where n_w is the number of planetary pinions and k_w is a coefficient that takes into account the unevenness of the distribution of the torque between the planetary pinions (between the flows).

In Fig. 6.92 the forces acting on one of the planetary pinions are shown. The radial forces $F_{ra} = F_{ta}\tan\alpha_w$ and $F_{rb} = F_{tb}\tan\alpha_w$ are balanced here.

In the ideal mechanism $k_w = 1$ and the peripheral forces on wheel a in the toothing with all the planetary pinions equal: $F_{ta1} = F_{ta2} = F_{ta3}$. Wheel a is balanced (see the force polygon in Fig. 6.93a). However, in a real gear, as a result of production errors and detail deformation under loading, the torque is distributed irregularly between the planetary pinions, $F_{ta1} \neq F_{ta2} \neq F_{ta3}$, and the balancing force F_S acts on the shaft of the central wheel (Fig. 6.93b). Thus the values of the coefficient k_w are substantially higher than 1. To decrease the unevenness of the torque distribution and balance the peripheral forces wheel a is produced without bearings, i. e., it *floats*, and is connected to the drive shaft using a toothed coupling, which allows compensation for possible radial displacements Δ_r of the pinion (Fig. 6.93c). In this case, wheel a self-installs under the action of the force F_S, tending to reach equilibrium and thus overcoming the action of the frictional and inertial forces. Then the values of the coefficient k_w are much lower: $k_w = 1.05–1.15$.

6.7.6 Number Matching of Wheel Teeth

In contrast to traditional gearings the calculation of planetary gears starts with number matching of the wheel teeth. *The tooth number z_a of the central pinion a* is set based on the *non-undercutting condition* of the dedendum: $z_a \geq 12$. It is assumed that $z_a = 21–24$ for H $\leq$ 350 HB, that $z_a = 18–21$ for H $\leq$ 52 HRC; and that $z_a = 18$ for H $>$ 52 HRC. Tooth number matching of the other wheels is carried out taking into consideration three conditions: *coaxiality, mounting, and adjacency*.

Let us consider the tooth number matching by using the example of a spur planetary gear train without displacement (Figs. 6.90 and 6.91).

Layouts according to Figs. 6.90 and 6.91a

z_a is assumed to be in compliance with the above recommendations. *The tooth number z_b of the stationary central wheel b* is determined according to the *set*

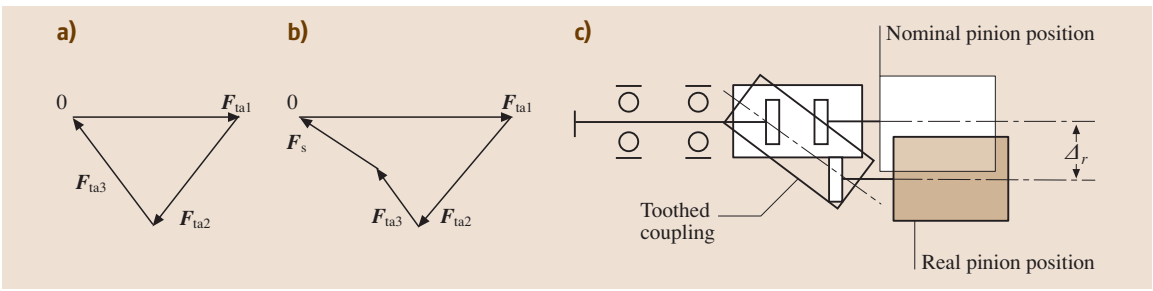

Fig. 6.93a–c Forces acting on the wheel a in the ideal (a) and the real (b) gear and (c) compensation of the radial displacement Δ_r with the help of the toothed coupling

transmission ratio u_{ah}^{b} from (6.16)

$$z_b = z_a \left(u_{ah}^{b} - 1\right) .$$

The tooth number z_g *of the planetary pinion* g is determined *according to the coaxiality condition*, in compliance with which the axle bases a_w of the gear sets with external and internal toothing are to be equal (Fig. 6.90)

$$a_w = 0.5(d_a + d_g) = 0.5(d_b - d_g) , \qquad (6.17)$$

where $d = mz$ is the pitch diameter of the appropriate gear wheel.

As the toothing modules of the planetary gear are equal, (6.17) takes the form

$$z_g = 0.5(z_b - z_a) .$$

Layout according to Fig. 6.91b

z_a is assumed. Then we have

$$z_b = z_a(u - 1)/c ,$$

where c is assumed to depend on the transmission ratio, according to:

The tooth number z_b after the calculation is rounded to a whole number that is divisible by the planetary pinion number. The coefficient is specified as

$$c = (u - 1)z_a/z_b .$$

Then we have

$$z_f = (z_b - z_a)/(c + 1) \quad \text{and} \quad z_g = cz_f .$$

For every layout the calculated tooth numbers are rounded to whole numbers. Furthermore, in accordance with Table 6.39, the coefficients of displacement x_1 of the pinion and x_2 of the wheel are chosen, and the coefficient B is determined as

$$B = 1000x_{sum}/(z_a + z_g) ,$$

where

$$x_{sum} = x_1 + x_2 .$$

According to the nomogram (Fig. 6.94) the toothing angle α_w of the gear is found.

Example

Determine the toothing angle with $z_a + z_g = 18 + 27 = 45$.

Solution

According to Table 6.39 we have $x_1 = 0.4$ and $x_2 = 1.02$, and consequently, $x_{sum} = x_1 + x_2 = 0.4 + 1.02 = 1.42$.

Then

$$B = 1000x_{sum}/(z_a + z_g)$$
$$= 1000 \times 1.42/(18 + 27) = 31.55 .$$

According to the nomogram (Fig. 6.94) we determine $\alpha_w = 26°55'$.

As the force calculation is not done and the modules of the toothing are unknown, for the layout in Fig. 6.91b

the modules of both steps are assumed to be equal. Tooth numbers z_a, z_g, and z_b calculated in this way are checked according to the conditions of mounting and adjacency.

Layouts according to Fig. 6.90 and Fig. 6.91a

The Condition of Coaxiality

$$(z_a + z_g)\cos\alpha_{wa} = (z_b - z_g)/\cos\alpha_{wb}\ ,$$

where α_{wa} and α_{wb} are toothing angles of the gear with external (index a) and internal (index b) toothing. From this condition

$$z_g = \left(\frac{z_b}{\cos\alpha_{wb}} - \frac{z_a}{\cos\alpha_{wa}}\right)\frac{\cos\alpha_{wa}\cos\alpha_{wb}}{\cos\alpha_{wa} + \cos\alpha_{wb}}\ .$$

The mounting condition requires coincidence of the teeth with tooth slots to have place in all the toothings of the central wheels with planetary pinions, otherwise the gear cannot be mounted. It is determined that, with a symmetrical arrangement of the planetary pinions, the mounting condition is met when the tooth sum of the central wheels $(z_a + z_b)$ is divisible by the number of planetary pinions n_w (usually $n_w = 3$), i. e., $(z_a + z_b)/n_w = \gamma$, where γ is any whole number.

Layout according to Fig. 6.91b

The Coaxiality Condition

$$(z_a + z_g)/\cos\alpha_{wa} = (z_b - z_f)/\cos\alpha_{wb}\ .$$

Hence

$$z_f = (z_b/\cos\alpha_{wb} - z_a/\cos\alpha_{wa}) \\ /(c/\cos\alpha_{wa} + 1/\cos\alpha_{wb})\ ;$$

$$z_g = cz_f\ .$$

If, in the strength analysis of the gears according to the layout in Fig. 6.91b, different modules for the gears with external $(z_a - z_g)$ and internal $(z_f - z_b)$ toothing are assumed, the coaxiality condition for such a gearing is

$$(z_a + z_g)m_a/\cos\alpha_{wa} = (z_b - z_f)m_b/\cos\alpha_{wb}\ .$$

Hence

$$z_f = \frac{z_b m_b/\cos\alpha_{wb} - z_a m_a/\cos\alpha_{wa}}{c m_a/\cos\alpha_{wa} + m_b/\cos\alpha_{wb}}\ ,$$

where the tooth number $z_g = cz_f$.

Sometimes for fulfillment of the *coaxiality condition* it is convenient for one gear to be helical. The coaxiality condition in this case becomes

$$(z_a + z_g)m_a/(\cos\beta\cos\alpha_{wa}) \\ = (z_b - z_f)m_b/\cos\alpha_{wb}\ .$$

The required tilt angle β of the tooth is determined from this condition. *The mounting conditions* of the gear are then $z_a/n_w = \gamma$ and $z_b/n_w = \gamma$.

For all layouts of planetary gears control of the *adjacency condition* is carried out, which requires that the planetary pinions do not touch the teeth. To this end the sum of the top crest radii, which is $d_{ga} = m(z_g + 2)$, must be less than the distance l between their axes (Fig. 6.92), i. e.,

$$d_{ga} < l = 2a_w \sin(180°/n_w)\ , \qquad (6.18)$$

where a_w is an axle base.

For the layouts in Figs. 6.90 and 6.91a the axle base forms

$$a_w = 0.5m(z_a + z_g)\ ,$$

and in accordance with (6.18) the adjacency condition is fulfilled if

$$(z_g + 2) < (z_a + z_g)\sin(180°/n_w)\ .$$

The axle base of the gear, which is produced according to any layout, is

$$a_w = (z_a + z_g) m_a \cos\alpha / (2 \cos\beta \cos\alpha_{wa}) .$$

The actual values of the transmission ratios of reduction gears must not differ from the nominal values by more than 4% for single-reduction units, 5% for double-reduction units, and 6.3% for triple-reduction units.

6.7.7 Strength Analysis of Planetary Gears

The first calculation phases for planetary gears (choice of material and heat treatment, determination of allowable stresses) are performed in the same way as for traditional cylindrical gearings (Sect. 6.3.7).

Strength analysis is carried out for all toothings according to the formulas for traditional gearings. For example, for the gearing shown in Fig. 6.90 it is necessary to calculate the external toothing of the wheels a and g, and the internal toothing of the wheels g and b. The modules and forces of these toothings are equal and internal toothing is faster in accordance with its behavior, and therefore *when the same material is used for the wheels it is sufficient to calculate only the external toothing*.

Only the main characteristics of the calculation for planetary gears are examined below. For the determination of the allowable stresses $[\sigma]_H$ and $[\sigma]_F$ the service life ratios Z_N and Y_N are found according to the equivalent loading cycle numbers $N_{HE} = \mu_H N_k$ and $N_{FE} = \mu_F N_k$. *The number of stress cycles* N_k of the teeth for the whole lifetime is calculated *only for wheel rotation relatively to each other*.

For the *central pinion*

$$N_{ka} = 60 n_w n'_a L_h ,$$

where n_w is the number of planetary pinions, L_h is the total operating lifetime of the gearing (h), $n'_a = (n_a - n_h)$ is the relative rotational frequency of the drive central pinion, and n_a and n_h are the rotational frequencies of the central pinion and the carrier (min^{-1}).

According to n'_a the circumferential velocity is determined, in compliance with which the accuracy degree of the gear is set and the coefficients K_{HV}, K_{FV} are chosen.

For *planetary pinions*

$$N_{kg} = 60 n_t n'_g L_h ,$$

where n_t is the loading number of the tooth per revolution and $n'_g = n'_a z_a / z_g$ is the relative rotational frequency of the planetary pinion.

The tooth of the planetary pinion is loaded twice per revolution in the toothing with wheels a and b. However, by determination of the cycle number it is assumed that $n_t = 1$, because the *contact strength* analysis takes into account that the tooth of the planetary pinion works with wheels a and b with different flanks. By determination of *the allowable bending stresses* $[\sigma]_{Fg}$ for the teeth of the planetary pinion the coefficient Y_A is set, taking into consideration the double-sided application of the load (under a symmetrical loading cycle). The values Y_A are assumed to be $Y_A = 0.65$, 0.75, and 0.9, respectively, for refined, quenched with radiofrequency (RF) current heating (or cemented), and nitrided steels.

The axle base a_w of a spur planetary gear train for the wheel set of the external toothing (of the central pinion with the planetary pinion) is determined as

$$a_w = 450 \left(u' + 1\right) \sqrt[3]{\frac{K_H T_1 k_w}{\psi_{ba} u' [\sigma]_H^2 n_w}} ,$$

where $u' = z_g / z_a$ is a gear ratio of the calculated wheel set, $k_w = 1.05$–1.15 is an unbalance factor between the planetary pinions, $T_1 = T_a$ is the torque on the shaft of the drive central pinion (N m), n_w is the number of planetary pinions, ψ_{ba} is the coefficient of the face width of the wheel, with $\psi_{ba} = 0.4$ for wheel hardness $H \le 350$ HB, $\psi_{ba} = 0.315$ for $H \le 50$ HRC, and $\psi_{ba} = 0.25$ for $H > 50$ HRC.

The width b_b of the central wheel b is $b_b = \psi_{ba} a_w$. The width b_g of the planetary pinion ring is assumed to be 2–4 mm more than the value of b_b, and the width b_a of the central pinion is assumed to be $b_a = 1.1 b_g$. *The toothing module* is $m = 2a_w / (z_g + z_a)$. The calculated module is rounded to the nearest standard value and then the axle base is specified as $a_w = m(z_g + z_a)/2$. Bending analysis is performed according to (6.7) as for standard gearings.

6.7.8 Design of Planetary Gears

Figure 6.95 shows the construction of a single-reduction epicyclic unit produced according to the layout of Fig. 6.90. In this construction the central drive pinion is a floating link. In the radial direction the pinion self-installs along the planetary pinions. In the axial direction the pinion is fixed from one side with a pin butt (1) and from the other side with a toothed coupling (2) with spring rings (3) installed in it. The pitch diameter of the toothed coupling (2) is assumed, for simplicity of manufacture, to be equal to the diameter d_1 of the central pinion. The coupling diameter is $d_c \ge d_1 + 6$ m,

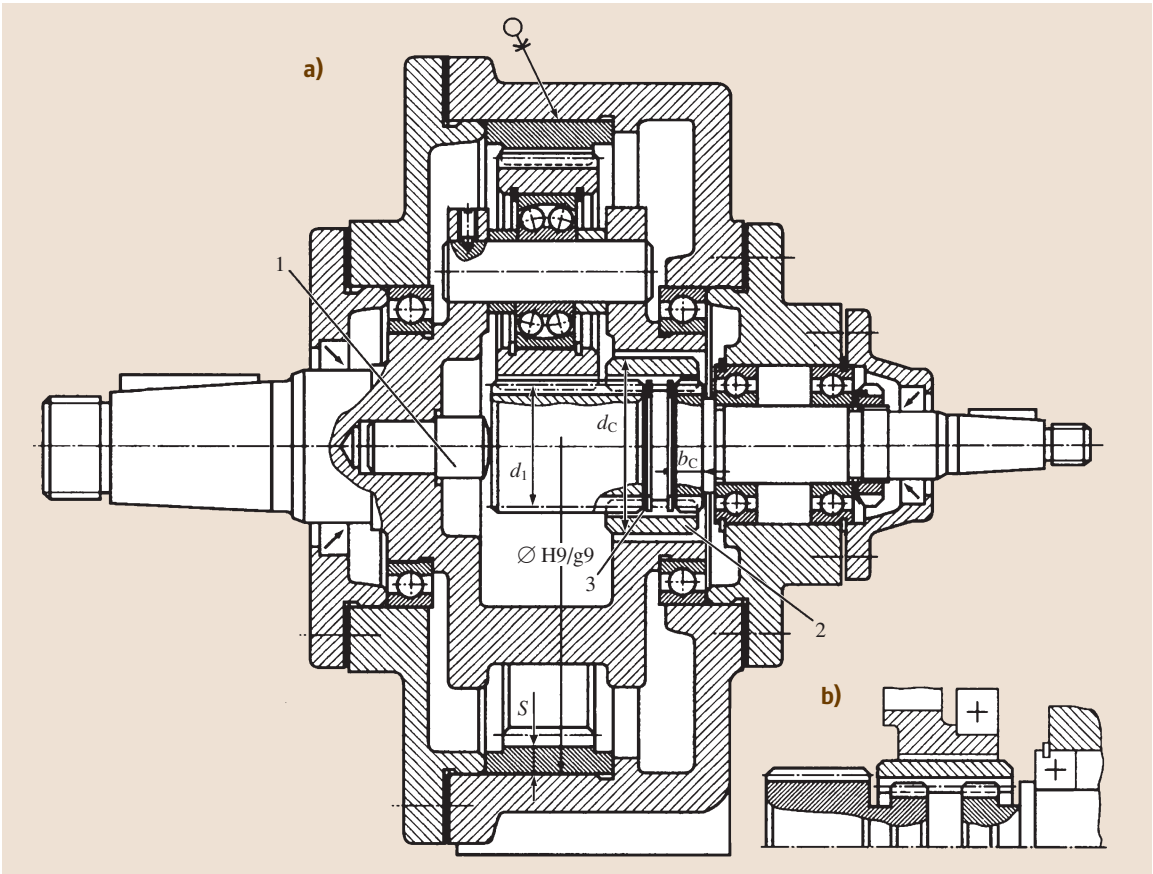

Fig. 6.95 (a) Planetary single-row gearbox according to the diagram of (b) execution version of the toothed coupling

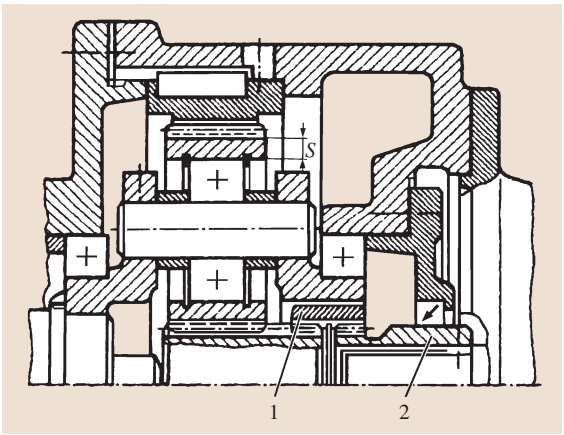

Fig. 6.96 Installation version of the toothed coupling on the shaft of the flange-mounted motor

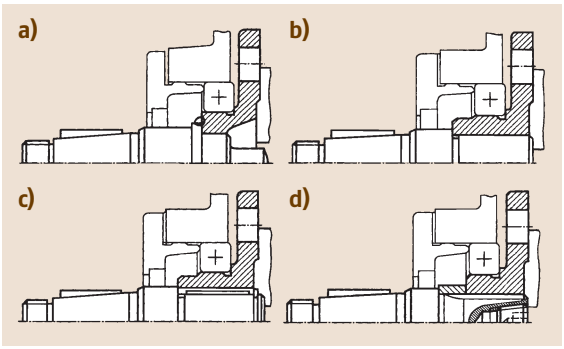

Fig. 6.97a–d Embodiments of the composite output shafts using (a) welded joints, (b) joints with interference, (c) key joints, and (d) spline joints

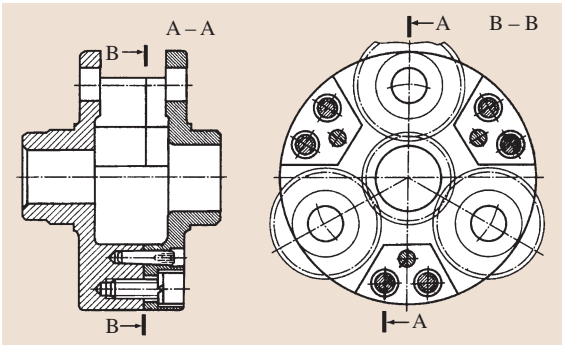

Fig. 6.99 Execution version of the composite carrier

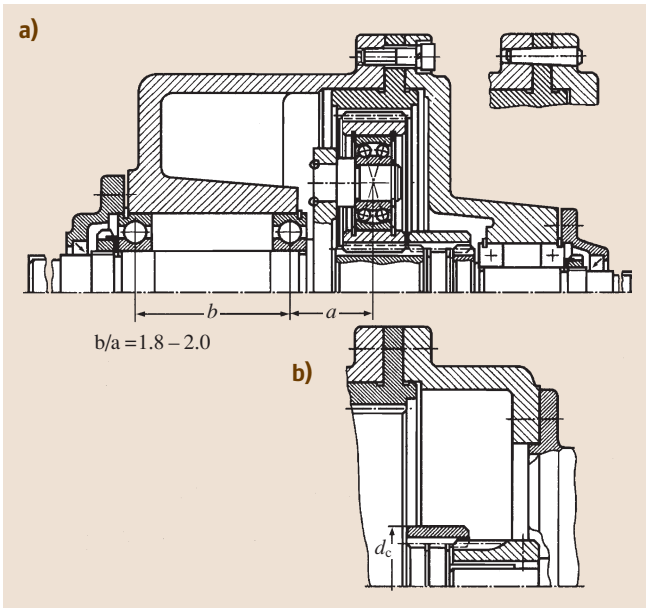

the width of the toothing is $b_c = (0.2–0.3)d_1$, and the thickness of the stationary wheel is $S = 2.2m + 0.05b_b$, where b_b is the face width of the stationary wheel b. In cases when the coupling (2) is not built into the carrier opening, its outer diameter is reduced (Fig. 6.95b).

In Fig. 6.95 the input high-speed shaft is mounted on ball radial bearings with retaining snap rings. The input shaft receives movement from the electric motor through the *joint sleeve* mounted on the bevel or cylindrical shaft extension. By design of the reduction gear motor the toothed coupling (1) is connected with the pinion (2) installed on the shaft of the flange motor, as shown in Fig. 6.96.

For reduction of stress accumulation it is necessary for the planetary pinions to self-install along the stationary central wheel. To this end, radial spherical balls or roller bearings can be applied. The thickness S (Fig. 6.96) of the planetary pinion rim (mm) is $S \geq 2m + 1$, where m is the toothing module.

The low-speed shaft of the reduction gear is cast from high-duty cast iron (Appendix 6.A Table 6.95, cast irons) as a single unit with the carrier (Fig. 6.95) or in the case of small-lot or single-part production it is cast from steel and joined with the carrier through welding (Fig. 6.97a), interference fit (Fig. 6.97b), a key joint (Fig. 6.97c), or a spline connection (Fig. 6.97d).

Carriers are made as one-piece castings from steel or high-duty cast iron, as shown in Fig. 6.95, welded according to Fig. 6.98, or compositely fastened with six screws and three pins (Fig. 6.99).

In the structures indicated in Figs. 6.95, 6.98, and 6.99 the carriers are mounted in the case on two bearings, and the axis of the planetary pinion enters the openings of two walls of the carrier. Recently carriers are more often being designed with one wall, with the planetary pinion axles being cantilevered. Figure 6.100 shows the structure of an epicyclic unit with cantilever axles of the planetary pinions. In Fig. 6.100a the input shaft is connected to the electric motor shaft by means of a joint sleeve. In Fig. 6.100b the drive is obtained directly from the flange motor shaft. The carriers are mostly three-leafed (Fig. 6.101).

In this case, it is convenient to install the central pinion on the drive shaft using a spline connection or a serrated joint (Fig. 6.102). In order for this pinion to self-install the fits of the involute spline connection

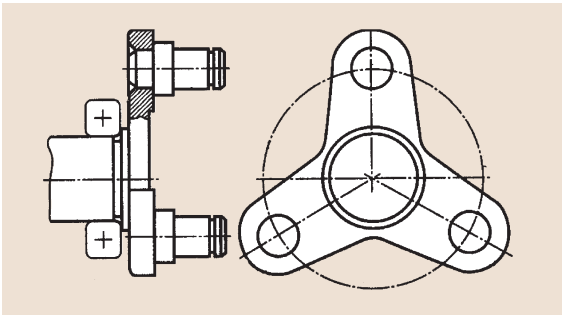

Fig. 6.101 Execution version of the three-leafed carrier

must have a large clearance along the centering surface (type H11/c11).

The wheel of the internal toothing withstands a considerable torque and must be tightly connected with the case. For this purpose the following are applied:

- Gluing of the wheel (Fig. 6.95) with an adhesive such as epoxy, phenol-formaldehyde, etc. The fit at a point of the wheel mating with the case is H9/g9.
- A key joint (Fig. 6.96).
- Flange fastening with screws and pins (Fig. 6.100).
- Mounting of three rolled or tapered pins along the circle (or in the radial direction) (Fig. 6.103); for air outlet *the flat* is taken off the roll pins (Appendix 6.A).

The simplest and modern solution is an adhesive joint.

Planetary gears made according to the layout in Fig. 6.91a differ from gears made according to the layout in Fig. 6.90 in the following two features:

1. The device for torque transmission from the carrier in the high-speed stage to the central pinion in the low-speed stage.
2. The case construction, in which many details are to be positioned, including two stationary wheels of the internal toothing.

All other elements of the epicyclic unit, e.g., the drive shaft, joint sleeves, planetary pinions, and carriers, are designed according to the same recommendations as for the elements of reduction gears of the layout in Fig. 6.90.

Torque transmission from the high-speed stage to the low-speed stage is carried out with the following methods:

- The spline shaft (1) produced as a unit with the central drive pinion of low-speed grade (Fig. 6.104).

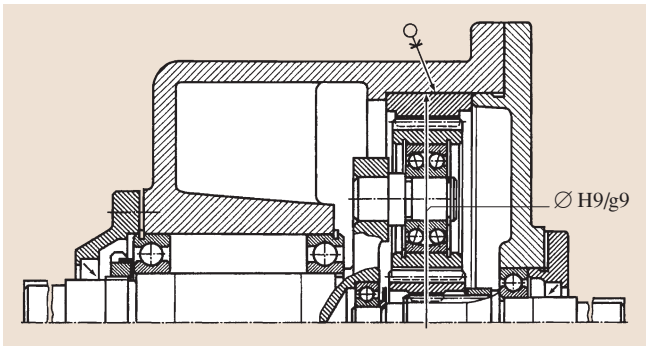

Fig. 6.102 Planetary gearbox with a central pinion mounted on the input shaft using a spline connection or a serrated joint

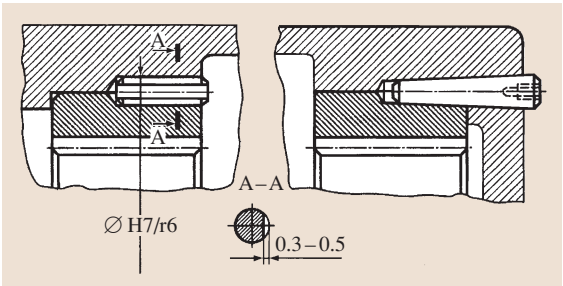

Fig. 6.103 Pin connection of the wheel of internal toothing to the case

- The toothed coupling (1) connecting the carrier of high-speed grade and the drive central pinion of low-speed grade (Fig. 6.105a,b).

In the middle of the reduction gear case a wall is foreseen, where the carrier bearings of high-speed and low-speed grades are positioned.

Planetary gears according to the layout in Fig. 6.91b differ from gears according to the layout in Fig. 6.91a

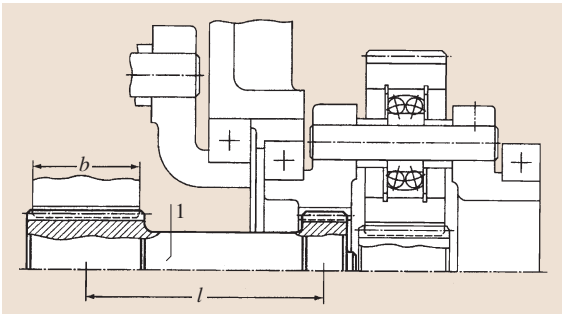

Fig. 6.104 Transmission of the torque from a high-speed step to a low-speed step with the help of a splined shaft

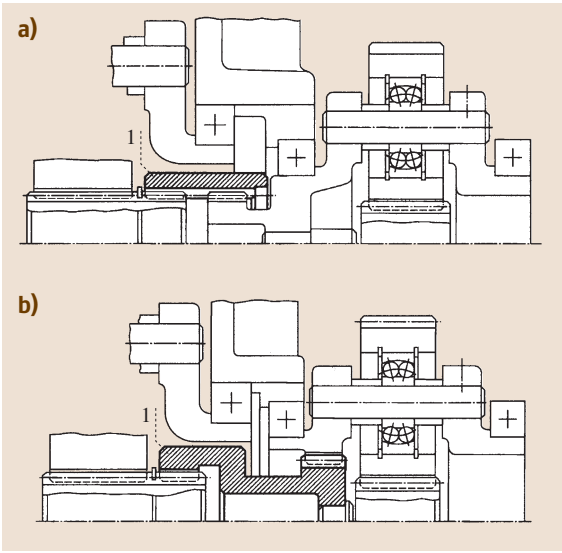

Fig. 6.105a,b Transmission of the torque from a high-speed step to a low-speed one with the help of coupling (a,b)

in the fact that the planetary pinions have two gear rings. Two bearings serve as supports of the planetary pinions; therefore the planetary pinions cannot self-install according to the central wheels. To decrease the stress accumulation along the tooth length the central drive pinion *a* is manufactured with barrel-shaped teeth, and the wheel *b* with the internal teeth is floating.

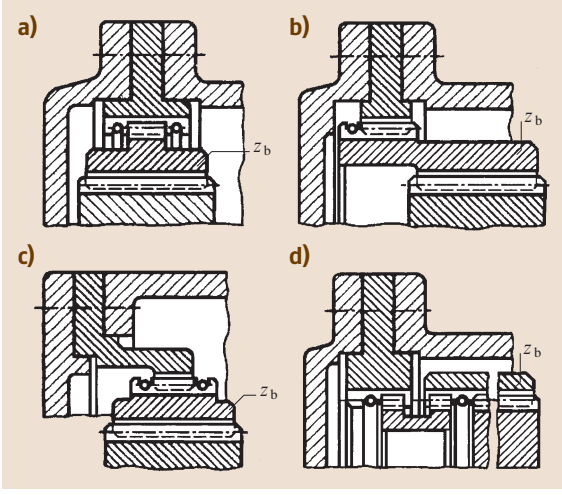

Fig. 6.106a–d Methods of connection of the floating wheel (a–d) with the case with internal toothing

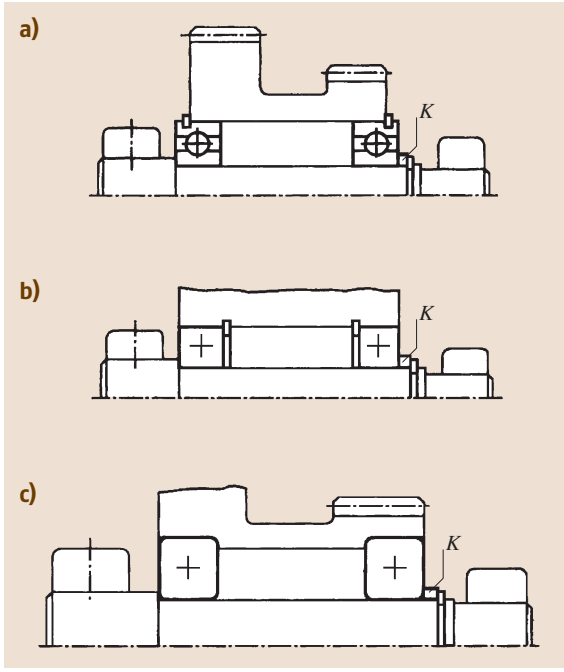

Fig. 6.107a–c Execution versions (a–c) of the supports of double-row planetary pinions

Depending on the location of the components of the planetary gear in the case the joining of the floating wheel *b* (tooth number z_b) with the other elements is carried out according to one of the choices shown in Fig. 6.106a–d. The other structural components of the planetary gears are designed according to the same recommendations as for gears having the layout shown in Fig. 6.90.

The performance variants of the planetary pinion supports are given in Fig. 6.107. The simplest solution is given in Fig. 6.107a. Instead of ball radial bearings, radial double-row spherical ball or roller bearings can be applied (Fig. 6.107b,c). In the supports of the planetary pinions, tapered roller bearings are also used, although rarely, because unit dismantling is needed for their adjustment. If it is not possible to insert the bearings given in Fig. 6.107 into the planetary pinions, needle (Fig. 6.108a) or friction bearings (Fig. 6.108b) are used.

In some epicyclic units constructions of planetary pinions with rotating axes are used. In Fig. 6.109a the simplest design is shown. In manufacture according to Fig. 6.109b radial double-row spherical ball or roller bearings can be applied as supports. Radial bearings with short cylindrical rollers are also used. The axis can be smooth, of constant diameter.

In all the versions shown in Fig. 6.109 matching or grinding of the compensatory rings K provides accuracy of the axial position of the details.

In order that the planetary pinions do not rotate relative to the axis, they are installed on the axis with slight interference (Fig. 6.110a), held with a set screw (Fig. 6.110b), or a roll pin (Fig. 6.110c).

Matching of Rolling Bearings

For support of the central shafts, ball radial single-row bearings are usually assumed, whereas for supports of planetary pinions, ball and roller spherical bearings are usually assumed. For calculation of the rolling bearings the support reactions F_{r1} and F_{r2} are defined. The main analytical models are given in Fig. 6.111.

The input and output shafts of reduction gears are loaded with the force F acting from the side of the toothing and the cantilever force F_C (from the sleeve, belt drive, or chain gear). The assigned rolling bearings are calculated based on a set lifetime according to the action on the support reaction (F_{r1} or F_{r2}).

Taking into account the largest possible unevenness distribution of the total torque to the flows, the force F (N) acting on the shaft from the side of the toothing is determined from the following formulas:

For the input shaft (layout in Fig. 6.111a)

$$F = 0.2 \times 10^3 T_1 / d_1 ,$$

where T_1 is the torque on the shaft (N m) and d_1 is the pitch diameter of the toothed coupling teeth (2) (mm), which connects the input shaft to the drive pinion (Fig. 6.95).

For the output shaft (layouts in Fig. 6.111b,c and Figs. 6.95 and 6.100a)

$$F = 0.1 \times 10^3 T_h / a_w ,$$

where T_h is the torque on the output shaft (the carrier) (N m), $T_h = T_1 u \eta$, and a_w is the axle base of the gear (mm).

The bearings of the planetary pinions are the most heavily loaded

$$F_{r\,max} \approx 2 F_{t\,max} ,$$

where $F_{t\,max}$ is the peripheral force (N) and $F_{t\,max} = 2 \times 10^3 k_w T_{1\,max} / (n_w d_1)$. Here, $T_{1\,max} = T_1$ is the maximum of the long-acting (nominal) torque on the drive pinion (N m) and d_1 is the pitch diameter of the drive pinion (mm).

The equivalent radial force for the bearing calculation under typical varying loading conditions is

$$F_r = K_E F_{r\,max} ,$$

where K_E is an equivalence coefficient.

The required radial dynamic load rating $C_{r,\,re}$ (N) of the planetary pinion bearings is determined from the formula

$$C_{r,\,re} = P_r \sqrt[k]{\frac{L'_{sah} n'_a z_a 60}{a_1 a_{23} 10^6 z_g}} ,$$

where $P_r = V F_r K_{dy} K_t$ is an equivalent radial load (N), $V = 1.2$ (the outer race rotates relative to the radial load), and L'_{sah} is the required bearing lifetime with given safety (h); $n'_a = (n_a - n_h)$ and z_a is the relative rotational frequency and tooth number of the central drive pinion, z_g is the tooth number of the planetary pinion, a_1 is a safety factor (Table 6.41), a_{23} is a use environment coefficient (Table 6.40: for spherical double-row ball-bearings $a_{23} = 0.5$–0.6, for spherical double-row roller bearings $a_{23} = 0.3$–0.4), $k = 3$ for ball bearings, and $k = 10/3$ for roller bearings.

6.8 Wave Gears

The wave gear is a power transmission in which rotation is transmitted by traversal of the deformation area of a flexible elastic section. A mechanical wave harmonic drive can be frictional and geared.

6.8.1 Arrangement and Operation Principles of Wave Gears

Frictional Wave Gears

The main elements of the gear are (Fig. 6.112a–c):

g – A flexible wheel representing a thin shell in the form of a cylinder with a bottom that is connected to the shaft

b – A rigid wheel connected to the case

h – A wave generator in the form of two rollers of major diameter, which are positioned on the carrier, connected with the high-speed shaft, and provide deformation of the flexible wheel

In practice there are also other embodiments of the main elements.

Figure 6.112a shows the relative position of the undistorted flexible g and rigid b wheels, with $d_g < d_b$ and $2W_0 = d_b - d_g$.

When installing the generator h the flexible wheel g is distorted, forming an ellipse (Fig. 6.112b). The power interaction of the wave gear details occurs at the contact points on the major ellipse axis. The generator presses the flexible wheel against the stiff wheel with sufficient force that the load is transmitted via frictional forces. With a stationary stiff wheel the rotation of the generator causes running-in of the flexible wheel to the stiff one and rotation of the flexible wheel in the direction opposite to the generator rotation.

Let us mark a point A on the flexible wheel g, at the contact with the rigid wheel b. After one revolution of the generator h clockwise, point A on the flexible wheel coincides with point A' on the stiff wheel (Fig. 6.112b), as the circumference of the flexible wheel with diameter d_g is less than that of the stiff wheel with diameter d_b. Therefore, the flexible wheel rotates in the direction opposite to the rotating sense of the generator. Figure 6.113 shows the flexible wheel before (circle) and after straining with the generator (ellipse). The maximum distortion in the direction of the major ellipse axis is indicated by W_0. The current distortion value W depends on the angle φ, which is measured clockwise from the major ellipse axis. The relation $W = f(\varphi)$ represents a wave function (Fig. 6.114). At the angle $\varphi = 2\pi$ two strain waves are observed and such a gear is called *two-wave*.

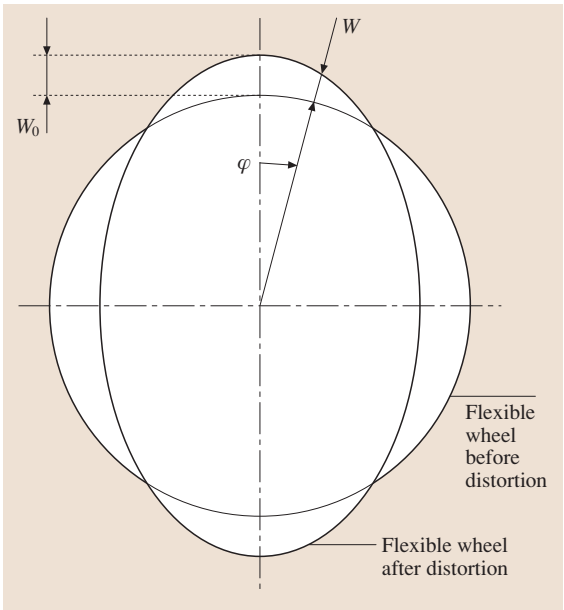

Fig. 6.113 Change of form of the flexible wheel due to straining

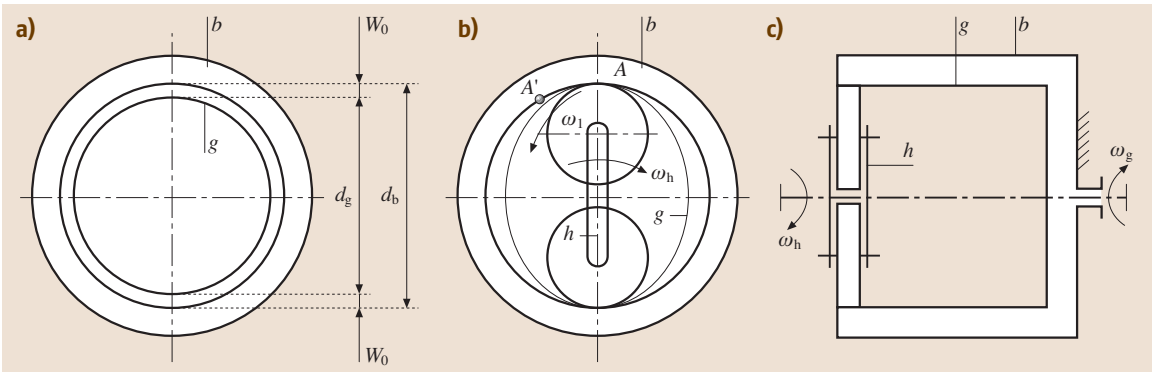

Fig. 6.112a–c Construction diagrams of the wave gear (**a**) before and (**b**,**c**) after straining of the flexible wheel

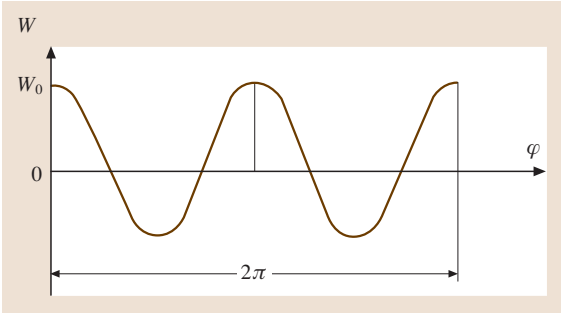

Fig. 6.114 Wave function of the deformation of the flexible wheel

Tooth Wave Gear

The flexible wheel g in such gears is a thin-walled cylinder. On its deformable end there is a gear ring with external teeth of involute profile. The flexible thin-walled cylinder plays the role of the resilient connection between the deformable O-ring seal and the stiff gear element, which can be the output shaft (Fig. 6.115a) or the case (Fig. 6.115b and c). *The rigid wheel b* has teeth with internal toothing. The tooth number z_b of the rigid wheel is greater than the tooth number z_g of the flexible wheel. *The wave generator h* represents a carrier (e.g., with two rollers) inserted into the flexible wheel. The flexible wheel, which distorts into the shape of an ellipse, forms two engagement zones along the major axis (Fig. 6.115b). In most cases, the generator is a pivotal element of the gear that is connected to the input shaft. The generator rotating with the angular velocity ω_h causes rotation of the flexible wheel with angular velocity ω_g (Fig. 6.115a) or of the rigid wheel with angular velocity ω_b (Fig. 6.115b,c).

In Fig. 6.116 the flexible wheel and tooth position before distortion are shown with hatches and without hatches after distortion. On straining of the flexible wheel with the generator under the action of the radial forces F_r the teeth of the flexible wheel move along the radius and engage with the teeth of the stiff wheel in the direction of the major ellipse axis. In the direction of the minor axis of the ellipse the deformation causes the teeth of the flexible wheel to move to the center and disengage from the teeth of the rigid wheel.

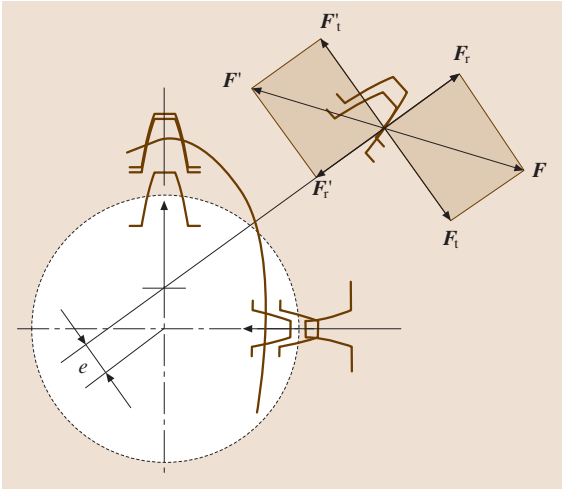

Fig. 6.116 Forces in the toothing of the wave gear

In the direction of the major axis of the ellipse meshing of the flexible wheel teeth with the rigid wheel teeth occurs along the entire depth of the tooth. By transfer from the major axis to the minor one the teeth of the flexible wheel gradually leave the mesh. A large number of the teeth are in simultaneous mesh: 25–40% of the teeth of the flexible wheel. In this way the gear can transmit a considerable torque even under slight load on every tooth.

With generator rotation by an angle φ a tooth of the flexible wheel moves in the radial direction by W, pressing the tooth of the rigid wheel with a force F that is directed along the normal line to the contact surfaces (Fig. 6.116). The force F can be represented in the form of the constituent forces: the peripheral force F_t and the

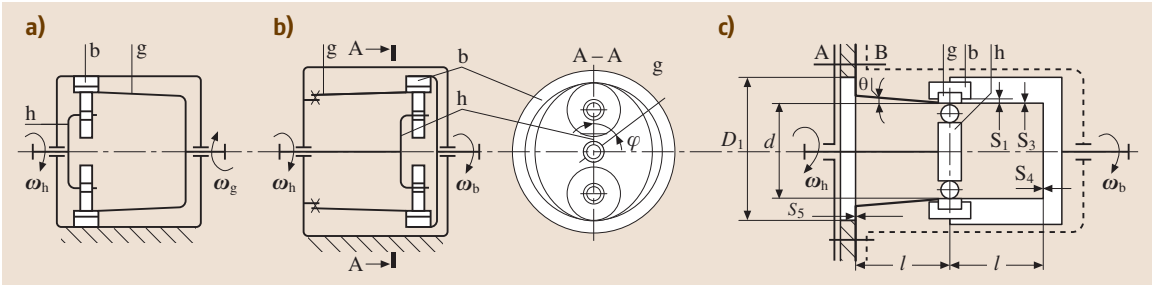

Fig. 6.115a–c Kinematic schemes of wave gears. **(a)** With a driven flexible wheel, **(b,c)** with a driven rigid wheel

radial force F_r. The reactions F_t' and F_r' act on the tooth of the flexible wheel.

If the generator is driving ($\omega_h \neq 0$), and the rigid wheel is fixed ($\omega_b = 0$), under the action of the force F_t' the flexible wheel rotates ($\omega_g \neq 0$) in the direction opposite to the generator rotation, as indicated by the minus sign in the formula for the transmission ratio, and as will be demonstrated hereinafter.

If the flexible wheel is stationary ($\omega_g = 0$), the rigid wheel rotates ($\omega_b \neq 0$) under the action of the force F_t in the direction of the generator rotation ($\omega_h \neq 0$), as indicated by a plus sign in the formula for the transmission ratio.

Figure 6.115c shows the layout of a wave gear with a stationary flexible wheel. Wave gears are the only power transmission that can transmit rotation *through the wall*, from a sealed space into a vacuum, without applying a rotatory seal. The flexible wheel g has the form of a blind sleeve with a flange, with which the wheel is fixed on the wall that separates the different media. The gear ring of the flexible wheel is in the middle sleeve part.

In wave gears each of the three primary elements can be driving. Thus, for example, in the case of a fixed flexible wheel and rotation of the rigid wheel in the counterclockwise direction, the flexible wheel acts upon the generator with a force F_r' (Fig. 6.116). The line of force action F_r' is along the normal to the curve that circumscribes the straining form of the flexible wheel. Under the action of the torque $T = 2F_r'\, e$ (where 2 is the number of strain waves) the generator rotates in the same direction as the rigid wheel.

6.8.2 Gear Ratio of Wave Gears

As with planetary gears, wave gears have three main elements that take external torques. Any main unit can be stopped.

1. The generator is stopped ($\omega_h = 0$). Rotation is transmitted from the flexible wheel with tooth number z_g to the rigid one (z_b), a common internal mesh

$$u_{gb}^h = \frac{\omega_g}{\omega_b} = \frac{z_b}{z_g} .$$

There is a plus sign in the formula, because the rotational directions ω_g and ω_b coincide.

2. The rigid wheel is stopped, $\omega_b = 0$ (Fig. 6.115a). This is the most frequent case (the standard wave gear).

Let us consider a differential wave gear with all three movable elements having angular velocities ω_g, ω_b, and ω_h. Let us choose a coordinate system that is quiescently bound to the generator. To do this assume that the angular velocity is $(-\omega_h)$ for the whole system. Then the elements have relative angular velocities

$$\omega_g - \omega_h\,; \quad \omega_b - \omega_h\,; \quad \omega_h - \omega_h = 0\,,$$

i. e., both wheels seem to rotate relative to the stationary generator. Then, as in the first case, we can write

$$u_{gb}^h = \frac{\omega_g - \omega_h}{\omega_b - \omega_h} = \frac{z_b}{z_g} .$$

If the rigid wheel is stopped, movement is transmitted from the generator to the flexible wheel and, therefore, $u_{hg}^b = \omega_h/\omega_g$ is determined. Supposing that $\omega_b = 0$ in the formula for the differential gear we have

$$\frac{\omega_g - \omega_h}{0 - \omega_h} = \frac{z_b}{z_g}\,;$$

$$-\frac{\omega_g}{\omega_h} + 1 = \frac{z_b}{z_g}\,;$$

$$u_{hg}^b = \frac{\omega_h}{\omega_g} = \frac{1}{(\omega_g/\omega_h)} = \frac{1}{1 - z_b/z_g}$$

$$= -\frac{z_g}{z_b - z_g} .$$

The minus sign shows that the sense of rotation of the flexible wheel is opposite to that of the generator.

3. The flexible wheel is stopped, $\omega_g = 0$ (Fig. 6.115b,c). Rotation is transmitted from the generator to the rigid wheel. It is necessary to find $u_{hb}^g = \omega_h/\omega_b$.

Supposing $\omega_g = 0$ in the formula for the differential gear we have

$$\frac{0 - \omega_h}{\omega_b - \omega_h} = \frac{z_b}{z_g}\,;$$

$$\frac{-\omega_h/\omega_b}{1 - \omega_h/\omega_b} = \frac{z_b}{z_g}\,;$$

$$-\frac{\omega_h}{\omega_b} = \frac{z_b}{z_g} - \frac{z_b\omega_h}{z_g\omega_b}\,;$$

$$\frac{\omega_h}{\omega_b} = \frac{-z_b/z_g}{(z_g - z_b)/z_g}\,;$$

Then

$$u_{hb}^g = \frac{\omega_h}{\omega_b} = \frac{z_b}{z_b - z_g} .$$

The senses of rotation of the generator and the rigid wheel coincide. The difference in the number of wheel

teeth is divisible by the wave number (as in planetary gears it is divisible by the planetary pinion number)

$$(z_b - z_g)/n_w = K_z \,,$$

where K_z is a whole number, with $u \geq 70 K_z = 1$, n_w is a wave number, and for the two-wave gear $n_w = 2$. Then

$$z_b - z_g = 2 \,.$$

Example

Determine the transmission ratios u^b_{hg} and u^g_{hb} for $z_g = 200$ and $z_b = 202$

$$u^b_{hg} = \frac{\omega_h}{\omega_g} = -\frac{z_g}{z_b - z_g} = -\frac{200}{202 - 200} = -100 \,,$$

$$u^g_{hb} = \frac{\omega_h}{\omega_b} = \frac{z_b}{z_b - z_g} = \frac{202}{202 - 200} = 101 \,.$$

6.8.3 Radial Deformation and the Transmission Ratio

From Fig. 6.112 it follows that $2W_0 = d_b - d_g$. For tooth wave gears with module m we have

$$2W_0 = d_b - d_g = m(z_b - z_g) \,.$$

Since $z_b - z_g = 2$, the radial deformation W_0 for wheels cut without displacement of the basic profile is $W_0 = m$.

For standard wave gears

$$u^b_{hg} = -\frac{z_g}{z_b - z_g} = -\frac{mz_g}{mz_b - mz_g} = -\frac{d_g}{d_b - d_g} = -\frac{d_g}{2W_0} \,.$$

In other words, *the transmission ratio in wave gears is equal to the ratio of the driven wheel radius to the difference of the radii of the rigid wheel and the flexible wheel or to the deformation dimension* W_0.

It follows that higher values of the transmission ratio u can be reached for low values of W_0, i. e., by small modules m. Major deformation dimensions W_0 correspond to lower values of u, for which the curvature of the flexible wheel and, therefore, bending stresses increase considerably in the toothing area.

The allowable range of the transmission ratio of the wave gear is

$$70 < u < 320 \,.$$

The lower limit on u is provided by the limit on the strength of the flexible wheel under bending stresses, whereas the upper limit is provided by the minimal module values ($m \geq 0.15$ mm).

Advantages of Wave Gears

1. The availability of a higher transmission ratio on one grade with a comparatively high value of the efficiency factor η. For one grade u up to 320 with $\eta = 0.7$–0.85.
2. The capability to transmit higher torques for smaller dimensions and mass due to the large number of teeth that engage simultaneously.
3. Operating smoothness and low kinematic inaccuracy due to two-zone and multipair toothing.
4. Rotation transmission from a sealed space without the use of rotatory seals.
5. Low loads on the shafts and bearings as a consequence of construction symmetry.
6. Operation with little noise.

Disadvantages

1. Production complexity of the thin-walled flexible wheel and the wave generator.
2. The need for special gear-shaping equipment to apply the small modules.
3. Limited rotational frequencies of the wave generator, leading to increased vibration.

Applications

Wave gears are applied in industrial robots and manipulators, in mechanisms with high transmission ratio, and also in devices with increased requirements of kinematic accuracy or tightness.

6.8.4 The Nature and Causes of Failure of Wave Gear Details

Some of the causes of failure of wave gear details are:

1. Fracture of the flexible wheel as a result of fatigue cracks in the tooth sockets, as the wheel is exposed to alternate bending stresses.
2. Bearing fracture of the wave generator as a consequence of the toothing force action and the resistance of the flexible wheel to deformation.
3. Skipping of the wave generator (rotation of the generator shaft without rotation of the output shaft) as a result of insufficient radial rigidity and great resilience of the wave generator and the stiff wheel for the transmission of high torques. Thereupon the teeth at the toothing entry rest with their tops against

each other, the stiff wheel bursts open, the generator is compressed, and skipping occurs.

4. Wear of the teeth. Insignificant wear of the teeth is caused by warping of the flexible wheel, which is deformable at one end; progressive wear is caused by tooth slipping through the entry into the toothing.

Alloy steel is used for *flexible wheels*. A billet in the form of a thick tube is refined with heat treatment. Strengthening with cold stiffening, including the tooth sockets, or with nitriding is recommended. Nitriding and cold stiffening of the gear rings are carried out after machining and tooth cutting. Cold stiffening increases the endurance limit by a factor of approximately 1.15, and nitriding increases it by a factor of about 1.4.

In Russia for *heavily loaded* flexible wheels (with low values of u) steels of heightened viscosity grades 38Х2МЮА (heat treatment, refinement, and nitriding, center stiffness 32–37 HRC, $\sigma_{-1} = 480–550\,\mathrm{N/mm^2}$), 40ХИМА (refining, 32–39 HRC, $\sigma_{-1} = 480–550\mathrm{N/mm^2}$), which are less sensitive to stress concentration, are used. *Intermediate-loaded and lightly loaded* flexible wheels are mostly produced from the steel grades 30ХГСИ (refined, 32–37 HRC, $\sigma_{-1} = 420–450\,\mathrm{N/mm^2}$, by further cloud-burst stiffening or nitriding $\sigma_{-1} = 480–500\,\mathrm{N/mm^2}$ (Appendix 6.A Table 6.95).

For welded flexible wheels steel grades such as 30ХГСА, 12Х18И10Т (18–22 HRC, $\sigma_{-1} = 280\,\mathrm{N/mm^2}$) are preferable) (Appendix 6.A Table 6.95).

The stiff wheels of wave gears are similar in construction to the wheels with internal teeth of standard and planetary gears. They are characterized by having a lower stress condition than flexible wheels. They are manufactured from standard structural steel grades 45, 40Х, and 30ХГСА with a stiffness that is 20–30 HB lower than that of flexible wheels. It is possible to produce stiff wheels from the iron grade ВЧ60) (Appendices 6.A Tables 6.95, 6.95)

The main criteria for the working capacity and the calculation of tooth wave gears are the toughness of the flexible wheel and also the static and dynamic load rating of the wave generator bearings.

6.8.5 Fatigue Strength Calculation of Flexible Wheels

Let us consider an element of the flexible wheel with thickness h and length l (Fig. 6.117) as a part of a circular ring with initial curvature r. After deformation of the flexible wheel by the generator the illustrated element

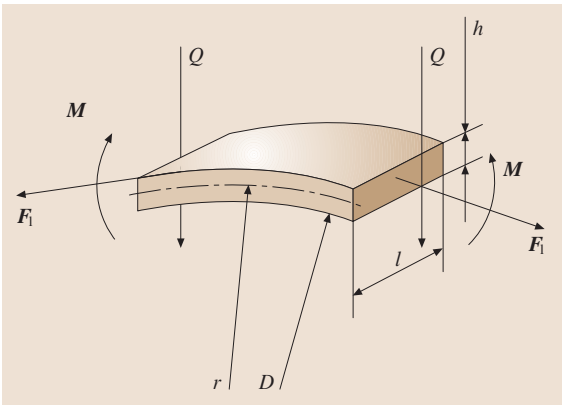

Fig. 6.117 Diagram for the strength calculation of the flexible wheel

has a curvature incrementation that can be represented as depending on the moment of deflection M.

As initial research has shown, the toughness of flexible wheels depends mainly on the stresses that arise as a result of the action of the deflection moment M.

Without taking into consideration the influence of the longitudinal force F_l or transverse force Q the general differential equation of the deflected ring axis has the form

$$\frac{1}{r^2}\left(\frac{\mathrm{d}^2W}{\mathrm{d}\varphi^2} + W\right) = -\frac{M}{EJ}\,, \tag{6.19}$$

where the left-hand side is the ring curvature after deformation, W is the radial displacement, $r = (D+h)/2$ is the radius of the median surface before deformation, and D is the diameter of the flexible wheel opening. On the right-hand side M is the moment of deflection, E is the elasticity module of the wheel material, and J is the moment of inertia of the cross section

$$J = \frac{\ell h^3}{12} = \frac{\ell h^2}{6}\frac{h}{2} = W_b\frac{h}{2}\,,$$

where W_b is the section modulus to bending. The minus sign corresponds to the configuration shown in Fig. 6.117, where moments of deflection that reduce the ring curvature are positive.

Let us transform the right-hand side of (6.19)

$$\frac{M}{EJ} = \frac{M}{EW_b\,(h/2)} = \frac{\sigma_\mathrm{F}}{E\,(h/2)}\,.$$

Calculating the changed equation (6.19) relative to the bending stresses σ_F we obtain

$$\sigma_\mathrm{F} = -\frac{Eh}{2r^2}\left(\frac{\mathrm{d}^2W}{\mathrm{d}\varphi^2} + W\right)\,.$$

Obviously, the bending stresses depend on the deformation law of the flexible wheel. By deformation according to the law $W = W_0 \cos(2\varphi)$, which is similar to that for an ellipse, we have

$$\sigma_F = -\frac{Eh}{2r^2}\left(-4W_0 \cos(2\varphi) + W_0 \cos(2\varphi)\right) .$$

It follows that the bending stresses vary, and that they reach maximum values for $\varphi = 0$ and 90°.

For $\varphi = 0°$

$$\sigma_F = \frac{3}{2}\frac{EhW_0}{r^2} .$$

For $\varphi = 90°$

$$\sigma_F = -\frac{3}{2}\frac{EhW_0}{r^2} .$$

In the general case we can write

$$\sigma_F = A_\sigma \frac{EhW_0}{r^2} ,$$

where A_σ is a coefficient that depends on the form of the deformation. This is particularly so for deformation of flexible wheels with a cam generator with a flexible bearing $A_\sigma = 1.75$.

The characteristics of the cycle of alternating symmetric changes of bending stresses are its amplitude $\sigma_a = \sigma_F$ and mean value $\sigma_m = 0$.

The availability of the gear ring and the tension under the action of the forces F_1 distinguish the real flexible wheel from the smooth ring. Both result in an increase of the acting stresses. Thus, the coefficient K_σ, which takes into account the influence of the gear ring and its tension on the strength of the flexible wheel, is applied to the rated relation ($K_\sigma = 1.5–2.2$; higher values correspond to lower module values and lower values of the rounded radii in the sockets between the teeth).

Upon installation the generator distorts the flexible wheel from only one side. Under the action of the torque the initial form and size of the deformation change in a real gear. This is due to the adjustment of the radial clearance in the supple bearing, the clearances between the bearing cup and flexible wheel, and the contact deformations in the supple bearing and deformations of the stiff wheel. This change in the initial form and deformation size results in an increase of acting stresses, which is taken into consideration through the insertion of the coefficient $K_s = 1.3–1.7$ into the design formula.

The loading of the flexible wheel with torque T and intersecting forces Q that cause the action of the shearing stresses is taken into account by means of insertion of the coefficient $K_\tau = 1.2–1.3$ into the design relation.

Thus, the formula for calculation of the equivalent stresses in flexible wheels has the form

$$\sigma_a = A_\sigma \frac{EhW_0}{r^2} K_\sigma K_s K_\tau .$$

The safety factor according to the fatigue strength of the flexible gear ring is determined from the formula

$$S_F = \sigma_{-1}/\sigma_a , \qquad (6.20)$$

where σ_{-1} is the endurance limit of the material used for the flexible wheel.

The strength condition of the flexible wheel (checking calculation) is

$$S_F \geq [S]_F , \qquad (6.21)$$

where $[S]_F = 1.6–1.7$. Higher values indicate a probability of nonfracture of greater than 99%.

In the case of the design calculation the diameter d of the flexible wheel opening is determined according to the fatigue strength criterion of the flexible ring (Sect. 6.8.6).

Bearing Calculation of Wave Generators

An operational peculiarity of wave generators is the fact that they rotate with high frequency of the input element reacting to high loads of the output elements. The cam wave generator is optimum in terms of load-carrying capacity. The required dynamic load rating of flexible bearings is determined according to the standard method for rolling bearings (Sect. 6.11.14). Wear of the teeth is insignificant and does not limit the gear lifetime in the case of correctly chosen mesh geometry, materials, heat treatment, and lubrication parameters.

6.8.6 Design of Wave Gears

Choice of Mesh Parameters

Tooth Profile. Involute teeth are used in the wave gears, with well-known technological advantages such as the availability of existing tools and the ability to provide sufficiently high multipair toothing under load. To cut involute teeth a tool with a 20° angle of the basic rack profile is used.

It should be noted that the stresses in the rim of the flexible gear wheel reduce when the socket width is increased to a size that is similar to or greater than the tooth thickness. Involute teeth with a wide socket can be cut with a tool with a reduced pitch line depth. The profile of involute teeth with a wide socket is accepted as the basis for the standard series of harmonic reducers for machine-building applications.

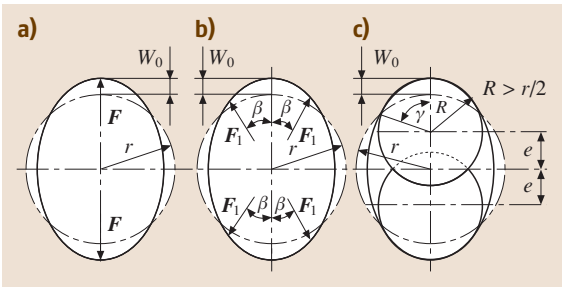

Fig. 6.118a–c Straining diagrams of the flexible wheel with a wave generator. **(a)** With two rollers, **(b)** with four rollers, and **(c)** disk

The construction of the generator determines the deformation form of the flexible wheel as: two-roller (Fig. 6.118a), four-roller (Fig. 6.118b), or disk-shaped (Fig. 6.118c). Any of these forms can be achieved with a *cam generator*. The cam generator retains the set deformation shape better than the others and is thus preferable.

The dimension W_0 of the initial deformation of the flexible wheel is a primary parameter for the calculation of the toothing and generator geometry.

Geometry of the Gear Rings of Flexible Wheels and Rigid Wheels. One of the main geometrical parameters of wave gears is the inner diameter d (mm) of the flexible wheel, the approximate value of which is determined according to *the fatigue strength criterion of the flexible ring*

$$d = 105\sqrt[3]{T/\left(0.16\sigma_{-1}\sqrt{u}/\left(K_\sigma\,[S]_\mathrm{F}\right)\right)}\,,$$

where T is a torque on the low-speed shaft (N m), σ_{-1} is the endurance limit of the flexible steel wheel material (N/mm^2), $K_\sigma = 1.5 + 0.0015u$ is the effective stress concentration factor, u is the transmission ratio, and $[S]_\mathrm{F} = 1.6–1.7$ is a safety factor (higher values of which denote a probability of nonfracture of greater than 99%).

For gears with a cam generator the computed diameter is adjusted according to the outer diameter D of the flexible bearing (Table 6.42).

The width $b_\mathrm{w} = (0.15–0.2)d$ of the gear ring and the thickness S_1 of the flexible wheel are calculated as

$$S_1 = 10^{-4}\left(65 + 2.5\sqrt[3]{u^2}\right)d\,.$$

The circle diameter of the sockets is determined as $d_{fg} = d + 2S_1$. Taking into account that the diam-

eter d_{fg} is similar to the pitch diameter of the flexible wheel, $d_g \approx d_{fg}$, the module is calculated as $m = d_g/z_g$. It is assumed that $z_g = 2u$ for gears according to (Fig. 6.115a) and $z_g = 2u - 2$ for gear according to (Fig. 6.115b,c).

The value of the module m (mm) is adjusted to the standard one:

Further, the tooth numbers z_g and z_b are specified, and displacements of the basic rack profile are selected, which provide the diameter d_{fg}. The pitch diameters of the wheels are then calculated: for the flexible one $d_g = mz_g$ and for the stiff one $d_b = mz_b$. The outer diameter of the flexible wheel is determined as $d_{ag} = d_{fg} + 2h_g$, where h_g is the tooth depth of the flexible wheel. When cutting the teeth with a narrow socket on the flexible wheel one has $h_g \approx (1.5–2.0)m$, and when using a wide socket one has $-h_g \approx (1.35–1.55)m$. Then other dimensions of the flexible wheel are set (see below) and the checking calculation is carried out according to the chosen deformation form determining the reserve of the fatigue strength from (6.20) and (6.21).

Design of Flexible Wheels and Rigid Wheels

The Structure of Flexible Wheels. Figure 6.119 shows the most commonly used structures of the flexible wheels of wave gears: (a) with a flexible bottom and a flange for connecting to the shaft, and (b and c) with a spline connection to the shaft. The splines can be cut on the outer (Fig. 6.119b) or inner (Fig. 6.119c) surface of the cylinder. The spline connection reduces the rigidity of the cylinder and, as a result of the axial mobility, decreases stresses in it.

Without the flexible bottom and due to the rigid connection of the cylinder to the shaft (Fig. 6.119d), stresses in the cylinder increase considerably, and the bending rigidity and the resulting load on the generator increase. Such a structure should not be used.

When a flexible wheel is produced as shown in to Fig. 6.119a, the axial yield is provided with a thin bottom at the transfer point of the cylinder to the shaft. *Welded variants* are applied to join the cylinder to the flexible bottom by using a flat butt weld (Fig. 6.119e) or an end joint (Fig. 6.119f). A welded connection of the flexible bottom to the shaft with a size of no more than d_1 (Fig. 6.119g) is also possible; on the flexible bottom an end joint is made according to the shaft diameter.

If the bottom has a flange, the joint can be bolted (Fig. 6.119a), a pin-hole, spline, a keyed, or pressure coupling. Usually a spline connection is used, which allows a relatively small dimension S_6 (Fig. 6.119h).

The shoulder a_1 (Fig. 6.119a) is introduced to reduce the stress concentration at the edges of the gear ring. Towards this end hollow chamfers of major radii

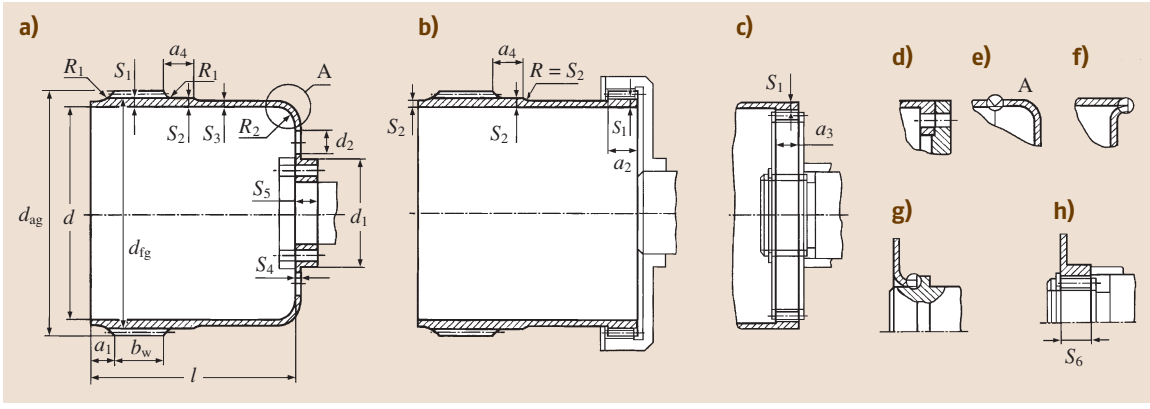

Fig. 6.119a–h Structure of the flexible wheels. (a,d–h) With a flexible bottom, (b,c) with a spline connection to the shaft

R_1 are produced between the gear ring and the cylinder. The openings d_2 increase the compliance of the flexible bottom and provide lubrication circulation. The number and dimensions of the openings are chosen to be as large as possible while still providing sufficient toughness and stability of the bottom.

Previously, d, d_{fg}, d_{ag}, b_w, and S_1 were calculated. Other dimensions given in Fig. 6.119 can be taken according to the following recommendations, which have been tested in practice

$$
\begin{aligned}
d_1 &= (0.6–0.8)d\,, & a_1 &\approx 2S_1\,,\\
l &= (0.8–1.0)d\,, & a_2 &\approx 0.5b_w\,,\\
d_2 &= 0.4(d-d_1)\,, & a_3 &\approx 0.7b_w\,,\\
S_2 &= (0.85–0.9)S_1\,, & a_4 &\approx 0.5b_w\,,\\
S_3 &= (0.6–0.7)S_1\,, & R_1 &\approx 3S_1\,,\\
S_4 &= 1.2S_3\,, & R_2 &\approx 3S_1\,.\\
S_5 &= 3S_1\,,
\end{aligned}
$$

The design of the flexible wheel in Fig. 6.119b is more universal due to the possibility of connection to the shaft or the case.

It is advisable to use a design with a flexible bottom Fig. 6.119a in large-lot production, when metal blocks can be obtained through die forming or expansion. If a method using plastic strain is difficult, welded structures are applied (Fig. 6.119e,f). In single-part production the billet for the flexible wheel as shown in Fig. 6.119a can be obtained by means of turning. However, it is necessary to take into account that the toughness decreases at the same time.

Flexible wheels of tight gears are made in the form of a closed cylinder (Fig. 6.115c), which increases its rigidity considerably, thus increasing the stress level in the cylinder and the load on the generator. To reduce these effects the cylinder length is increased. Transfer

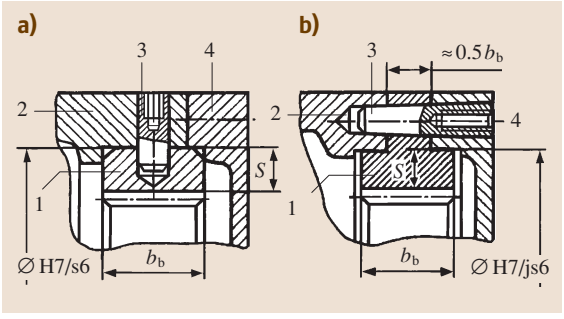

Fig. 6.120a,b Connection with the case of the rigid wheel. **(a)** Without a flange and **(b)** with a flange

of the cylinder to the wall is carried out conically and completed with a thin aperture. The conical area is necessary for ease of installation of the generator with the wheel. The diameter of the flexible wheel d_g and toothing parameters are calculated in the same way as for standard wave gears. The face width is assumed to be $b_w = (0.12–0.18)d$. Other dimensions are assumed to be (Fig. 6.115c)

Structure of Stiff Wheels. The stiff wheels of wave gears are similar to the wheels with internal teeth used in standard (with stationary axes) and planetary gears (Figs. 6.95, 6.96, 6.100, and 6.103).

The stiff wheel (1) (Fig. 6.120a) is pressed into the case (2), while the interference fit and three or four pins (3) apply a torque. In the structure shown in Fig. 6.120b the stiff wheel (1) has a flange and centering spigots for mounting the wheel into the case (2) and the cover (4) on the wheel. The wheel structure in Fig. 6.120a is easier to construct, but mounting and dismantling of the stiff wheel are not as convenient. The structure in Fig. 6.120b provides greater wheel rigidity.

The face width b_b of the stiff wheel is designed to be 2–4 mm thicker than that of the flexible one. This allows lower requirements on the positional accuracy of the wheels in the axial direction. The thickness of the stiff wheel is assumed to be $S \approx 0,085d_b$, with the following check on the operating conditions: the maximum radial displacement under load from the toothing forces should not exceed $(0.05–0.02)h$, where h is the tooth setting depth. For involute teeth with a narrow socket one has $h \approx (1.3–1.6)m$, and for teeth with a wide socket one has $h = m$.

Design of Wave Generators

Roller generators are physically simple and easy to manufacture, but they have free areas of the flexible wheel (Fig. 6.118a,b), which do not allow the set deformation form under load to be guaranteed. In view of their small dimensions, bearings for the roller bearers have a limited lifetime, which is why such generators are applied in *lightly loaded* gears.

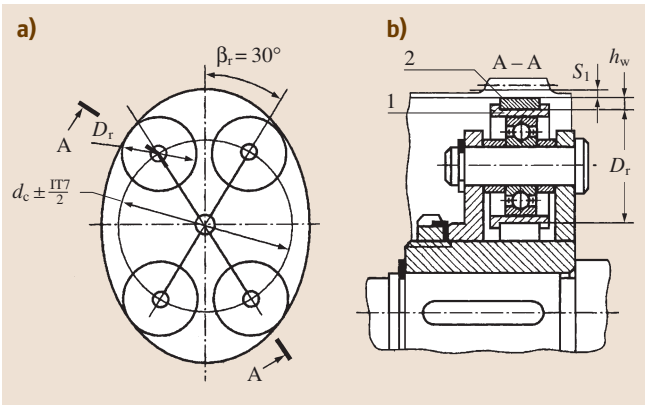

Fig. 6.121a,b Execution version of the four-roller generator

The structure of a four-roller generator is shown in Fig. 6.121. So that the flexible wheel does not flare with the rollers, a jar washer (2) is placed along its inner diameter. In Russia this jar washer is made from the same material as the rollers, e.g., steel 100Cr6 (50–58 HRC) (Appendix 6.A Table 6.95). Furthermore, the jar washer increases the rigidity of the system made up of the flexible wheel and the jar washer and thus reduces distortion of the deformed shape under load. The thickness of the jar washer is assumed to be $h_w \approx 1.5 S_1$. As a roller a rolling bearing, on which the washer (1) is pressed to the ledges, can be used. The ledges are intended to protect the jar washer (2) from axial displacements. The thickness of the washer (1) is assumed to be equal to h_w.

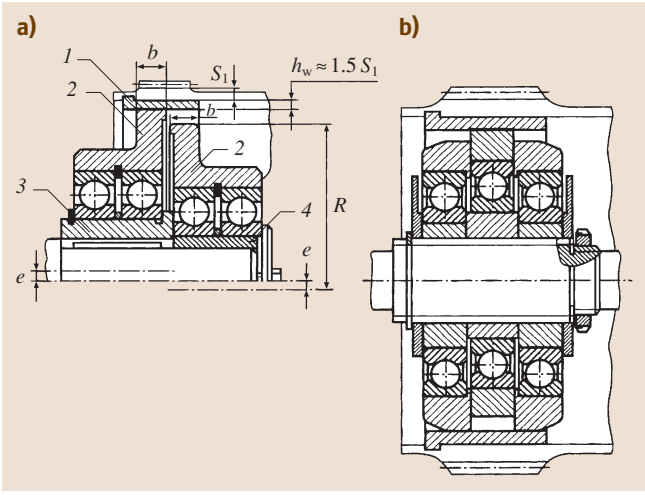

Fig. 6.122a,b Execution version of the generator with disks. **(a)** Two single disks, **(b)** one double disk and one single disk

The diameter of the roller centers is

$$d_c = d + 2W - D_r \,,$$

where d is the inner diameter of the jar washer, W is a radial displacement of the strained flexible wheel at the contact point with the roller, and $D_r \leq 0.33d$.

Disk Generators. The layout of a disk generator is shown in Fig. 6.118c, The structure variants are given in Fig. 6.122. A flexible wheel strained with a generator is positioned along the disk circles on the bow 2γ (Fig. 6.118c), which contributes to keeping the deformation form in the loaded gear. The radii R of the disks and eccentricity e are selected so that the angle γ is 20−40° for the set size of deformation W_0. Usually, $e/W_0 = 3–3.6$, where a lower values means higher γ and lower u.

Each generator disk (2) (Fig. 6.122a) is positioned on two bearings, which protects the disks from warping. The bearings are located on the cylindrical eccentrically positioned shaft journals. The eccentric journals (3 and 4) are formed directly on the shaft and placed on the shaft in the form of bushings. Both bushings are machined as one detail with eccentricity e and a key slot, which is then cut up and fitted onto the shaft. One of its sections is turned through 180°, then the position accuracy of the eccentrics is defined only by the position accuracy of the keys on the shaft. The position accuracy of the eccentrics can be increased by the application of a spline connection with an even number of splines.

As for the roller generator a jar washer (1) is installed to prevent the flexible wheel from flaring. Fixing of the jar washer is difficult in the disk generator because of the axial displacement. In the structure shown in Fig. 6.122a the ledge that fits into the groove of the flexible wheel holds the washer. The ledge height is limited by the allowable value of the elastic tensile strain of the flexible wheel at installation of the jar washer (i. e., it must not exceed it by more than a tenth of a millimeter), which does not guarantee safe blocking of the washer. Moreover, as a stress concentrator, the groove reduces the toughness of the flexible wheel. In Russia the material of the jar washer is steel 100Cr6 (50–58 HRC). The material of the disks is structural steel 45, 40X with quenching of the work surface up to 48–50 HRC (Appendix 6.A Table 6.95).

The offset position along the shaft axis sets up unequal deformation conditions of the flexible wheel in two areas and unbalances the generator load. To decrease this effect the thickness of the disks is reduced

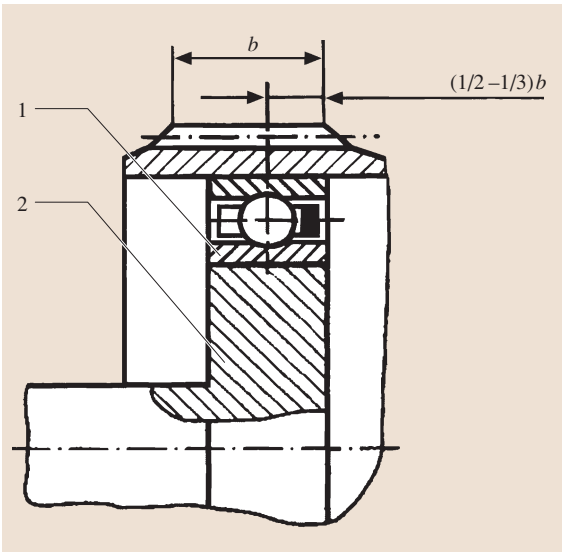

Fig. 6.123 Execution version of the cam generator

to $b \approx 0.1R$. Imbalance in the axial plane can be substantially decreased by applying the generator structure shown in Fig. 6.122b, where one double disk is located symmetrically relative to another single disk. The disk wrap is eliminated through their mutual fit along the ends, which allows installation of each disk on only one bearing. In the structure shown in Fig. 6.122b high execution accuracy of the axial dimensions of the corresponding details is required, the tolerance ranges of which are assigned on the basis of dimension series taking into account axial clearances in the bearings. In power trains the bearings of the disk generator operate under high loads. Thus, the bearing diameter should be chosen to be as large as possible to be in the range of the disk diameter.

Cam Generators. Cam generators consist of an oval cam (2) with a special flexible rolling bearing (1) (Fig. 6.123) pressed on it. The cam profile is designed equidistantly to the accepted deformation form of the flexible wheel, where the initial cam radius is $r = 0.5d$ (Fig. 6.118), where d is the inside diameter of the bearing (Fig. 6.124). The flexible bearing has thin-walled racers, which allows radial deformation of the racers commensurate with their thickness and provides transmission of the rotary motion through the strained racers.

The cam generator retains the deformation shape of the flexible wheel under load better than other generators. With a view to equalizing the load along the tooth

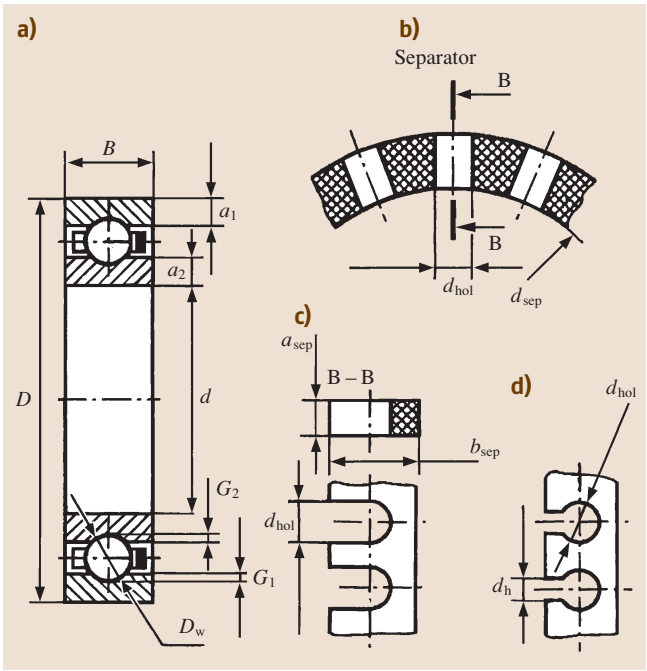

Fig. 6.124 (a) Flexible bearing and (b–d) embodiments of the separator

length and to reduce the axial force on the flexible bearing, the generator is installed in the middle of the gear ring and nearer to the back end.

Flexible bearings (Fig. 6.124a) are distinguished from standard bearings not only by their smaller

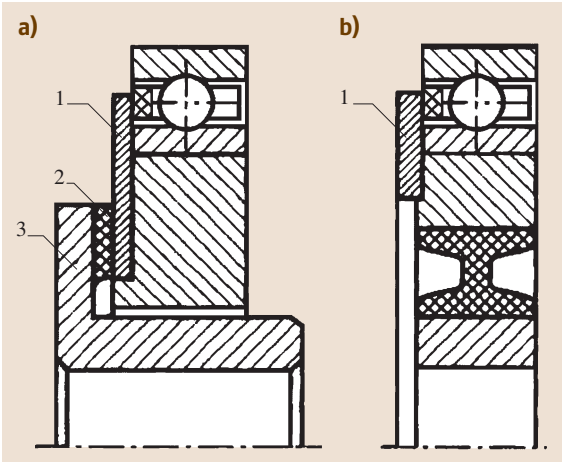

Fig. 6.125a,b Connection of the generator to the shaft by means of an elastic washer (a) and by means an elastic element with increased flexibility under angular warps (b)

racer thickness, but also by the structure of their retainer. The retainer is manufactured from material with a relatively low coefficient of elasticity (textolite, phenilon) with a U-shaped housing. (Fig. 6.124b,c). As a result of the bridge deflections and action of the axial component of the compressive force, under load the retainer is squeezed out of the bearing. It is held, e.g., with a disk (1), fastened to the end of the cam generator (Fig. 6.125). The friction between the retainer and the thrust ring increases losses, which are smaller with a self-closing retainer structure (Fig. 6.124d).

The basic parameters of flexible bearings are (Fig. 6.124):

Table 6.44 Parameters of flexible bearings

Racer thickness	$a_1 \approx a_2 \approx (0.020-0.023)D$
Depth of the racer grooves	$G_1 \approx G_2 \approx (0.05-0.06)D_w$
Inner diameter of the retainer	$d_{sep} = d + 2a_2 + 0.02D + 0.05D_w$
Retainer thickness	$a_{sep} = (0.055-0.060)D$
Retainer width	$b_{sep} = (1.2-1.3)D_w$
Width of the retainer groove	$d_{hol} = (1.01-1.03)D_w$
Housing width	$d_h = D_w$

The parameters of flexible ball journal bearings are given in Table 6.42.

A flexible bearing with opening diameter d is installed on the cam, the diametral dimensions of which are designed to be in the tolerance range $js6$ ($js7$). The outer race of the flexible bearing is mated according to the distance D (Table 6.42) from the inner diameter of the flexible wheel with tolerance range $H7$.

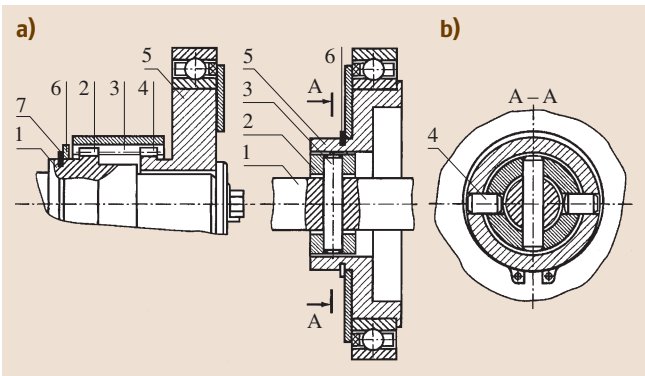

Fig. 6.126a,b Connection of the generator with the shaft by means of the toothed coupling (**a**) of the fixed joint (**b**)

Joining of the Generator to the Shaft. Dead and sliding joints are used for joining the generator to the shaft. In a cam generator with a *dead* joint the cam is installed onto the shaft by means of the usual method, whereby the transmission of the torque is carried through a key joint or spline connection or an interference join. A dead joint can be applied in the case of full coaxiality of the stiff wheel axis and the rotation axes of the generator and the flexible wheel, which can only be achieved with very high requirements of manufacturing accuracy. Deviation from coaxiality results in an uneven load distribution in the toothing zones and an imbalance of power. As a result service life may be reduced and the shaft may even suffer breakage.

For compensation of the kinematic element coaxiality a *sliding* joint can be used to connect the generator to the shaft. This is made with the help of resilient members or fixed joints. In the structure shown in Fig. 6.125a the resilient member is designed in the form of an elastic washer (2), vulcanized to the metal disks (1 and 3), which are further connected to the cam and the shaft. The elastic element shown in Fig. 6.125b possesses increased yielding due to the angular warps. The disadvantage of these joints is the strength reduction of rubber after a certain time.

In the structure shown in Fig. 6.126a the fixed joint is similar to the toothed coupling: the shaft (1) and cam (5) of the generator have gear rings (2 and 4) with external teeth. The washer (6) and the spring ring (7) limit the movement of the bushing (3) in the axial direction.

In the reduction gears swing joint of the generator to the shaft with a cross-shaped position of the pins is used (Fig. 6.126b). The pin (3) goes through the shaft (1) and the bushing (2); two pins (4) go through the bushing (2) and the cam (5). The pins are mounted in the openings with clearances. The internal cam face (5) prevents the pin (3) from falling out, and the spring ring (6) and external shaft face hold the pins (4).

All the structures shown in Figs. 6.125 and 6.126 allow radial and angular cam movements.

For sliding joint the cam generator is the most convenient configuration. For a disk generator, joining of the generator to the shaft with a sliding joint is difficult. In such structures self-adjustment of the elements should be carried out by means of the sliding joint of the rigid wheel with the case or the shaft, which is more difficult and more expensive.

6.8.7 Thermal Conditions and Lubrication of Wave Gears

Thermal conditions of wave gears are calculated in accordance with the known relations (see, e.g., the thermal design of worm-and-wheel gearboxes, Sect. 6.5.13). The allowable oil temperature for reduction gears in industrial applications is $[t] = 70–80°C$. A heat transfer coefficient of as $K = 8–12$ is assumed for small, closed rooms lacking in ventilation. For rooms with intensive ventilation one uses $K = 14–18$, and in the case of fanning $K = 21–30\,\mathrm{W/(m^2\,°C)}$. With a fan installed on the high-speed shaft of the reduction gear, the lower values of this range are used for a rotational frequency of $n \le 1000\,\mathrm{min^{-1}}$, whereas the higher values for K apply for rotational frequencies of $n \ge 2800\,\mathrm{min^{-1}}$.

For reduction gears used in machine-building applications fluid mineral oil with kinematic viscosity of $68–100\,\mathrm{mm^2/s}$ is recommended. If needed, a semisolid lubricant is used. The bearings of the generator and the toothing are lubricated by mounting the reduction gear and is occasionally done online. To change the semisolid lubricant takes approximately 1000 working hours.

A semisolid lubricant can be used in the case of vertical installation of the reduction gear axis. A special oil feeding unit is mounted in the reduction gear for liquid oil lubrication (Fig. 6.127). Under the action of centrifugal forces oil rises inside the *feeding cone*, goes through the openings (1) and clearance (2) into the generator and thereby reaches the bearing and toothing. The structure in Fig. 6.127 is recommended for rotational frequencies of $n \ge 960\,\mathrm{min^{-1}}$.

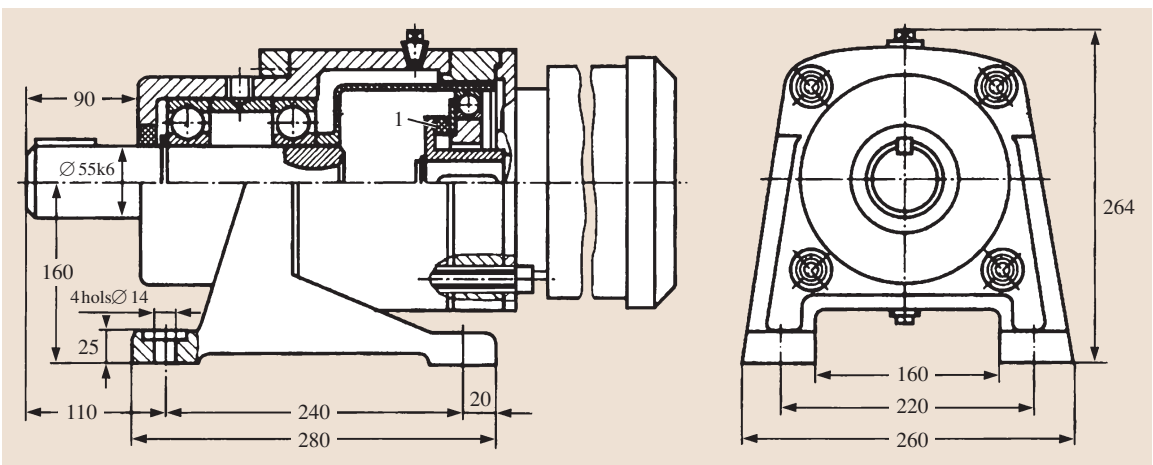

Fig. 6.129 Harmonic motor-reducer

It is recommended to use a quantity of oil in the reduction gear such that its level reaches the center of the lower ball of the flexible bearing when the reduction gear is in a horizontal position. For $n < 960\,\mathrm{min}^{-1}$ and vertical shaft installation it is possible to fill the reduction gear with oil completely.

6.8.8 Structure Examples of Harmonic Reducers

Wave gears are standardized, with the internal diameter of the flexible wheel ranging from 50 to 250 mm, torques from 35 to 5600 N m, and transmission ratios from 76 to 275.

Figure 6.128 shows a typical structure of a harmonic reducer. Distinctive features of the structure are: the double-seat shaft of the generator, the junction of the cam generator with the shaft with an articulated shaft coupling (Fig. 6.126b), the welded connection of the flexible wheel cylinder to the bottom, the spline connection of the flexible wheel to the shaft, the axial fixation of the output shaft bearings in the case with spacing bushing (1) and three adjusting screws (2), the joint with interference of the stiff wheel with the case, and the cylindrical form of the internal housing without inner valleys and pockets, which simplifies casting and cleaning after casting and machining.

Figure 6.129 shows a harmonic reducer with removable legs mounted to the cylindrical case with screws. Distinctive features of this reducer are: the cantilever position of the generator on the electric motor shaft, the junction of the generator with the shaft with the vulcanized elastic washer (1); the flexible wheel is pressed with the following machining, the joint with interference of the flexible wheel to the shaft, and the fixation of the stiff wheel on the case with screws and pins.

6.9 Shafts and Axles

6.9.1 Introduction

Gear wheels, pulleys, chain wheels, and other revolving machine parts are installed onto shafts and axles. A *shaft* is intended for transmission of the torque along its axis, for holding the details that are located on it, and for withstanding the action of the forces acting on these details. An example is the shaft of a reduction gear (Fig. 6.130). Under operation the shaft experiences the action of *bending and torsion* stresses, and in some cases extra tension or compression stress [6.70–77].

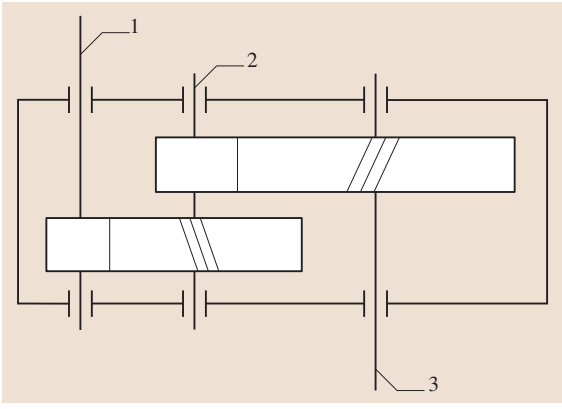

Fig. 6.130 Diagram of the cylindrical double-reduction gear unit

An *axle* only supports the details installed on it and takes the forces acting on these details. An example is the axle of a railroad car (Fig. 6.131). In contrast to a shaft an axle does not transmit torque and therefore *does not experience torsion*. An axle can be *fixed* or *can rotate* with the details placed on them. Rotating axles provide a better operating environment for the bearings. Fixed axles are cheaper but require integration of the bearings into the details rotating on the axles.

Most shafts have an invariable nominal axle geometry, i. e., they are *stiff* shafts. A special group includes *flexible* shafts that have a variable form of the geometrical axles. Depending on the form of the geometrical axles, shafts are divided into *straight* (Fig. 6.132) and *indirect* crankshafts, which serve to transform alternating motion into rotational motion (or vice versa), and *eccentric* crankshafts.

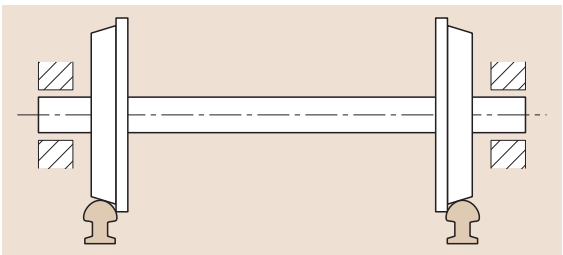

Fig. 6.131 Axles of a railroad car

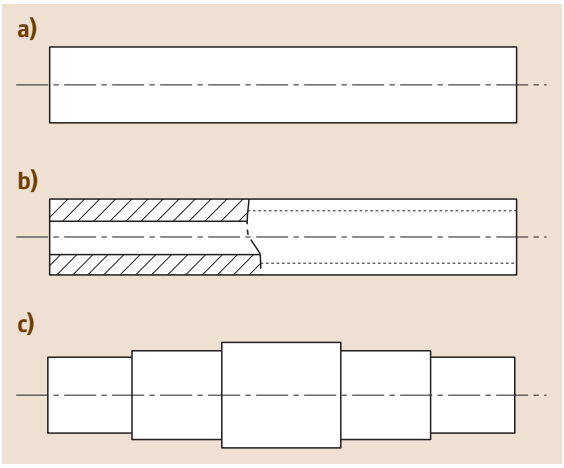

Fig. 6.132a–c Straight shaft. **(a,b)** Single-diameter part, **(c)** multidiameter shaft

As a rule, the axles used are straight. Straight shafts and axles have the form of bodies of revolution and differ little from each other in design. Straight shafts and axles can be of constant diameter: *single diameter* (Fig. 6.132a,b) or *multidiameter* (most shafts, Fig. 6.132c).

Depending on the form of the cross section there are *solid* and *hollow* shafts, and axles (with axial opening, Fig. 6.132b). Hollow shafts are used for mass reduction, as well as when other details and materials must be passed through the shafts or positioned inside the details or materials (oils, cooling gases, and liquids).

Depending on the outer outline of the cross section the shafts are divided into a *spline* and a *key*, which have a spline profile or a profile with a key groove along a certain length. Shafts are also classified according to conventional features, e.g., according to the relative speed of rotation in the unit (e.g., in the reduction gear in Fig. 6.130) as high-speed 1, medium-speed 2, and low-speed 3, or according to position in the unit: input 1 (drive), countershaft 2, and output 3 (driven). *Journals* serve as supports for shafts and axles. Intermediate journals are called *necks*.

Shaft Form According to Length

Based on data of uniform strength it is advisable to design shafts similar to bodies with equal bending resistance in their longitudinal section, outlined by a cubic parabola. *Multidiameter shafts* approximate to the form of a body with equal resistance. This form also simplifies manufacture and mounting of the details on the shaft.

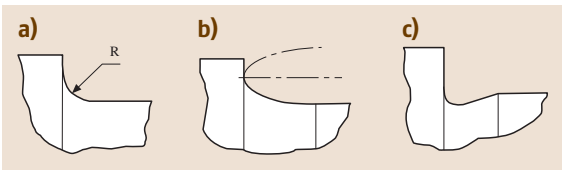

Fig. 6.133a–c Transition shaft sections. **(a)** With a hollow chamfer of the constant and **(b)** varying radius, and **(c)** with a groove with rounding

Transitional sections of the shafts and axles between two stages of different diameters are designed as follows. For a hollow chamfer of constant radius (Fig. 6.133a), a hollow chamfer is a surface of the graded junction from the light section to the major one; for a hollow chamfer of varying radius (Fig. 6.133b), with a groove with a fillet for outlet of the grinding wheel is used (Fig. 6.133c). Transitional sections are stress concentrators. An effective method for stress concentration reduction in the transitional sections is to increase their yielding (e.g., by means of increasing the hollow chamfer radii and introducing balancing grooves). Strain hardening (cold hardening) of the hollow chamfers increases the load-carrying capacity of shafts and axles.

Shaft and Axle Materials

Carbon and alloy steels (Table 6.45) are the basic materials for shafts and axles due to their toughness, their high elasticity coefficient, and the strengthening ability and availability of the required cylindrical blanks through forging or rolling.

In Russia for shafts and axles subjected to a rigidity criterion and not heat-treated, steel grades E 295 and E 355 (EN) are mainly used. Heat-treated medium carbon and alloy steel grades 35 (GOST) [6.78–88], C 46, C 45 (EN), and 37 Cr 4 (DIN) are used for most shafts. Alloy steel grades 40 NiCr 6 (DIN), 40 NiCrMo 4 KD (EN), 30 MnCrTi (DIN), 20 CrMo 5 (DIN), and others are used for high-duty shafts of critical machines (Appendix 6.A Table 6.95). Shafts made from these steels are usually refined, quenched with a high-temperature tempering, or surface-hardened by heating with RF current and low-temperature tempering (spline shafts).

Alloy steels are used following certain constructive reasons, e.g., the need to provide the required contact or bending strength of the teeth cut directly on the shaft, or the need to obtain the required qualitative characteristics of the surface layers on individual shaft areas.

For high-speed shafts rotating in a friction bearing, high journal hardness is required. In this case, shafts are

produced from cemented steel grades 20CrS4 (DIN), 14NiCr10 (5732) (DIN), 20MnCr5G (DIN) or nitrided steel grades 40NiCrMo4KD (EN), 41CrAlMo7 (EN) (Appendix 6.A Table 6.95). Chrome-plated shafts have the greatest wear resistance. Based on experience in automobile construction, chromium plating of crankshaft journals increases the lifetime of regrinding by three to five times.

For shafts where the dimensions are defined by the rigidity criterion, it is advisable to apply only strong heat-treated steels in order to guarantee the service life of splins and other wearing faces.

For the production of shaped shafts (crankshafts, shafts with major flanges and openings, and other heavy shafts) high-duty cast irons (with globular graphite), and inoculated cast irons are used along with steel. The lower toughness of iron shafts is substantially compensated for by the more exact forms of the shafts (especially crankshafts), the decreased stress concentration sensibility of iron, lower sensibility (because of lower elasticity coefficient) to inaccurate bearing positions in multiple-bearing shafts, and lower additional dynamic load due to their greater damping capacity. Long hollow shafts are sometimes manufactured from composite materials by means of multilayer winding of a band on a straight plug.

Rounds are used as billets for steel shafts with a diameter of up to 150 mm, and forgings are used for shafts with large diameter and shaped shafts. Shafts are sometimes welded from tubes or sheets with welded or set flanges. Shafts are subjected to turning and mounting surfaces are ground. High-duty shafts are ground over their entire surface.

6.9.2 Means of Load Transfer on Shafts

The main forces acting on shafts are forces from the gears. The forces on the shafts are transmitted through the details set on them: gear or worm wheels, pulleys, chain wheels, half-couplings, etc.

The three-dimensional diagram in Fig. 6.134 shows the forces loaded on the shafts of a double-reduction cylindrical gear unit with helical gearing. In analytical models these forces, as well as the torques, are shown as concentrated, applied at the center of the hubs (Fig. 6.135). The influence of the weight of the shaft and the installed details is neglected (with the exception of heavy flyweights and so on). Frictional forces in the bearings are not taken into account.

Transmission of the torque is carried out through junctions: with interference, spline, key joints, frictional bevel rings, etc. In joints with interference, cylindrical elements are mainly used because they are easier

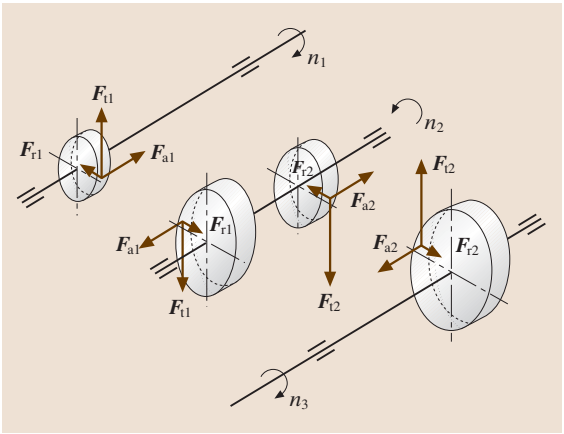

Fig. 6.134 Diagram of the forces loading the shafts of a double-reduction gear unit

to produce. Bevel connections are applied for ease of installation on the shaft and removal of heavy details, for quick detail replacement, e.g., changeable pinions, for the provision of the required interference, and to increase the accuracy of detail centering. Bevel connections are mostly produced on the end sections of the shafts; the required axial force is provided by a nut or a screw and face washer.

Radial forces are transmitted through direct contact of the hub set on the shaft (the most common case), or through bearings (crankpins of the crankshafts). Axial forces are transmitted as follows: those that are substantial in size are transmitted through the detail stop into the shoulders of the shaft (Fig. 6.136a) or through interference fitting of the details; medium forces are

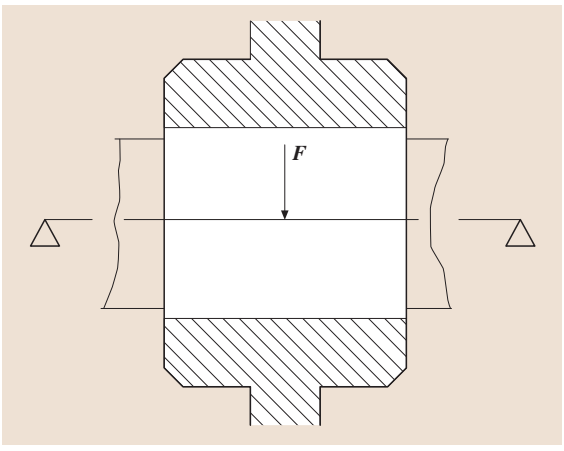

Fig. 6.135 Transmission diagram for the radial force from the wheel hub to the shaft

transmitted through nuts (Fig. 6.136b) or spring planar thrust rings (Fig. 6.136c); and light forces are transmitted through spring rings and stop screws.

6.9.3 Efficiency Criteria for Shafts and Axles

The main efficiency criteria for shafts and axles are strength and rigidity. If necessary, the shafts are calculated on chatter stability. For strength analysis of shafts and axles, the bending moment and torque, together with longitudinal force diagrams, are used. In operation, shafts and rotating axles experience the action of cyclically changing stresses. Strength is estimated by using the safety factors S_y in the static strength analysis of shafts and axles, and with S for fatigue strength analysis; rigidity is estimated by the deflection, angular deflections, or torsion of the sections at the installation points of the details. It is known from practice that the fracture of shafts and axles of high-speed machines is in most cases due to fatigue, so fatigue strength analysis is the main consideration.

The most important force factors in shaft and axle design are the torques T and the moment of deflection M. The influence of stretching and compressive forces on strength is rarely taken into account.

6.9.4 Projection Calculation of Shafts

The projection calculation of shafts is carried out based on the static strength in order to determine the approximate diameter of the single grades. At the beginning of the calculation only the torque T is known. It turns out that the moments of deflection M can be calculated only after the shaft design has been determined, when the length and application sites of the acting loads have been determined by the system setup. This is why the projection calculation for shafts is carried out based only on torsion, and the influence of bending, stress con-

The radial force F is applied to the middle length of the shaft end)

centration, and the pattern of stress change on the shaft strength is compensated for by increasing the allowable stress $[\tau]_t$ on the torsion.

In the projection calculation for reduction gear shafts the cross-sectional diameter of the typical area is usually determined at the end of the input (1) and output (3) shaft and the installation position of the gear wheel on the countershaft (2) (Fig. 6.130). The diameters of other areas are assigned by working out the shaft design, taking into account functionality, fabrication technique, and assembly.

The diameter d (mm) of the rated shaft cross section is determined from the formula

$$d \ge 10\sqrt[3]{T/(0.2\,[\tau]_t)}\,,$$

where T is the torque acting in the rated shaft cross section (N m) and $[\tau]_t$ is the allowable stress on the torsion (N/mm^2).

The values of the allowable stresses on the torsion $[\tau]_t$ for the determination of the diameter d of the input (output) shaft end are given, depending on the load condition, strength, and material hardness, according to Table 6.46.

A sketch to work out the shaft design is then made, specifying its form and dimension after the choice and calculation of the bearings, the calculation of the connections that take part in the driving torque transmission, and the design of the structural components resulting from the chosen fixation methods and adjustment of the axial position of the installed on the shaft details, of the shaft itself in the case, as well as the machining technique for the individual areas.

6.9.5 Checking Calculation of Shafts

After a complete design embodiment of the shaft, a checking calculation for the static strength, the fatigue strength, and the rigidity is carried out. In the analytical model, the shafts are regarded as bars on rigid pivoted mounts.

By the choice of the bearing type it is supposed that the shaft deformations are small and, if the bearing allows at least a slight tilt or journal displacement (e.g., in the range of the clearances between the rolling elements and the rings), it is considered a pivoted mount, either *hinged immovable* or *hinged movable*. Rolling or friction bearings simultaneously taking radial and axial forces are considered as hinged immovable (*fixed*) supports (Fig. 6.137a–c), and bearings taking only radial forces are considered hinged movable (*floating*) supports.

The relative support is positioned in the middle of the width of the radial rolling bearings (Fig. 6.137a) or at a displacement a from the face for radial-thrust bearings (Fig. 6.137b). For tapered roller bearings $a = 0.5[T + (d + D)e/3]$, where T is the mounting height, d is the opening diameter, D

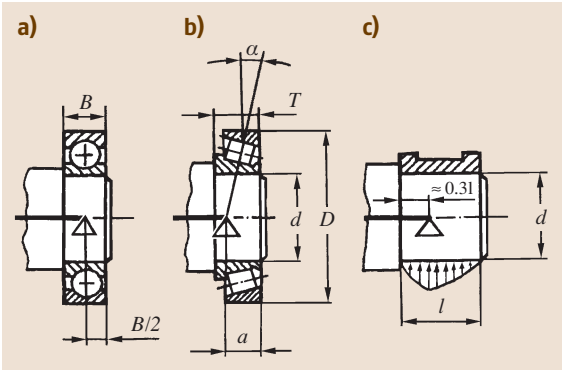

Fig. 6.137a–c Position of the relative support for installation of the bearing: **(a)** radial, **(b)** radial-thrust, and **(c)** friction bearing

is the outer diameter, and e is the axial loading factor.

In shafts rotating with non-self-installing friction bearings, the stress along the length l of the bearing is distributed unevenly as a result of shaft deformation. Thus, the relative pivoted mount is displaced in the direction of the loaded spacing (Fig. 6.137c), on the condition that $0.3l \leq 0.5d$.

Calculation Procedure

The calculation is carried out in the following manner: the analytical model is diagramed according to the drawing of the assembling shaft unit (Fig. 6.138), on which all the external forces that load the shaft are plotted, locating the planes of their action on two mutually perpendicular planes (horizontal X, vertical Y). Then the reaction at the supports is determined in the horizontal and vertical planes. In the same planes the bending moment M_x and the M_y diagram is plotted. The twisting moment diagram M_t, and the longitudinal force F_a diagram are plotted then separately. At the application points of the external bending moments the rated bending moments are determined to the left and to the right of the section.

The cantilever area of the output (input) shaft can be loaded with the radial force F_c (Fig. 6.138) acting from the side of the joint sleeve, belt, or chain drive. If the direction of the force vector F_c is not known beforehand, the bending moment M from this force is plotted separately, without superposing it onto the planes X and Y.

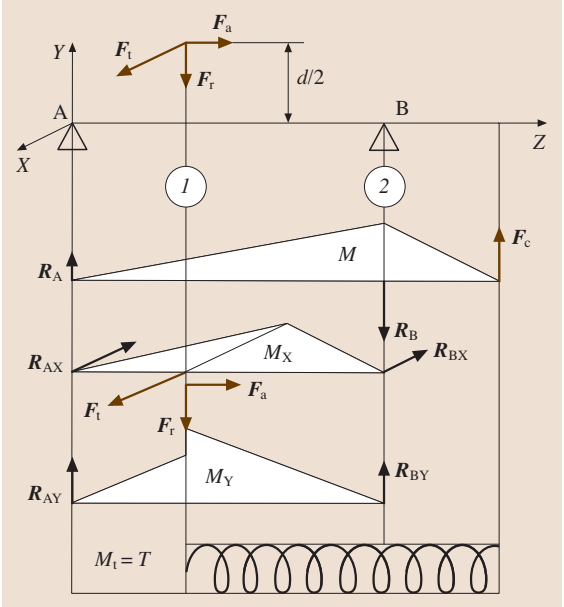

Fig. 6.138 Diagram for the strength calculation of a shaft

Weak sections are ascertained on the basis of the moment diagrams, the dimensions and form of the shaft cross sections, and the availability of the stress concentrators. Two to three sections that are loaded with moments are usually selected, where external forces, moments, support reactions, or form change points along the shaft length are applied.

Weak sections for the analytical model in Fig. 6.138 of the output shaft of the reduction gear are the following:

- Section 1, at the point of the gear wheel installation, which is loaded vt the twisting moment M_t and the bending moments M_x, M_y, and M. Potential stress concentrations are located at the interference fit of the wheel hub onto the shaft, key groove, and splines.
- Section 2, at the point of the rolling bearing installation, which is loaded with the twisting moment M_t and the bending moment M. The stress concentrator is an interference fit of the bearing cone onto the shaft.

Here one should bear in mind that the shaft diameter in section 2 is, as a rule, less than the shaft diameter in section 1. The shaft strength is checked in these weak sections.

Static Strength Calculation

Checking of the static strength is carried out with a view to prevent plastic strains during the action of short-time overloads (e.g., during run-up, acceleration, speed reversal, braking, or response of the security device).

The overload value is calculated by taking into account the specific character of the machine operation according to the starting moment of the electric motor, the limiting moment on release of the overload clutch, the inertial moments caused by sudden braking, etc.

The overload factor $K_0 = T_{max}/T$ is used in the calculation, where T_{max} is a maximum short-term acting torque (overload moment) and T is the nominal (rated) torque.

The normal stresses σ (N/mm^2) and shearing stresses τ (N/mm^2) are determined from the calculation in the shaft section concerned under maximum loads

$$\sigma = 10^3 M_{max}/W + F_{max}/A \,,$$

$$\tau = 10^3 M_{t\,max}/W_t \,,$$

where $M_{max} = K_0(\sqrt{M_x^2 + M_y^2} + M)$ is a total bending moment, N m; $M_{t\,max} = T_{max} = K_0 T$ is a twisting moment (N m), $F_{max} = K_0 F_a$ is an axial force (N), W and W_t are modules of the shaft section in the bending and torsion calculation (mm^3), and A is a cross-sectional area (mm^2).

The partial load factor according to the normal $S_{y\sigma}$ and shearing $S_{y\tau}$ stresses is

$$S_{y\sigma} = \sigma_y/\sigma\ ; \quad S_{y\tau} = \tau_y/\tau\ ,$$

where σ_y and τ_y are the yield strengths of the shaft material under bending and torsion (N/mm^2) (Table 6.45).

The general load factor according to the yield strength in the case of joint action of the normal and shearing stresses is

$$S_y = S_{y\sigma} S_{y\tau} / \sqrt{S_{y\sigma}^2 + S_{y\tau}^2}\ .$$

Static strength is provided if $S_y \geq [S]_y$. The minimum allowable value of the reserve coefficient in the yield strengths is assumed to be in the range $[S]_y = 1.3–2.0$, depending on the importance of the structure and the consequences of shaft fracture, accuracy determination of loads and stresses, the level of the production technique and control, and the similarity and stability of the material.

Fatigue Strength Calculation

Under the action of environmental stresses the rotating shafts are subjected to *periodic loading*. A short-cut calculation for *regular loading* (with constant parameters of the loading cycle during the entire running time) is given below. More precise calculations according to the revised summation theory of the damage by irregular loading are given in specialized literature.

As a consequence of the shaft rotation, bending stresses at different points of its cross section change according to the completely reversed cycle (Fig. 6.139a) with the following parameters: σ_a is a stress cycle amplitude and $\sigma_m = 0$ is a mean stress. Torsion stresses are proportional to the torque and change according to the zero-to-tension stress cycle (Fig. 6.139b) with the following parameters: τ_a a stress cycle amplitude, τ_m a mean stress, and $\tau_a = \tau_m$. The choice of the zero-to-tension stress cycle for the torsion stresses is based on the fact that the shafts transmit running torques that vary in value but which are constant in direction.

In the short-cut fatigue strength calculation the parameters of the cycle are rated according to the maximum of the long-term load. The calculation is carried out in the checking form of the assurance factor S in the sections presumed to be weak, as previously determined in accordance with the shaft form, bending moment diagram, and the position of the stress concentration zones.

Strength is guaranteed if $S \geq [S]$. The minimum allowable value of the load factor is $[S] = 1.5–2.5$. A value within this range is assumed, depending on the degree of certainty of the effective load determination and taking into account the importance of the structure, on the empirical basis of the previous calculations and control over the behavior of the machine in operation.

For each of the fixed presumably weak sections the general load factor S is calculated as

$$S = S_\sigma S_\tau / \sqrt{S_\sigma^2 + S_\tau^2} \geq [S] \ ,$$

where S_σ and S_τ are safety factors for the normal and shearing stresses

$$S_\sigma = \sigma_{-1D}/\sigma_a \ ,$$
$$S_\tau = \tau_{-1D}/(\tau_a + \psi_{\tau D}\tau_m) \ .$$

Here σ_a and τ_a are stress amplitudes, τ_m is a mean stress (Fig. 6.139), and $\psi_{\tau D}$ is an influence factor of the stress cycle unbalance for the shaft section concerned.

Stresses in the weak sections are determined from the formulas

$$\sigma_a = 10^3 M_c / W \ ,$$
$$\tau_a = 10^3 M_t/(2W_t) \ , \quad \tau_m = \tau_a \ ,$$

where $M_c = (\sqrt{M_x^2 + M_y^2} + M)$ is a resultant bending moment (N m), M_t is a twisting moment ($M_t = T$) (N m), and W and W_t are modules of the shaft section for bending and twisting (mm^3).

The influence factor $\psi_{\tau D}$ of the stress cycle imbalance for the shaft section concerned is

$$\psi_{\tau D} = \psi_\tau / K_{\tau D} \ ,$$

where ψ_τ is a sensitivity index of material to the stress cycle unbalance (Table 6.45).

The endurance limits of the shaft in the section are

$$\sigma_{-1D} = \sigma_{-1}/K_{\sigma D} \ ,$$
$$\tau_{-1D} = \tau_{-1}/K_{\tau D} \ ,$$

where σ_{-1} and τ_{-1} are the endurance limits of the smooth specimens in the completely reversed cycle of bending and twist (Table 6.45), and $K_{\sigma D}$ and $K_{\tau D}$ are reduction factors for the endurance limit.

The values $K_{\sigma D}$ and $K_{\tau D}$ are determined from the relations

$$K_{\sigma D} = (K_\sigma / K_{d\sigma} + 1/K_{F\sigma} - 1)/K_v \ ,$$
$$K_{\tau D} = (K_\tau / K_{d\tau} + 1/K_{F\tau} - 1)/K_v \ ,$$

where K_σ and K_τ are effective stress concentration factors of bending and twist. The influence on the endurance limit of the shaft form change in the axial direction or the cross section is also taken into account (transition area, key groove, splines, thread, etc.). Pressure at the installation point of the details mounted with interference (gear wheels, rolling bearings) is also a stress concentrator. Stress concentration decreases the endurance limit. $K_{d\sigma}$ and $K_{d\tau}$ are influence factors of the dimensions of the absolute cross-section (Table 6.47). The higher the absolute dimensions of the cross section of the detail, the lower the endurance limit. $K_{F\sigma}$ and $K_{F\tau}$ are influence factors of the surface finish (Table 6.48). With increasing surface roughness the endurance limit of the detail is lowered. The development of corrosion considerably reduces the endurance limit during operation. K_v is an influence factor of surface hardening (Table 6.49). Surface hardening of the detail increases the endurance limit considerably. Surface hardenings are more effective than volumetric ones, which are often accompanied by impact strength reduction and an increase in the stress concentration sensitivity. For example, case-hardening and quench-hardening increase the fatigue strength by 30–40% or more in comparison with volume quenching for the same hardness.

The values of the coefficients K_σ and K_τ are taken from tables. For a step junction with a hollow chamfer

(Fig. 6.140a–c) the values are taken from Table 6.50; for the key groove they are taken from Table 6.51; for the spline and thread areas of the shafts they are taken from Table 6.52. For estimation of the stress concentration at the installation points of the details with interference on the shaft, the ratios $K_\sigma/K_{d\sigma}$ and $K_\tau/K_{d\tau}$ (Table 6.53) are used.

In the case of action in the rated section of some stress concentration sources the most dangerous one is taken into account (the highest value $K_{\sigma D}$ or $K_{\tau D}$).

The stiffness calculation of the shafts is carried out in cases where their deformation (linear or angular) substantially influences the operation of the details mated with the shaft (gear wheels, bearings, and joints), producing an increase in contact stress concentration, an increase of wear, a reduction of fatigue strength, and a decrease of accuracy and evenness of rotation and displacement.

Bending and torsion stiffness are distinguished. The bending stiffness of the shafts is estimated according to the linear f and angular θ displacements under the action of forces and bending moments. Displacements are determined from the strength methods of materials. The required bending stiffness is provided under the conditions $f \leq [f]$ and $\theta \leq [\theta]$.

The allowable values $[f]$ and $[\theta]$ depend on the function of the shaft or the axles and are mainly determined by means of the correct operational conditions of

the gears and bearings. Elastic shaft displacements have little influence on the operation of gears with flexible couplers. In gearings they produce mutual warp of the wheels and separation of the axles, which is especially adverse for Novikov gears.

For the involute gearings of reduction gears the allowable wrap angles $[\theta]$ (radians) can be determined from the formula

$$[\theta] = 10^{-3} K_p \psi_{ba} \mathrm{HB_{me}}/600\,,$$

where K_p is a coefficient taking into account the influence of the gear wheel position relative to the bearings (Table 6.54), ψ_{ba} is a width coefficient, and $\mathrm{HB_{me}}$ is the mean hardness of the work tooth surface of the low-speed wheel.

The rigidity of the shafts rotating in the bearings must provide ease and smoothness of rotation, as well as sufficient stress distribution in contact, which finally will influence the lifetime of the bearings.

The total tolerance on the coaxiality of the cone and the outer race of the rolling bearings, which is caused by an unfavorable combination of various kinds of machining errors, assembly and deformation of the bearings, and the shaft and case details under the action of the load, is estimated from the maximum permissible angle $\theta_{\max}$ of the mutual wrap between the axles of the bearing racers that is mounted on the bearing unit.

The maximum permissible angle $\theta_{\max}$ of mutual warp of the bearing racers is defined, for which the lifetime can be proved to be not less than the required time. The values of the maximum permissible angle

are the following: $\theta_{max} = 8'$ for radial single-row ball bearings with normal radial clearance; $\theta_{max} = 5'$ for radial-stop ball single-row bearings with a contact angle of $\alpha = 26°$; $\theta_{max} = 2'$ for radial bearings with short cylindrical rollers; $\theta_{max} = 2'$ for tapered bearings with rollers without modified contact; and $\theta_{max} = 1'$ for quill axial roller bearings.

The angle θ_d of the mutual racer warp, which is caused by the deformation of the shafts and cases in the working unit, must not exceed $\theta_d = 0.2\theta_{max}$. The values θ_{max} and consequently the allowable rotary angles θ_d of the deflection shaft curve in the supports depend on the kind of bearing. The values θ_d for the self-installing bearings mounted in the rigid cases are in the range $0.4–1.6'$.

The torsion rigidity of the shafts is estimated from the twist angle under the action of the torque. Torsion rigidity is often not of vital importance and, in this case, this calculation is not carried out.

6.9.6 Shaft Design

When starting shaft (axle) design it is necessary to find out which details will be chosen, what kind of support is most appropriate for the given shaft, and under what load conditions the set of shaft details will react. It is also necessary to imagine the assembly order of the entire unit and, finally, to specify the manufacturing conditions of the shaft, i. e., the probable means of production. In the initial stage the shaft design is outlined approximately by defining the diameters of the single areas.

The input and output shafts of different machines, mechanisms, and devices that transmit torque have cylindrical or tapered end faces for mounting of half-couplings, pulleys, chain wheels, gear wheels, etc.

The permissible torques T (N m) transmitted by the shaft ends are determined from the formula

$$T = 10^{-3} K d^3 ,$$

where $K = \pi[\tau]/16(\mathrm{N/mm^2})$, and d is the diameter of the shaft end (mm).

The values of the coefficient K and their corresponding allowable twisting stresses $[\tau]$ are:

Table 6.55 Influence factor K of allowable twisting stress $[\tau]$

20	4.0
28	5.6
40	8.0
56	11.2
80	16.0
112	22.4

Recommendations according to the choice of the allowable stresses $[\tau]$ and correspondingly coefficient K depending on the load conditions and mechanical characteristics of the shaft material are given in Table 6.45.

The permissible torques transmitted with the cylindrical shaft ends are given in Table 6.56; for example, the values of the allowable torques are chosen for the reduction gears and reduction gear motors as follows:

- For input shafts: $K = 8.0$ (K may chosen equal to 4.0, 5.6 or 11.2)
- For output shafts: $K = 5.6$ (K may be chosen equal to 4.0 or 8.0)

The end shaft diameter can also be chosen according to the value of the transmitted torque by the set coefficient K (N/mm^2) (Table 6.56).

The diameters of the other areas are fixed in shaft structure development, taking into account their functionality, production technique, and assembly. To this end empirical dependencies can be used. Thus the diameters of the crankshaft journals are determined from empirical formulas depending on the diameter of the motor cylinder; the diameters of the work spindles are calculated depending on the main geometry of the machine, etc.

Before adjustment of the shaft structure important questions must be solved such as the transmission method of the torque in the joint shaft–hub and the fastening manner of the details onto the shaft from the axial displacement.

The shaft strength with the action of the varying stresses is to a great extent caused by its structural forms at the transition points between the grades, positions of splines, grooves, openings, turnings, etc., where there is stress concentration of bending and twist. To increase the fatigue strength of the shafts, various techniques of technological strengthening and structural improvement that provide stress concentration reduction are applied.

Thus, for example, if the transition from the shaft area with the diameter d to the area of the major diameter is carried out using hollow chamfers, the radius r_1 (Fig. 6.142a) of the hollow chamfer should be as large as possible, as the stress concentration factor increases with the reduction of the ratio r_1/d. For $r_1/d < 0.1$ the stress concentration factor can be equal to 2 or more. For the purpose of decreasing the stress concentration, elliptic hollow chamfers with dimensions $b = (0.4–0.45)d$ and $a = 0.4b$ (Fig. 6.142b), or hollow chamfers outlined with two interfacial circular arcs are used.

In those cases when, due to some structural consideration, small radii of the hollow chamfers have to be used, it is recommended that a recessed undercut of the shaft into the shoulder be carried out (Fig. 6.142c).

Balancing grooves on the shaft (Fig. 6.142d) and on the end of the mating component (Fig. 6.142e) reduce the stress concentration on the shaft surface from the component fit with interference. These measures decrease the stress concentration by 15–25%. Inclusion of the circular turnings on the ends increases the yielding of the hub, making the pressure distribution more even along the length of the joint. Extension by ~ 5% of the shaft area diameter at the point of interference connection increases the shaft yielding under the hub ends, thus reducing the stress concentration factor. A key groove executed with a disk mill (Fig. 6.142f) generates less stress concentration than that machined with a shank milling cutter. Involute splines generate less stress concentration in comparison with straight-sided splines.

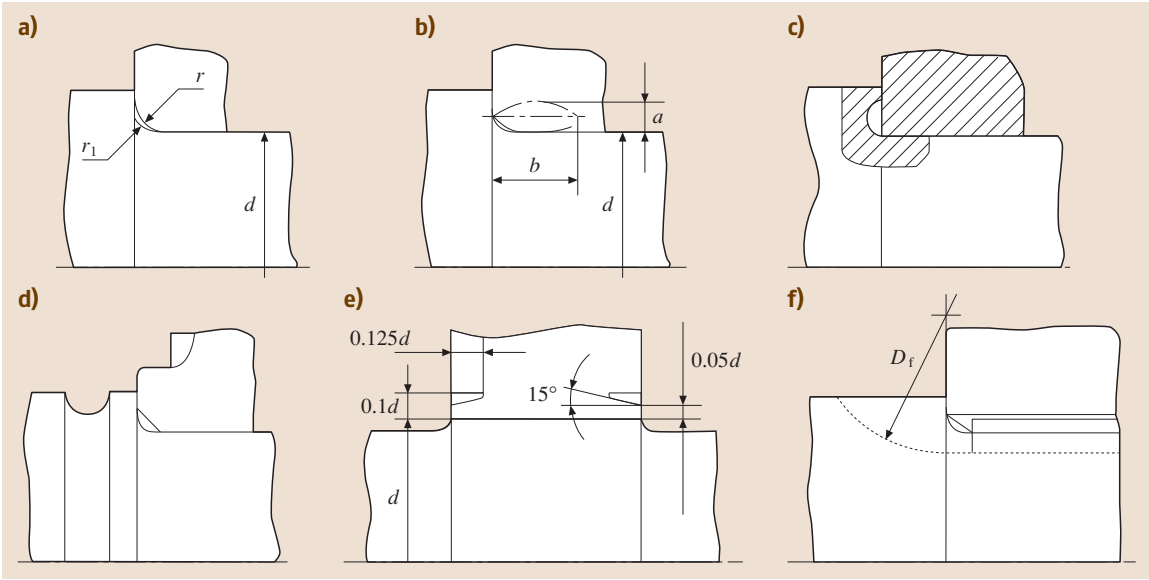

Fig. 6.142a–f Increase of the fatigue strength of the shafts using **(a)** a hollow chamfer of constant radius, **(b)** an an elliptic hollow chamfer, **(c)** a hollow chamfer with recessed undercut, **(d)** an unloading groove on the shaft and **(e)** in the mating component, **(f)** a key groove with a disk cutter, but not an end-milling cutter

The spline connection reduces the fatigue strength of the shaft less than the key joint.

Component fastening on the shaft using lock screws, adjusting nuts, cutting rings, etc., increases stress concentration and consequently reduces the fatigue strength of the shaft. Thus it is advisable to use axial fastening for the components. When an opening application for the lock screws or pins, nut threads, grooves for the elastic rings, etc., cannot be avoided, measures should be adopted to decrease stress concentration at these points.

Shaft hardening by structural means at the positions of the transverse openings can be carried out by the following methods: countersinking the hole, removal of a flat along the hole, and insertion of a bronze (a material with a lower coefficient of elasticity) bushing into the hole. These measures can decrease the stress concentration by 20–40% or more.

The thread is characterized by considerable stress concentration. The stress concentration factor for the thread substantially depends on the thread vee-radius R between the threads. For high-duty shafts it is recommended to use a thread with vee-radius $R = (0.125–0.144)P$, where P is the thread pitch.

Another reason for stress concentration is fretting wear (friction corrosion) that results from the slightly varying relative displacements of the shaft and the mated component, which are in turn caused by flexural or torsional strain. The stress concentration is especially strong in those cases in which the component is set on the shaft with interference and when it transmits loads to the shaft.

The fatigue strength of the shafts under the hubs can be raised with plastic forming (breaking-in with a roller), chemicothermal treatment (nitriding), surface hardening, and treatment with a laser beam and plasma. The quality of the surface layer in the weak sections distinctly affects the fatigue strength of the shaft, especially at stress concentration sites. The structure of the journals is caused by the type of shaft bearing applied (rolling bearing or sleeve bearing). The journal diameter of the friction bearing is chosen depending on the required strength and rigidity of the shaft and the overall dimensions of the whole structure. To increase the reliability of the friction bearing it is usually helpful to increase the journal diameter, but it must be borne in mind that journals are end faces of the shaft and according to the assembly conditions they are designed to have a smaller diameter than the middle parts of the shaft.

To decrease wear the journals are heat treated or chemicothermally treated (hard-surfacing, cementing, nitriding), leaving the core viscous. Above all this is relevant for bearing units working with contaminated lubricants, for which abrasion is typical.

If the shaft has rolling bearings, the diameter and length of the shaft journals for the bearing are determined from the dimensions of the chosen bearing. Technical requirements (roughness, deviation of the form and position) for the mounting and bearing front faces must meet the requirements for ball and roller bearings.

Tolerance ranges for the diameters of the mounting shaft surfaces, as well as the fit for the bearing joint with the shafts (axles), are fixed according to the accuracy grades of the bearings. The nature of the mating of the bearing with the shaft and the choice of the fit depend on whether the inner race of the bearing rotates or not relative to the radial load that affects it, and on the direction and value of the acting load intensity, etc.

When fastening the inner races of the rolling bearings on the shaft in the axial direction structural measures must be taken to provide the correct mounting, dismantling, and required maintenance of the bearings in operation.

As a result of the temperature increase during operation of the product, the shaft can become elongated, which is why fixing of the shaft from the axial displacement must be done such that the shaft elongation does not cause jamming of the bearings or lead to the occurrence of secondary stress.

The method of shaft fastening from the axial displacement is chosen depending on the kind of bearings that are mounted on the shaft (adjustable or non-adjustable), and on the working conditions of other components that mate with the shaft.

The machining accuracy of the journals (necks) for friction and rolling bearings is of great consequence. Because of the different component types that are set on the shafts and the axles, the greatest demands are made on the mounting of gear and worm wheels and pulleys of high-speed belt drives with regard to the coaxiality of the shaft sections bearing these components relative to the journals (necks). For gears with toothing this results from the necessity of providing the standards of kinematic accuracy and of contact; for pulleys it is necessary to decrease imbalance and, consequently, dynamic loads and vibrations.

Thus, for example, the coaxiality tolerance of a mounting shaft surface with a diameter of 56 mm for gear wheels, a pitch diameter of 240 mm with kinematic accuracy degree 7 of the gear is 0.025 mm.

Certain accuracy demands, if necessary, can also be made for other sections or structural shaft components;

for example, the tolerances on the symmetry and parallelism of the key groove of the shaft axles are fixed in order to provide the possibility of assembling the shaft with the component mounted on it and to provide even contact of the key and shaft surfaces.

6.9.7 Drafting of the Shaft Working Drawing

Introduction

Dimensioning. In the working drawings the *minimum* number of dimensions must be set, but they must be *sufficient* for the production and control of the component. The dimensions given in the drawings can be classified as being:

- *Functional*, determining qualitative product indexes: dimensions of the assembly measuring chains, mating dimensions, diameters of the shaft sites for gear and worm wheels, couplings, bearings and other components, and thread dimensions on the shafts of the adjusting nuts
- *Free* (dimensions of the nonjoining surfaces)
- *Reference*

Functional dimensions are set in the working drawings of the components, having been taken from the drawing of the assembly unit (reduction gear, gearbox) and from the layouts of the dimensional chains. Free dimensions are set, taking into account the fabrication technique and control convenience. Reference dimensions are not subjected to execution according to the given working drawings and are not controlled during component manufacture. Reference dimensions are marked with an asterisk and a notation such as "* Dimensions for reference" is added in the standards.

Extreme Dimensional Deviations

For all the dimensions given in the working drawings extreme deviations are indicated in millimeters. It is permissible not to indicate extreme deviations of dimensions that fix areas of different roughness and accuracy of the same surface, of the heat-treated zone, the coating and knurling zone, as well as the diameters of the knurled surfaces. In these cases, the sign "≈" is marked directly on such dimensions. If necessary extreme deviations of the *rough* or *very rough* accuracy degree according to the Russian standard [6.55] (Table 6.57) are set for these dimensions instead of using this sign.

If extreme deviations (tolerances) are not given individually for the appropriate nominal dimensions, the *overall dimensional tolerances* according to the Russian standard [6.55] are applied, fixed according to four accuracy degrees: accurate f, mean m, rough c, and very rough v (Table 6.57). For the choice of the accuracy degree the common accuracy of the corresponding industry is taken into account.

The overall dimensions are applied for the following dimensions with undisclosed individually extreme deviations:

- For linear dimensions (e.g., outer and inner diameters, radii, distances, shoulder dimensions, dimensions of the dull edges, outer rounded radii and chamfer dimensions)
- For angular dimensions, including angular dimensions that are usually undisclosed, i. e., right angles or angles of regular polygons
- For linear and angular dimensions, which are obtained by ready-mounted component machining

References to the overall tolerances of the linear and angular dimensions are given in the standards, indicating the number of the standard and the letter symbol of the accuracy degree required, e.g., for the accuracy degree *mean*: "Overall tolerances according to GOST 30893.1-m" or "GOST 30893.1-m".

The individual extreme deviation of the linear dimensions is indicated according to one of the three following methods:

- Reference designations of the tolerance ranges, e.g., 63H7
- Values of the extreme deviations, e.g., $64^{+0.030}$

Table 6.57 Extreme deviations of the linear dimensions according to [6.55]

Accuracy degree	Extreme deviations for the intervals of the dimensions (mm)					
	0.5–3	> 3–6	> 6–30	> 30–120	> 120–400	> 400–1000
Accurate f	±0.05	±0.05	±0.1	±0.15	±0.2	±0.3
Mean m	±0.10	±0.10	±0.2	±0.30	±0.5	±0.8
Rough c	±0.20	±0.30	±0.5	±0.80	±1.2	±2.0
Very rough v	–	±0.50	±1.0	±1.50	±2.5	±4.0

- Reference designation of the tolerance ranges with indication of the extreme deviation values in brackets to the right: $18P8\left(^{-0,018}_{-0,045}\right)$

The first method is recommended in the case of nominal dimensions, which are included in the series of standard numbers [6.83]. The second method is used in the case of nonstandard numbers on the nominal dimensions, and the third is used with standard numbers, but with inadvisable tolerance ranges.

Extreme deviations of chain dimensions are assigned according to the results of the probability-theoretical calculation of the corresponding dimensional chains. Approximately extreme deviation of the chain dimensions can be taken according to the compensation method:

- If compensator is a component that is scraped or ground according to the results of the measurement by assembly, with a view to decreasing the machining allowance of the tolerance ranges of the chain dimensions should be assumed: of the openings H9, of the shafts h9, others $\pm$ IT9/2.
- If a gasket package serves as a compensator, the tolerance ranges of the chain dimensions are assumed to be H11, h11, $\pm$ IT11/2.
- If a thread pair serves as a compensator, as a consequence of its wide compensating possibilities, the tolerance dimensional ranges are assumed to be: H14, h14, $\pm$IT14/2.

Extreme deviations of the thread diameters are shown in the component working drawings in accordance with the fits of the threaded connections that are given in the working drawings of the assembly units, for example, for the threads in the openings M20-7H, M16-3H6H, M30 ×1.5-2H5C, and for the threads on the shafts M42-8g, M16-2m, M30 ×1.5-2r.

Form Tolerances and Tolerances on the Surface Position

During machining of the components errors arise not only in the linear dimensions, but also in the geometry, as well as the errors in the relative position of the axles, surfaces, and structural components of the details. These errors can exert an unfavorable influence on the efficiency of the machinery, producing vibrations, dynamic loads, and noise. The first group of accuracy requirements is caused by the installation of the rolling bearings (Russian standard [6.89]). It is important for rolling bearings that the rolling paths of the racer are not distorted. Racers are very compliant and on installation they adopt the form of the mounting surfaces of the shafts and cases. To decrease the shape defects of the rolling paths form, tolerances are set for the mounting surfaces of shafts and cases.

The relative warp of the outer and inner races of the bearings increases shaft rotation and power waste resistance, and reduces the lifetime of bearings. Race warp can be caused by:

- Axial deviations of the mounting surfaces of the shafts and the case
- Perpendicularity deviations of the datum faces of the shaft and case
- Deformations of the shaft and case in the working unit

To limit these deviations the tolerances on the mounting surface position of the shaft and case are set in the working drawings.

The second group of accuracy requirements results from the necessity to abide by kinematic accuracy standards and contact standards of tooth and worm gears [6.28, 29, 41]. The achievement of the requisite accuracy depends on the positional accuracy of the mounting surfaces and the datum faces of the shafts, as well as the mounting openings and the datum faces of the wheels. Thus, the tolerances on the datum face position are set in the working drawings of the shafts, gear, and worm wheels.

The third group of accuracy requirements is caused by the need for limitation of possible component unbalance. Allowable imbalance values are defined in [6.86] depending on the kind of product and its operating conditions. The standards of allowable imbalance are described by the equation $en = \text{const.}$, where e is a specific imbalance (g mm/kg), which is numerically equal to the displacement of the mass center from the rotation axles (micrometer), and n is a rotational frequency (min^{-1}). In this respect it is convenient to make *demands* on the single component surfaces *in the form of the coaxiality tolerances* in the working drawings.

Base axles and surfaces are indicated in the working drawings with equilateral hatched triangles connected with a frame, where the designation of the base is written with a capital letter.

If the tolerance on the form or the position is not given individually for the appropriate element of the detail, overall tolerances on the form and position according to [6.56] are applied, being fixed for three accuracy degrees (in decreasing accuracy order): H, K, and L. By the choice of the accuracy degree, the com-

mon accuracy of the appropriate industry is taken into account.

References to the overall tolerances on the form and position are given in technical specifications, indicating the number of the standard and the letter symbol of the accuracy degree, e.g., for the accuracy degree *K*: "Overall form and position tolerances according to GOST 30893.2-K" or "GOST 30893.2-K."

The overall tolerances on the dimensions, form, and position are given in the technical specifications with a note like: "Overall tolerances according to GOST 30893.2-mK" or "GOST 30893.2-mK."

In the cited example *m* is the *mean* accuracy degree of the overall tolerances for the linear dimensions according to GOST 30893.1, and *K* is the accuracy degree of the overall tolerances on the form and position according to GOST 30893.2.

The form and position tolerances are rounded to the nearest number (μm) from the series of the preferable numbers after their determination (Table 6.58).

Surface Roughness

Of the roughness parameters set in [6.82] the following are the most widely used in machine construction:

- *Ra* is an arithmetic mean profile deviation (micrometers) (the main of the high-altitude roughness parameters is set for all unmachined surfaces)
- *Rz* is a cusp height of the profile (micrometers) (determined according to five measurements of the cusp heights, set for the surfaces after casting, forging, and engraving)
- *tp* is a relative bearing length of the profile, where *p* is a value of the profile section level

The parameter *tp* contains the contact area estimation of the mating surfaces. It is set for mating surfaces that require tightness, contact rigidity, wear resistance, or cohesive resistance (e.g., components connected by interference).

For the designation of surface roughness special characters are used in the working drawings according to [6.82]. Designation of the dominant roughness is shown in the upper-right corner of the working drawing field.

The values of the roughness parameter *Ra* can be taken from Table 6.59.

Positioning of Dimensions, Datum Designations, Form and Position Tolerances, Roughness, and Technical Requirements in the Component Drawing

For convenience, all the information needed for the component manufacture is organized into the following system. In the component working drawings, fir solids of rotation (shafts, pinion-shafts, worms, wheels, cartridges, and bearing caps) the following should be set (Fig. 6.143):

- Axial linear dimensions: located under the component drawing, in as small as possible number of levels of dimension lines (2–3).
- Datum reference designations: under the component drawing.
- Reference designation of the form and position tolerances: under the component drawing in one or two levels.
- Reference designation of the roughness parameters: in the upper parts of the component drawing. In the faces: under the component drawing. In both cases, reference roughness designations are located in the immediate proximity to the dimension line.
- Specify line notes, indicating surfaces for heat treatment and coating: above the component drawing.

Technical requirements are located above the main inscription, and if there is not enough space they are placed to the left of the main inscription. Technical requirements are written in the following order:

1. Requirements for the material, workpiece, heat treatment, and the material properties of the finished part (HB, HRC)
2. Guidelines about dimensions (dimensions for references, rounded radii, angles, etc.)
3. Overall tolerances on the dimensions, forms, and positions
4. Tolerances on the forms and mutual surface position, for which there are no conventional graphic characters in [6.80]
5. Surface quality requirements (guidelines about finish, coating, roughness)
6. Units of measurement that have to be indicated for the dimensions and extreme deviations given in the technical requirements

Performance of the Shaft Working Drawing

Dimensions and Extreme Deviations. In the shaft working drawings the mating, chain, and overall and free dimensions are set. Figure 6.143 shows a method for axial dimensioning of the shaft. The dimensions are indicated in this figure: C_1 and C_2 are the matings (lengths of the key grooves); G and P are overall and chain dimensions, K_1 and K_2 coordinate the position of the key grooves, which is convenient for the control with a vernier caliper or with a trammel; l_1 is the length of the shaft extension (conjunctive dimension), l_2 and l_3 are the lengths of the mating surfaces. The dimensions l_1, l_2, l_3, and l_4 correspond to the consecutive phases of the shaft turning. In this example, the dimen-

sions C_1, C_2, and P are functional, whereas the others are free.

In the shaft working drawings by means of the note on the magnification scale (4 : 1) the form and dimensions of the grooves are given for the outlet of the grinding wheel and the cavities for the outlet of the thread-cutting tool. The depth of the key groove, the dimension t_1 according to the Russian standard [6.90] (Fig. 6.144a), is also set. If the key groove located on the shaft end is through, it is convenient for the control to the dimension $(d - t_1)$.

On the conic shaft end the depth of the key groove t_1' (Fig. 6.144b) is determined from the formula

$$t_1' = t_1 + 0.025l\,,$$

where t_1 is assumed for the shaft diameter d_2 according to [6.85].

Sometimes the depth t_1 of the key groove is shown on the mean diameter d_2 of the shaft. In this case, the distance to the measuring section is set in the shaft drawing (Fig. 6.144b).

The tolerance ranges are specified for the mating dimensions in accordance with the fits shown in the component drawing. Extreme deviations in the tolerance ranges for the recommendations given above are assigned for the chain dimensions. Extreme deviations, mostly of the *mean accuracy degree* (Table 6.57), are specified for the free dimensions. Designation of the tolerance range is indicated for the width of the key groove: for the straight key P9, and for the semicircular key N9.

Extreme deviation of the key groove depth t_1 (Fig. 6.144) with key section up to 6×6 mm: +0.1 mm; 6×6 – 32×18 mm + 0.2 mm. Extreme deviations for the dimensions $(d - t_1)$ are assigned accordingly: −0.1 and −0.2 mm.

The tooth length of the total profile to the runout is given in the shaft working drawings that have the elements of the spline connections. For the roughness designation on the lateral surfaces the profile of one tooth is shown. The reference designation of the spline connection elements of the shaft according to the corresponding standard is given on the line-note in the technical requirements.

Form Tolerances and Surface Position Tolerances

The shaft in the working unit rotates in the rolling bearings. As the rolling bearings are manufactured with relatively high accuracy, the production errors of their components are usually neglected. This is why the work axle is *a general axle*, designated with the letters AB in Fig. 6.145. The general axle is a straight line passing through the cross-points of each of the two mounting surfaces for the rolling bearings with the mean cross-sections of these surfaces.

As a consequence of unavoidable errors, the general axle does not coincide with the rotation axles of the shaft after manufacture. The required accuracy demands of single-component production are assigned in the shaft drawing. The guidelines for the value determination of the form and surface position tolerances are given in Table 6.60 in accordance with the positions in Fig. 6.145.

The destination of each of the form or position tolerances is as follows:

- The tolerance of the cylindrical mounting surfaces for the rolling bearings (position 1) is specified to limit geometry deviations of these surfaces and in this way to limit geometry deviations of the roller paths of the racers (according to [6.89] the following individual constituents of this tolerance should

- The coaxiality tolerance of the mounting surfaces for rolling bearings relatively to their mutual axles (position 3) is set to limit the warp of the rolling bearing racers.
- The coaxiality tolerance of the mounting surface for the gear and worm wheel (position 4) is specified to guarantee kinematic accuracy standards and contact standards of tooth and worm gears.
- The coaxiality tolerance of the mounting surface for half-coupling, pulley, chainwheel (position 5) is set to decrease the imbalance of the shaft and the components installed on this surface. The coaxiality tolerance according to position 5 is set by a rotational frequency of more than $1000\,\mathrm{min}^{-1}$.
- The perpendicularity tolerance of the datum shaft face (position 6) is specified to decrease the warp of the racers and geometry distortion of the rolling path of the inner race.
- The perpendicularity tolerance of the datum shaft face (position 7) is set only when mounting narrow gear wheels ($l/d < 0.7$) on the shaft. The tolerance is set to guarantee execution of the contact standards of the teeth in the gear.
- Symmetry and parallelism tolerances of the key groove (position 8) are specified to guarantee the possibility of shaft assembly with the component installed on it and an even contact surface between the key and the shaft.

The tables referred to in Table 6.60 are given below. The values of θ according to Table 6.61 are used by shaft rigidity checking. Figure 6.146 shows an example of a shaft drawing.

surface ⌀ $56x6 - t = 19\,\mu m$,

$T_{ci} = 0.5 \times 19 = 9.5\,\mu m$, $T_{ci} = 0.010\,mm$.

Coaxiality tolerances (position 3) of the mounting surfaces ⌀50*k*6 with length $B_1 = 35\,mm$. For a ball radial bearing according to Table 6.61 $T_{so} = 0.1 B_1 T_{sow} = 0.1 \times 35 \times 4 = 14\,\mu m$. After round-up this yields $T_{so} = 0.012\,\mu m$.

The coaxiality tolerance (position 4) of the mounting surface ⌀56×6. With the kinematic accuracy degree 7 of the gear for the gear wheel with pitch diameter 240 mm according to Table 6.63, the accuracy degree of the coaxiality tolerance is 6. According to Table 6.62 therefore $T_{so} = 0.025\,mm$.

The rotational shaft frequency $n < 1000\,min^{-1}$ and tolerance in position 5 are not set. The perpendicularity tolerance (position 6) of the shaft collar with diameter $d_0 = 56\,mm$. For a ball radial bearing the tolerance accuracy degree is 8 (Table 6.60). According to Table 6.64 the tolerance is $T_{pr} = 0.025\,mm$.

The tolerance in position 7 is not set, because there is no collar on the shaft.

Parallelism and symmetry tolerances of the key groove (position 8): dimensional groove tolerance [6.53]: $t_{sp} = 43\,\mu m$. Then $T_{pa} = 0.5 t_{sp} = 0.5 \times 43 = 21.5\,\mu m$; $T_{pa} = 0.020\,mm$. $T_{si} = 4 t_{sp} = 4 \times 43 = 172\,\mu m$; $T_{si} = 0.16\,mm$.

6.10 Shaft–Hub Connections

6.10.1 Key Joints

For transmission of torque between the shaft and the gear, worm wheels, pulleys, chainwheels, half-couplings, etc., mounted on it, *straight and semicircular* keys are mostly used. Stationary key joints are the most efficient, which combine with an interference fit of the hub on the shaft, provide with hub centering on the shaft and exclude contact corrosion. *Feather and sliding keys* are sometimes used in movable joints of the hub with the shaft in the axial direction (e.g. a movable pinion unit of the speed gearbox). Because of their low load-carrying capacity, these joints are changed into sliding spline connections in the case of a new design [6.76, 90–99].

Straight keys have a rectangular cross-section, and their ends are chamfered from one or two faces (Fig. 6.147a) or flat (Fig. 6.147b). Rounded faces of the key ease installation of the component on the shaft in the case of a slight mismatch of the lateral faces of the key and the groove in the hub. The standard foresees definite values of the width b and the height h of the key cross-section and the groove depth on the shaft t_1 and in the hub t_2. The lengths l of the keys are also standardized. Thus, the key represents a steel bar mounted in the grooves of the shaft and the hub.

The groove in the hub is made by means of a broaching or shaping cutter. The groove for the key on the shaft is made with a shank milling or disk cutter. Manual fitting is often needed for grooves made with a shank-milling cutter. Side narrower key faces with the height h are active.

The main efficiency criterion of the key joints is strength. The keys are chosen from standard tables depending on the shaft diameter, and then the joint is checked for strength. The dimensions of the keys and the grooves are matched so that their shearing and bending strength is guaranteed if the condition of bearing strength is met, which is why the main analysis of the key joints is a bearing calculation.

The operating mode, the material strength of the components, and fit type are taken into consideration by the choice of the allowable stresses $[\sigma]_{st}$.

Joints with straight keys (Fig. 6.148) are checked for bearing according to the strength condition

$$\sigma_{st} = 2\times10^3 T/(dkl_c) \le [\sigma]_{st} ,$$

where T is a torque (N m), d is the shaft diameter (mm), $k = h - t_1$ is an extension of the key from the shaft (the entry depth of the key into the hub) (mm), l_c is a rated key length (mm) (see Fig. 6.147), and $[\sigma]_{st}$ is an allowable bearing stress (N/mm^2).

By the projection calculation the rated key length is determined from the strength condition

$$l_c \ge 2\times10^3 T/(dk[\sigma]_{st}) .$$

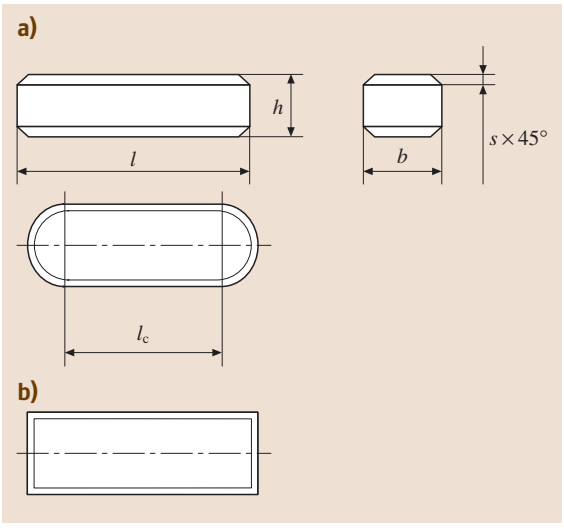

Fig. 6.147a,b Straight keys. **(a)** With chamfered faces, **(b)** with flat faces

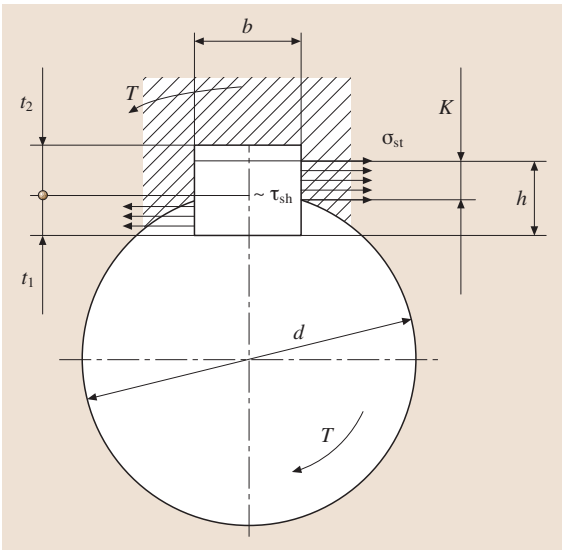

Fig. 6.148 Analytical model of the key joint

The key length $l = l_c + b$ with chamfered $l = l_c$ or with flat ends is chosen from the standard series. The hub length l_{hu} is fixed by ≈ 10 mm more than the key length. To decrease the unevenness of the stress distribution along the height and the length of the key the joint length is limited: $l_{hu} \leq 1.5d$. If the hub length $l_{hu} > 1.5d$ is obtained according to the results of the key joint calculation, so it is advisable to apply a spline connection or an interference connection instead of a key joint.

The strength condition according to shearing stresses is

$$\tau_{sh} = 2 \times 10^3 T/(dbl_c) \leq [\tau]_{sh} ,$$

where b is the key width (mm) and $[\tau]_{sh}$ is the allowable shearing stress (N/mm^2).

A semicircular key represents a disk part with the diameter D and the thickness b. The key height $h \approx 0.4D$ and the length $l \approx 0.95D$.

The groove on the shaft for the semicircular key is made with a disk cutter; in the hub it is made with a broaching cutter or a shaping cutter. Such a fabrication method provides ease of installation and removal of the key, with interchangeability of the connection. A manual fit is usually not needed. The key in the shaft groove self-installs and does not require extra fastening to the shaft.

The disadvantage of such a connection is a weakening of the shaft cross-section with a deep groove, which decreases the fatigue strength of the shaft. Thus, semicircular keys are applied by transmission of relatively low torques. Semicircular keys, like straight ones, work with the *side faces* (Fig. 6.148). The keys are standardized; for every shaft diameter d the values b, h, t_1, t_2 and D are given in the standard. The keys are checked for strength according to bearing stresses σ_{st} and shearing stresses τ_{sh} in compliance with the formulas given for straight keys; $l_c \approx l$.

Materials of Keys and the Choice of Allowable Stresses

Medium-carbon steels with tensile stress $\sigma_t \geq 590$ N/mm^2 serve as the material for the keys (e.g. steel grades E 355 (EN), C 46, C 45 (EN), C 50 E (EN), Appendix 6.A Table 6.95). The values of the allowable stresses of the steel shaft for the key joints are chosen depending on the load condition and operating conditions of the connection from Table 6.66 (the shaft is made of steel).

Higher values are taken under constant load, lower ones are under varying load and operation with impacts. In the case of reverse load $[\sigma]_{st}$ is reduced 1.5 times. The allowable stress on the key shearing is $[\tau]_{sh} = 70–100$ N/mm^2. The higher value is taken under constant load.

Table 6.66 Allowable stresses $[\sigma]_{st}$ for key joints (steel shaft)

Connection type, hub material	$[\sigma]_{st}$ (N/mm^2)
Fixed, steel hub	130–200
Fixed, hub is iron or steel casting	80–110
Sliding without load, steel hub	20–40

The key joint is labor-intensive in manufacture. By the torque transmission considerable local deformations of the shaft and the hub characterize it, which results in uneven pressure distribution on the contact area of the mounting surfaces of the shaft and the hub, as well as on the active faces of the key and the key grooves, which in turn decreases the fatigue shaft strength. Thus, application of the key joints must be limited. They should be used only an interference fit, for the given torque cannot be made in consequence of insufficient material strength of the wheel.

With torque transmission through the key joint, application of the wheel fits on the shaft with clearance is prohibited, and the transition fits are undesirable. If there is a clearance in the connection, the shaft rotation runs with surface slipping of the shaft and the wheel opening, which results in wear-out. This is why the interference should by made with the torque transmission with the key on the mounting surfaces of the shaft and the wheel opening, which guarantees nonopening of the junction.

With the torque transmission with the key joint the fits for the wheels can be assumed according to the following recommendations:

Cylindrical straight	$H7/p6 (H7/r6)$,
Cylindrical helical and worm	$H7/r6 (H7/s6)$,
Bevel	$H7/s6 (H7/t6)$,
Gearboxes	$H7/k6 (H7/m6)$.

The fits with a great interference are given in brackets for the wheels of reverse gears.

For the cases that do not have jointing planes along the shaft axes (e.g. in gearboxes), the choice of the wheel fits is determined by the assembly technique. Assembly is carried out inside the case in the straightened conditions, which is why transition fits are applied for the wheels of gearboxes.

When mounting the gear wheels on the shafts with interference it can be difficult to match the key groove

of the wheel with the shaft key. For ease of installation it is recommended that a guiding cylindrical shaft part with the tolerance range $d11$ (Fig. 6.149a) be foreseen. Sometimes instead of the direction along the cylindrical surface the shaft end is directed to the cone.

Toward the same end the key is beyond the bounds of the component (Fig. 6.149b). With such an execution the length of the shaft slot remains the same. Therefore, the variant in Fig. 6.149b is preferable, although it is more difficult to produce, as the groove for the extension of key is made on the mating component. In either of the two considered variants at first the key groove of the wheel is matched with the key by means of free turning of the wheel relative to the shaft, and then the wheel is pressed onto the shaft.

Mounting surfaces for gear and worm wheels are mostly ground. This is why it is desirable to make a groove for the grinding wheel outlet on the shaft in front of the thrust collars. The key fits are regulated for straight and semicircular keys. The width of the straight key and the thickness of the semicircular one are within the tolerance range $h9$. The following dimensional tolerance ranges are recommended:

- Width of the key groove of the shaft for the straight key: $P9$
- Width of the key groove of the shaft for the semicircular key: $N9$
- Width of the key groove of the hole:
  - With a fixed joint of the irreversible gear: $JS9$
  - With a fixed joint of the reversible gear: $P9$
  - With the sliding joint for the straight key: $D10$

6.10.2 Spline Connections

The cusps (teeth) on the shaft form a spline connection, which enter the corresponding valleys (splines) in the hub. The effective areas are the flanks of the cusps. The cusps on the shaft are made by milling, planning, or rolling in the cold condition with profile rollers according to the method of longitudinal knurling. The valleys in the axle seat are manufactured by broaching or slotting. The spline connections are applied for the fixed joint with the shaft, for the sliding joint along the shaft without load, and the sliding joint under load.

Connections with a straight-sided profile are the most commonly used. They have a constant cusp thickness (Fig. 6.150). The standard foresees three series of connections with a straight-sided profile: *easy*, *medium*, or *difficult*, which differ in height and cusp number z. The difficult series has more elevated cusps with a higher number and is recommended for the transmission of high torques.

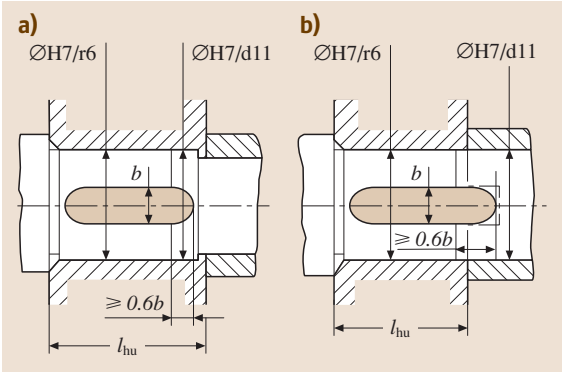

Fig. 6.149a,b Variants with easy assembly of the key joint: **(a)** with a guiding cylindrical section, and **(b)** with a groove in the mating component

Centering (providing coincidence of the geometrical axes) of the connectable components is carried out along the outer D diameter, the inner d diameter, or the lateral faces b. The choice of centering method depends on the requirements for centering accuracy, and the hardness of the hub and the shaft. The two first methods guarantee the most precise centering. The clearance in the contact of the surfaces of the centering method is practically absent, but is considerable in the noncentering one.

Centering Along the Outer Diameter D (Fig. 6.150a)

In this case, machining accuracy of the mating surfaces is provided in the hole through broaching work and on the shaft through grinding. Along the diameter D trim-

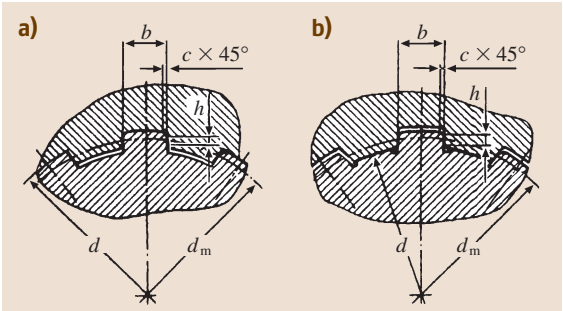

Fig. 6.150a,b Spline connection with a straight-sided profile and centering according to **(a)** the outer diameter or **(b)** the inner diameter

ming is guaranteed on one of the transition fits. Along the inner diameter d there is clearance between the components. By transmission of the torque to the effective lateral faces bearing stresses σ_{st} act. The height of the contact area is

$$h = 0.5(D-d) - 2c\,,$$

where c is the dimension of the bevel.

It is supposed that the peripheral force is applied on the mean diameter of the cusp

$$d_m = 0.5(D+d)\,.$$

In accordance with machining technology for the centering surface in the hole (broaching work), centering along the outer diameter can be used in the case of a low-hardness hub (≤ 350 HB).

Centering along the Inner Diameter d (Fig. 6.150b)

Centering along the inner diameter d is applied with a high-hardness hub (≥ 45 HRC), e.g., after quenching, when calibration of the hub by means of broaching or drift is difficult. The machining accuracy of the mating surfaces is guaranteed in the hole through grinding on the internal grinding machine and on the shaft through grinding of the valley, in accordance with the fact the grooves for the grinding wheel outlet are foreseen.

Along the diameter d, transition fit mating is provided. The dimension h of the contact area is determined in the same way as for outer-diameter centering.

Centering along D or d is used in connections that require high coaxiality of the shaft and the hub (for installation of gear or worm wheels on the shafts in gearboxes of cars, machines, reduction gears, as well as pulleys, chainwheels, and half-couplings on the outlets and the inlets of shafts).

Centering along the Lateral Faces b

In this case, the evident clearance is found in the component mating along the diameters D and d, and the clearance is practically missing on the lateral faces. This decreases the centering accuracy, but guarantees the most even load distribution between the cusps. Thus, centering along the lateral faces b is applied for transmission of considerable torques or those that vary in value or direction, in the case of rigid requirements to the backlash and in the absence of high demands to the centering accuracy, e.g., spline connection of car drive shafts.

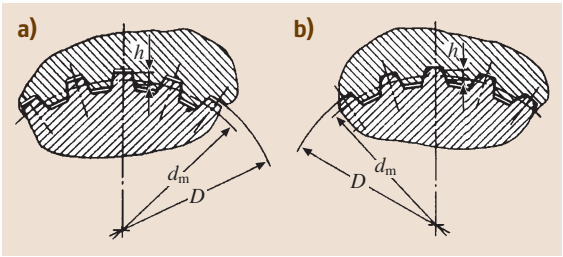

Fig. 6.151a,b Spline connection with involute profile and centering according to **(a)** side faces of the teeth or **(b)** the outer diameter

Connection with an Involute profile (Fig. 6.151)

This approach is applied in fixed and sliding joints. The lateral cusp face is outlined along an involute profile (such as the tooth profile of the gear wheels). The involute profile is distinguished from a straight-sided one by its increased hardness due to cusp thickening and a graded junction at the base. Through cusp manufacture a very good debugged fabrication technique of gear wheel teeth is applied. The joints guarantee a high centering accuracy. The outer diameter D is assumed to be the nominal diameter of the joint. The lower cusp height ($h \approx 1.1m$, where m is the module) and a greater profile angle (here 30°) distinguish them from the teeth of gear wheels, due to a lack of rolling.

In comparison with straight-sided joints, connections with an involute profile are characterized by higher load-carrying capacity as a consequence of their greater contact area, higher tooth number, and increased hardness. They are applied for the transmission of high torques and are considered as promising ones.

Centering is usually done along the tooth surfaces s (Fig. 6.151a), and rarely along the outer diameter D (Fig. 6.151b). Just as in gear wheels the joint parameters are recorded by means of the module m. The mean diameter is $d_m = D - 1.1m$. The height of the contact area for centering along s is $h = 0.9m$ and for centering along D it is $h = m$ ($m = 0.5$–10 mm).

Calculation of Spline Connections

Spline shafts and hubs are manufactured from medium-carbon and alloy steels with tensile stress $\sigma_t > 500\,\mathrm{N/mm^2}$. Failure of the spline connections is caused by damage to the effective surfaces, e.g., wear, bearing, and jamming.

The main criteria for the efficiency of spline connections are bearing and wear resistance of the work surfaces. Wear of the tooth surfaces is caused by microdisplacement of the joint components as a conse-

Table 6.67 Allowable stresses $[\sigma]_{st}$ for spline connections

Type of joint	$[\sigma]_{st}$ (N/mm^2) with hardness	
	≤ 350 HB	≥ 40 HRC
Fixed	60–100	100–140
Sliding without load (pinion unit of a gearbox)	20–30	30–60
Sliding under load (joint of a driveshaft)	–	5–15

quence of resiliency under the action of the radial force and torque, or a mismatch of the rotation axes (because of the presence of clearances, and errors of production and assembly).

Joint parameters are chosen from standard tables depending on the shaft diameter, and then the efficiency criterion calculation is carried out.

To provide the required efficiency a checking analysis is carried out. Bearing and wear of the work surfaces are due to the bearing stresses σ_{st} acting on the surfaces.

The short-cut (approximate) calculation is based on the limitation of the bearing stresses σ_{st} by the allowable values $[\sigma]_{st}$, which are fixed on the basis of field experience with similar structures

$$\sigma_{st} = 2\times 10^3 T K_t/(d_m z h l_c) \le [\sigma]_{st} ,$$

where T is a rated torque (the highest of the long-acting torques under varying loading conditions) (N m), K_t is an irregularity ratio of load distribution between the teeth (that depends on the manufacturing accuracy, the errors of the pitch angles of the cusps and mating sockets, the value of the radial clearance, and the working conditions), $K_t = 1.1–1.5$, d_m is the mean diameter of the joint (mm), z is a cusp number, h is a working cusp height (mm), l_c is a working joint length (mm), and $[\sigma]_{st}$ is the allowable bearing stress (N/mm^2).

In Table 6.67 the values of $[\sigma]_{st}$ are given for products of general engineering and hoist transport systems that are intended for a long lifetime. Higher values are assumed for easy loading conditions.

Through the projection calculation of the spline connections the length of the cusps l_c is determined after the choice of the section dimensions according to the standard. If $l_c > 1.5d$ is obtained, the dimensions and heat treatment are changed or another kind of joint is assumed. The length of the hub is assumed to be $l_{hu} = l_c + (4–6)$mm or more, depending on the joint structure.

Adjusted bearing and wearing calculations are worked out for straight-sided spline connections and load conditions; the design philosophy of the joint, the working surface grind, the required lifetime, etc., are taken into account.

The component fits of the spline connections are regulated by standards. Mostly the fits of the straight-sided splines according to Table 6.68 and involute ones according to Table 6.69 are used.

6.10.3 Pressure Coupling

Load-Carrying Capacity of Pressure Coupling

Interference connections are widely used in practice for the transmission of torque, axial forces, and bending moments. Connections along the cylindrical surfaces are primarily spread. The nature of the joint is such that the shaft is connected to a bushing that has a hole diameter slightly smaller than that of the shaft. At the junction site the components strain elastically and a contact pressure p arises on the surface of the contact, leading to frictional forces on the joint surface that are

able to take the external axial force F_a and the torque T (Fig. 6.152). The short-cut calculation for interference joints is based on the assumption that the contact pressures p are evenly distributed along the contact surface.

Pressure couplings are applied to the junctions of gear and worm wheels, pulleys, chainwheels, inner races of rolling bearings, rotors of electric motors with a shaft, and to junctions of rings of gear and worm wheels, etc., and disks. They are used in the production of composite crankshafts, units of drive chains, junctions of railway wheels with axes, and tires. Component connections with interference are considered permanent connections, as they allow a limited amount of dismantling and reassembly.

Cylindrical joints, depending on the installation method, are divided into those that are mounted by means of insertion and heating of the female part (bushing) or those that are mounted by means of cooling of the male part (shaft).

Component insertion is carried out on hydraulic, screw, or lever presses. To prevent tearing and to decrease the insertion forces the mating surfaces are lubricated with oil.

The reheating temperature must be lower than that of low-temperature tempering, so that structural changes do not occur in the metal. For cooling of the shaft carbonic acid or liquid air is used.

At present, so-called *thermomechanical* component *joints* are used more often, being produced from *shape-memory* alloys (iron–manganese, copper–aluminum–nickel, copper–zinc–aluminum, etc.), which are characterized by the possibility of diffusion-free transformation of one solid solution into another as a result of mechanical effects or thermal action. This property is particular to, e.g., nickel–titanium alloys, which experience *reversible martensitic transformation*. It characterizes the ability of the material, which is deformed in the martensitic state (by low temperature), to recover partially ($\approx 25\%$) obtained inelastic deformation during the following heating and transition into the austenitic state.

To form the thermomechanical joint, e.g., the bushing is manufactured from a shape-memory alloys. It is cooled in liquid nitrogen (so the material is in a martensitic state), the hole is strained with a drift in the radial direction to the formation of technological clearance by the following installation of the bushing on the mating shaft. Assembly is carried out at ambient temperature. Subsequent heating of the bushing with ambient heat results in the corresponding recovery of the previous hole dimensions as a consequence of the transition of the material into the austenitic state, leading to the formation of interference in the joint. Such joints are widely applied in aeronautical and space engineering, nuclear-power engineering, and medicine (automatic relays, space antenna drive mechanisms, and self-sealed joints).

The male part (shaft) is given the index 1, and the female part (bushing) has the index 2. A bushing is interpreted as any component installed on the shaft: a hub

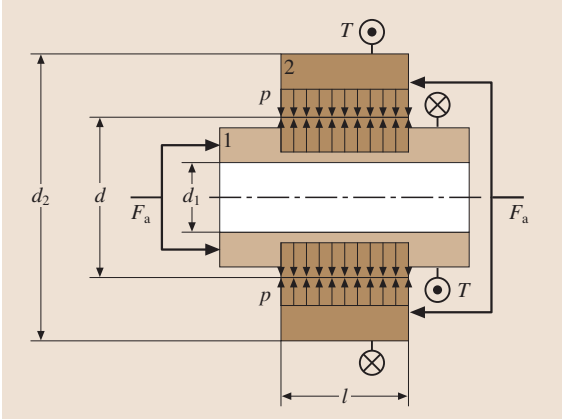

Fig. 6.152 Diagram for the determination of the load-carrying capability of interference joints

of gear or worm wheels, pulleys, chainwheels, and the inner race of bearings, etc.

The efficiency conditions of the interference connection are the lack of relative displacement of the components under the action of the axial force F_a and the lack of relative component turning under the action of the torque T.

The shafts rotate relative to the loads acting on them. This is why stresses change cyclically in some ranges at any contact point per revolution of the shaft. Stress cycling results in the effect of surface layer fatigue of the component material, in microslip of the mounting surfaces, and as a result, in wear, i. e., in so-called contact corrosion. The interference of the joint in this case is progressively decreased and there comes a point at which the hub turns relative to the shaft.

To prevent contact corrosion, or to reduce its influence in interference connections, a definite traction reserve K should be included, which is assumed to be:

- For the wheels of the output shafts of reduction gears, on whose ends there is

  A joint sleeve: $K = 3$
  A chain wheel: $K = 3.5$
  A belt drive sheave: $K = 4$

- For the wheels of the countershafts of reduction gears: $K = 4.5$

Calculation of Pressure Coupling Loaded with a Torque and an Axial Force

The purpose of the calculation is to match the interference fit. The basic data are as follows: required for transmission rotatory torque T (N m), axial force F_a (N), as well as d – the joint diameter (mm), d_1 – the diameter of the central axial hole of the shaft (mm), d_2 – the passage outer diameter of the bushing (of the wheel hub, the outer diameter of the rim, etc.) (mm), l – the mating length (mm), and materials of the connecting components, and the roughness parameters of the mating surfaces.

Matching of the fit is carried out in the following order:

1. *Average contact pressure* (N/mm^2)

$$p = KF/(\pi dlf) ,$$

where K is a traction safety factor; $F = \sqrt{F_a^2 + F_t^2}$ is a relative total peripheral force (N), $F_t = 2\times10^3 T/d$ is a peripheral force (N), and f is a traction coefficient (friction).

Material pair	f when mounting by	
	Insertion	Heating
Steel–iron	0.08	0.14
Steel–steel	0.08	0.14
Steel–bronze (brass)	0.05	0.07
Iron–bronze (brass)	0.05	0.07

2. *Component deformation* (μm)

$$\delta = 10^3 pd(C_1/E_1 + C_2/E_2) ,$$

where C_1, C_2 are stiffness factors

$$C_1 = [1 + (d_1/d)^2]/[1 - (d_1/d)^2] - \nu_1 ,$$
$$C_2 = [1 + (d/d_2)^2]/[1 - (d/d_2)^2] + \nu_2 ,$$

where E is a coefficient of elasticity (N/mm^2), being for steel 2.1×10^5, iron 0.9×10^5, tin bronze 0.8×10^5, for tinless bronze, and for brass 10^5; ν is Poisson's ratio: being for steel 0.3, for iron 0.25, and for bronze and brass 0.35.

3. *Allowance for pressing down of microasperities* (μm)

$$u = 5.5(Ra_1 + Ra_2) ,$$

where Ra_1 and Ra_2 are the arithmetic-mean deviations of the surface profile of the shaft and the hole, respectively. Generally, $Ra_1 = 0.8$ μm and $Ra_2 = 1.6$ μm.

4. *Allowance for thermal deformation* (μm)
By fit matching in mating of the components, which heat in operation to relatively high temperatures, thermal deformations that loosen the interference are calculated according to the formula

$$\delta_t = 10^3 d[(t_2 - 20\,^\circ\mathrm{C})\alpha_2 - (t_1 - 20\,^\circ\mathrm{C})\alpha_1] .$$

Here t_1 and t_2 are the average volumetric temperatures of the shaft and the bushing, respectively; α_1, α_2 are the linear expansion coefficients (1/°C) of the shaft and the bushing, respectively, being for steel $\alpha = 12\times10^{-6}$, for iron $\alpha = 10\times10^{-6}$, and for bronze and brass $\alpha = 19\times10^{-6}$.

5. *Minimum interference* (μm), required for load transmission,

$$[N]_{\min} = \delta + u + \delta_t .$$

6. *Maximum interference* (μm), permissible with the component strength (of the hub, ring, etc.),

$$[N]_{\max} = [\delta]_{\max} + u .$$

Here $[\delta]_{max} = [p]_{max}\delta/p$ (μm) is the *maximum deformation* permissible for the strength of the joint components, where $[p]_{max}$ (N/mm^2) is the maximum pressure allowable for the strength of the male or female part, being the lowest of

$$[p]_{max2} = 0.5\sigma_{y2}\left[1-(d/d_2)^2\right] \quad \text{or}$$
$$[p]_{max1} = 0.5\sigma_{y1}\left[1-(d_1/d)^2\right] .$$

For a shaft without a central hole ($d_1 = 0$), one has $[p]_{max\,1} = \sigma_{y1}$, where σ_{y1} and σ_{y2} are the yield strengths of the material of the male and female parts (N/mm^2), respectively.

7. *Fit choice*
According to the values $[N]_{min}$ and $[N]_{max}$ the fit is chosen from Table 6.73, to meet the conditions $N_{min} \geq [N]_{min}$ and $N_{max} \leq [N]_{max}$.
In Table 6.73 the values of the minimum N_{min} and maximum N_{max} stochastic interferences (for the usually assumed probability of 99.73%) are determined from the formulas, taking into account the dimensional dispersion of the shaft and the hole and as a result of interference dispersion.
8. For the chosen fit, the insertion force or the reheating temperature of the component are determined
Insertion force (N)

$$F_s = \pi dl\, p_{max} f_s ,$$

where $p_{max} = (N_{max} - u)p/\delta$ (N/mm^2) is the pressure from interference N_{max} of the chosen fit and f_s is a traction coefficient (friction) due to insertion:

Table 6.71 Recommended values of traction coefficient f_S due to insertion

Material pair	f_s
Steel–steel	0.20
Steel–iron	0.14
Steel–bronze (brass)	0.10
Iron–bronze (brass)	0.08

Reheat temperature of the female part °C

$$t = 20°\text{C} + (N_{max} + Z_a)/(10^3 d\alpha_2) ,$$

where Z_a is a clearance (mm); for convenience of assembly it is assumed to depend on the shaft diameter d:

Table 6.72 Recommended clearance Z_a values

d (mm)	Z_a (μm)
Over 30 to 80	10
Over 80 to 180	15
Over 180 to 400	20

The reheating temperature must be such that there are no structural changes in material. The allowable temperature for steel is $[t] = 230–240$ °C while for bronze it is $[t] = 150–200$ °C.

Interference Connections with Electroplated Coatings

The load-carrying capacity of interference connections can be considerably increased by covering the electroplated coating on the mounting surfaces. Figure 6.153 shows the results of comparison testing of interference joints. Electroplated coatings were layered on the mounting surfaces with a thickness ranging from 0.01 to 0.02 mm. The joints were assembled by means of two methods: insertion (columns a) and with shaft cooling in liquid nitrogen (columns b). In the latter case clearance of 0.05 mm to the side formed between connected surfaces when assembled. The displacement force F_0 is assumed as a unit of comparison for the control junction without coating, which is assembled by means of insertion (without shaft cooling). It is evident

from Fig. 6.153 that covering increases the displacement force by a factor of 2–4.5. The load-carrying capacity of joints assembled by means of shaft cooling exceeds the strength of the connection assembled by means of insertion in by a factor of 2 for joints without coating and by factors of 1.2–1.3 for joints with soft coatings (Cd, Cu, and Zn). For joints with hard coatings (Ni and Cr) the load-carrying capacity is lower when assembled with cooling than when assembled with insertion.

The traction increase by electroplated coatings is caused by interdiffusion in the case of high pressure of the coating and parent metal, which is accompanied by the formation of the intermediate structures. This explains the close approximation to one value of the traction coefficient f (the right ordinate in Fig. 6.153), which actually represents the shearing resistance of the intermediate metal layer.

Application of soft coatings and assembly with shaft cooling increase the load-carrying capacity of the joints by a factor of 3–4 in comparison with joints without coating assembled by means of insertion. Consequently, for a set external load there is the possibility of using fits with lower interferences and corresponding lower tension stresses in the female part (bushing) and compression in the male part (shaft). Moreover, electroplated coatings protect contact surfaces from corrosion and avoid welding.

Calculation of Interference Connections Loaded with a Bending Moment

In some cases, the interference joints, e.g., the connections of gear wheels with shafts, are subjected to loading by a bending moment.

Considering the shaft to be absolutely hard, it can be imagined that the shaft rotates around the axis, which is

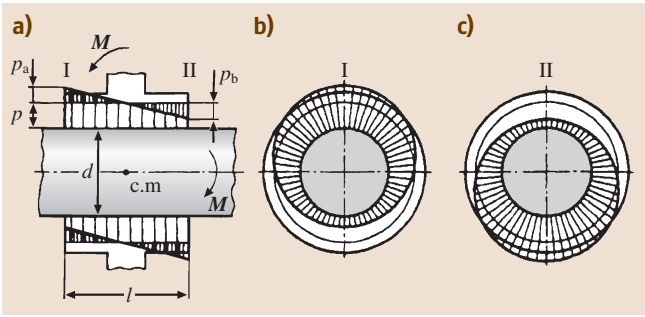

Fig. 6.154a–c Analytical model of connections with interference loaded with a bending moment. **(a)** Summation of diagrams of pressure from interference and bending moment, **(b,c)** the sickle-shaped nature of the total stresses on the faces of the components I and II, respectively

perpendicular to the drawing plane, and passes through the center of mass (c.m.) of the joint (Fig. 6.154a), relative to the bushing under the action of the bending moment M.

By loading of the interference joint with a bending moment M, the pressure p_b diagram, which is characteristic for bending (Fig. 6.154a), is overlaid on the pressure p diagram after the fit. As a result, the pressure distribution changes along the joint length, i. e., there is an increase in the compression zone and a decrease in the tension zone. It is known that the upper part of the joint receives half of the bending moment and the lower part receives the other half. In the cross-sections of the joint, e.g., on ends I and II of the hub, a circular pressure diagram first takes on a sickle-shaped nature (Fig. 6.154b,c). A pressure change does not diminish the ability of the joint to support an axial force and a torque, as the total value of the frictional forces is constant.

The efficiency condition of the joint is the nonopening of the junction in the most unloaded contact zone. Without opening of the junction the residual pressure is assumed to be equal to $p_{\min} = 0.25p$, where p is a pressure from the fit (N/mm^2)

$$p = 10^{-3}\delta/[d(C_1/E_1 + C_2/E_2)] ,$$

where $\delta = N_{\min} - u$.

The highest pressures p_b (N/mm^2) from the bending moment M (N m) are determined by analogy with the bending formula

$$p_b = \frac{10^3 M}{2W}\frac{4}{\pi} \le 0.75p ,$$

where $M/2$ is the part of the bending moment that falls on the upper (or lower) half of the joint, $4/\pi$ is a factor taking into account the sickle-shaped nature of the summary pressure diagram along the circle of the journal, and $W = dl^2/6$ is a bending modulus of the diametral axial section of the journal (mm^3).

After transformation the formula for calculation of the allowable bending moment (N m) is obtained from the prevention condition of the junction opening

$$M \le 0.2\times 10^{-3} dl^2 p .$$

Obviously, the allowable bending moment is proportionate to the squared length, which is why it is advisable to increase the length l when increasing the load-carrying capacity of a joint that is subjected to the action of the considerable bending moment.

Fit Connection on a Conical Shaft Part

Fit connections on a conical shaft part are mainly applied to fasten the components onto the shaft ends (Fig. 6.155). Interference and contact pressures are formed, e.g., with nut tightening that loads the connection with an axial force F_t. In contrast to cylindrical connections, bevel connections are easily installed and dismantled without special tools. Other advantages over cylindrical connections are: precise centering, the possibility of checking the interference through the axial displacement or pull force, the possibility of repeated assembly and dismantling, as well as retorques in the case of interference slackening in operation. These connections are considered promising ones, which widens their application field.

The pressure p (N/mm^2) on the work surface due to the axial pull force F_t (N) is

$$p = F_t/[\pi d_m l(\tan\alpha + f)] ,$$

where d_m and l are, respectively, the mean diameter and the joint length (mm), f is a traction coefficient (friction) ($f \approx 0.12$), and α is a gradient angle of the cone generatrix to the shaft axis.

For the shaft ends the taper 1 : 10 is the most commonly used, $\alpha = 2°51'45''$, $\tan\alpha = 0.05$. The torque T (N m) which the connection can transmit is

$$T \le 0.5 \times 10^{-3} F_t d_m f_r ,$$

where f_r is a surface friction factor $f_r = f/(\tan\alpha + f)$.

The required pull force for transmission through the joint for a set torque T becomes

$$F_t = 2 \times 10^3 KT/(d_m f_r) ,$$

where $K = 1.3–1.5$ is a traction safety factor.

Along with these tightening joints, tapered connections are used in dead joints and rarely in dismantled structures, where the interference is formed without application of thread pieces, but, e.g. by, means of insertion with a standardized impact or insertion on the rated axial displacement, or by means of heating of the female part (cooling of the male part). Recommended tapers for such connections are 1 : 50 to 1 : 30.

6.10.4 Frictional Connections with Conic Tightening Rings

Frictional connections with conic tightening rings are used for the installation of components such as gear wheels, pulleys, chainwheels, and half-couplings on shafts.

These connections transmit torques and axial forces due to the frictional forces on the contact surfaces of the shaft and the hub with conic rings installed in the annular gap between the shaft and the hub (Fig. 6.156). In Russia the rings are produced from spring steel 55 Si (EN), etc. (Appendix 6.A Table 6.95). By tightening the nut on the shaft (Fig. 6.156a) or the screw in the hub (Fig. 6.156b) the conic rings are elastically deformed and pull against one another. Then the outer rings are

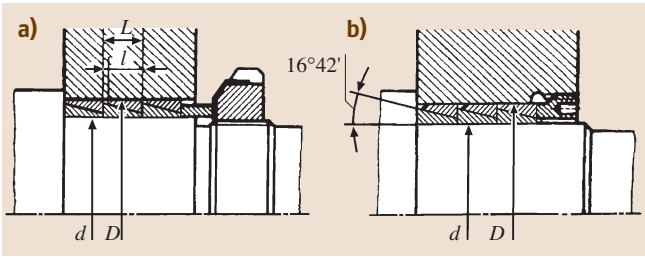

Fig. 6.156a,b Tightening methods of conic rings: **(a)** with a nut on the shaft or **(b)** with a screw in the hub

strained and tightly pressed to the hub, and the inner rings are compressed and tightly pressed to the shaft, leading to interference on the surface of the shaft and the hole.

The connections allow *hub* mounting on the shaft in any angular and axial positions, provide easy assembly, dismantling, good positioning, and tightness, do not loosen the shaft section with grooves or turnings, but need precise ring production with compliance to strict coaxiality of their outer and inner surfaces.

The required tightening force of the ring set for assembling is determined from the formula

$$F_t = F_{t1} + F_{t2} ,$$

where F_{t1} is a force required for the ring deformation when eliminating the mounting clearances; F_{t2} is a force required for formation of the mounting pressure on the shaft, which is equal to $100\,\mathrm{N/mm^2}$.

Table 6.74 shows dimensions of the rings, and values of the axial tightening forces F_{t1} and F_{t2}, transmitted turning moments T, and axial forces F_a for contact pressure of $p = 100\,\mathrm{N/mm^2}$. For $p = 200\,\mathrm{N/mm^2}$ the values of T and F_a are doubled, while for $p = 50\,\mathrm{N/mm^2}$ they are halved. Pressures are chosen depending on the toughness and sliding strength of the contacting surfaces. The values of T and F_a given in Table 6.74 correspond to the traction coefficient (friction) on the mating surfaces $f = 0.12$.

When mounting some ring sets it should be taken into account that a portion of the tightening force overcomes the axial constituents of the friction forces on the ring surfaces. Therefore the moment or the axial force transmitted with the second set amounts to approximately one-half, with the third set it amounts to one-quarter, and with the fourth one it amounts to one-eighth of the nominal values given in Table 6.74.

Tolerance ranges of the mounting surfaces are as follows:

Table 6.75 Recommended tolerance ranges

	Shaft	Hole
$d(D) \le 38\,\mathrm{mm}$	$h6$	$H7$
$d(D) \ge 40\,\mathrm{mm}$	$h8$	$H8$

Example

Select the parameters of the connection with the conic rings for transmission of the torque $T = 700\,\mathrm{N\,m}$ from the spur gear for a shaft with a diameter of 50 mm.

Solution

It follows from Table 6.74 that one ring set with diameter $d = 50\,\mathrm{mm}$ can transmit a torque of $405\,\mathrm{N\,m}$. The second set installed next to the first one transmits half of the load, $202.5\,\mathrm{N\,m}$; the third one transmits $101.25\,\mathrm{N\,m}$. Thus, three ring sets provide the torque transmission: $405 + 202.5 + 101.25 = 708.75\,\mathrm{N\,m}$, which guarantees transmission of the set torque in the situation.

The tightening force depends on the set number and for a diameter of 50 mm (Table 6.74) it is

$$F_t = F_{t1} + F_{t2} = 23.5 + 73 = 96.5\,\mathrm{kN} .$$

6.11 Rolling Bearings

6.11.1 Introduction

A bearing is a support or a guide determining a position of movable parts relative to other mechanism components. Bearings working mainly for movement with rolling friction are called *rolling bearings*, and those for movement with sliding friction are called *friction bearings*. Rolling bearings include details with rolling paths and solids of revolution [6.72, 99–105].

The advantages of rolling bearings are the following:

1. Complete interchangeability, readiness to operate without additional adjustment or debugging.
2. Small axial dimensions, simplicity of assembly and operation.
3. Low need for lubrication. Bearings with safety washers or integral seal are filled with a semisolid lubricant at production. This reserve is sufficient for their entire lifetime.

4. Low losses of friction, especially for breakaway and low rotational frequencies, slight heating under operation.
5. Low use of scarce nonferrous metals during manufacture.
6. Low production costs due to mass manufacturing.

The disadvantages of rolling bearings are the following:

1. Large radial dimensions
2. Axial and radial rigidity are low and vary according to the rotary angle
3. High rotation resistance, noise, and short lifetime at high rotational frequencies
4. Sensitivity to impact and vibrational loads

Application

Rolling bearings are the main type of supports in machines: in cars there are more than 30 types of bearings, in trucks there are more than 120, and in the airplanes, more than 1000, etc.

6.11.2 Classifications of Rolling Bearings

Rolling bearings transmit forces between the shaft and the case by their relative rotation. The forces loading the bearing are divided into:

- *Radial* forces acting in the direction perpendicular to the bearing axis
- *Axial* forces acting in the direction parallel to the bearing axis

Rolling bearings are classified according to the following main features:

- According to the form of the solids of revolution (Fig. 6.157) ball (a) and roller (b–h), where the latter can be designed with rollers that are cylindrical short (b), long (c), needle (d), taper (e), and cambered (f) with a small (7–30 μm side) convexity of the rolling surface (camber) and spiral hollow (g).
- According to the direction of the supported load: radial, to be loaded by radial forces; some types can also receive axial forces; radial-thrust, to be loaded by radial and axial forces; adjustable-type bearings cannot work without axial force; thrust, to be loaded by axial forces, they do not take radial force; thrust-radial, to be loaded by axial and low radial forces.
- According to the row number of the solids of revolution: single row, double row, and four row.
- According to the main design features: self-installed (e.g., spherical bearings self-install by angular displacement of the shaft axes and the hole in the case) and non-self-installed, with cylindrical or conic holes, binary, etc.

Division of bearings depending on the action direction of the supported load is relative in a number of cases. For example, a widespread ball radial single-row bearing is successfully applied for perception not only combined (radial and axial loads acting together), but also merely axial loads, and thrust-radial bearings are usually used only for bearing axial loads. In addition to these main types of bearings, various modifications are also produced.

6.11.3 Main Types of Bearings

The ball radial single-row bearing (Fig. 6.158a) is intended for load transfer of radial and limited axial forces of any direction, is one of the most common and cheap types of bearings. Its load rating is lower than that of roller bearings of the same dimensions. It can operate under the action of axial force only at high rotational frequency, i. e., in conditions for which flat-thrust bearings are not suitable.

It guarantees axial fixing of the shaft in two directions. Being non-self-installed it allows small angles of mutual warp of the inner and outer races, the values of which depend on the radial clearances in the bearing. With the same overall dimensions these bearings oper-

ate with lower friction losses and with higher rotational shaft frequency than bearings of other structures.

The ball radial spherical double-row bearing (Fig. 6.158b) is intended for perception of radial forces, but it can also receive limited axial forces in any direction. The presence of the axial constituent results in an imbalance of the force distribution between the rows. The radial dynamic load rating is lower than that of radial single-row bearings.

The rolling path on the outer race is machined along the circle. This is why the bearing is able to self-install and to operate at considerable (up to 1.5−4°) warp of the inner race (of the shaft) relative to the outer race (of the case). It is used in units with nonrigid shafts and in structures in which an appropriate coaxiality of the holes in the cases cannot be provided.

A ball radial-thrust single-row bearing is shown in Fig. 6.158c. The main embodiments differ in the initial contact angles: $\alpha = 12$, 15, 26, and 36°. The higher α, the higher the axial rigidity and the dynamic load rating, but the lower the allowable radial load and limit rotation frequency (because of the influence of gyroscopic effects). This bearing is intended for bearing radial and axial forces of one direction only; it cannot run under the action of radial force only without axial force.

For the perception of axial forces of any direction and for double-sided shaft fixing these bearings are installed on the shaft in pairs. On assembly, the unit the bearings should be adjusted for approximately zero clearance between the balls and the grooves of the races under steady thermal conditions. In some machines (e.g., machine tools), at adjustment, pair bearings are assembled with prior interference, whereby the bearing rigidity and rotational accuracy increase.

Radial-thrust bearings differ from radial bearings in that they have a greater number of balls that can be positioned in the bearing as a consequence of the presence of the chamfer on the outer race. Thus, their rigidity and dynamic load rating are higher.

The ball radial-thrust double-row bearing (Fig. 6.158d) is intended for bearing considerable radial, axial, and combined loads with high rigidity requirements. They are manufactured with a prior interference.

The ball radial-thrust single-row bearing with a split-face inner (or outer) race and a contact at three or four points (Fig. 6.158e) is intended for bearing radial and double-sided loads in the conditions of restricted dimensions in the axial direction.

The main embodiment of the ball thrust bearing is a single bearing (Fig. 6.159a). It is intended for bearing axial force of only one direction. It runs worse on horizontal shafts than on vertical ones and requires good adjustment or constant tightening of the races with the springs. One bearing race is installed on the shaft according to the interference fit. It is very sensitive to assembling accuracy. Because of increased gyroscopic effects it is used at considerably lower rotational frequencies than other ball bearings.

Other embodiments include:

- Single with a free race self-installed along the spherical outer surface and a jar washer (Fig. 6.159b); the jar washer compensates for any lack of parallelism between the supporting surfaces of the case and the collar of the shaft.
- Double thrust bearing with three races (Fig. 6.159c); the central race fixed onto the shaft has two grooves, it is used for bearing axial forces in both directions.

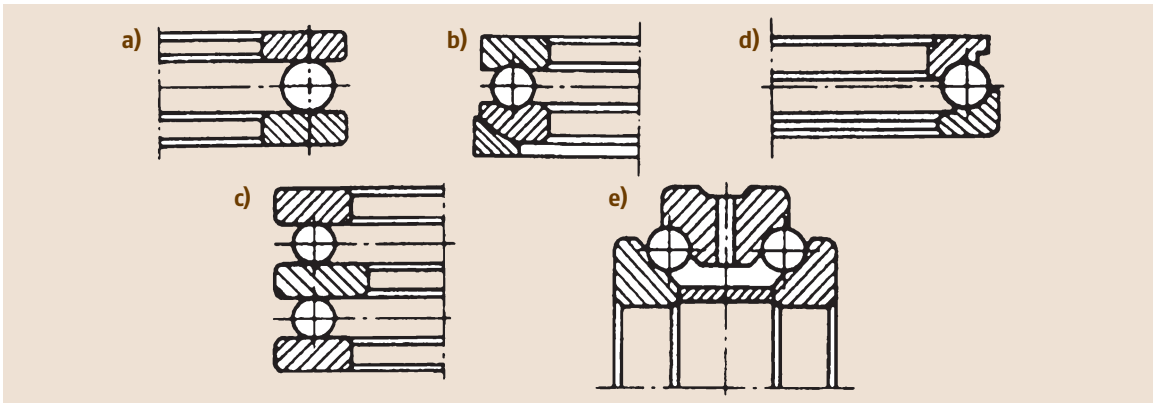

Fig. 6.159a–e Ball bearings. **(a)** Thrust single, **(b)** thrust with a spherical jar washer, **(c)** thrust double, **(d)** thrust-radial single, **(e)** thrust-radial double

The ball thrust-radial bearing allows higher rotational frequencies than does the thrust bearing. It is less sensitive to mutual warp of the races than the ball thrust bearing.

Embodiments of the ball thrust-radial bearings include:

- Single (Fig. 6.159d), used for bearing radial and axial forces in one direction.
- Paired with a contact angle of 60° (Fig. 6.159e), for which the direction of the forces is axial on both sides and radial.

The roller radial single-row bearing with short cylindrical rollers of the main embodiment, with ledges on the inner race and without ledges on the outer race (Fig. 6.160a), can bear only radial force. Roller bearings are noted for their higher dynamic load rating than that of ball bearings. Split assembly of the inner (with a roller set) and outer races is possible, which allows axial mutual race displacement, which is why application as a floating bearing is possible.

Bearings with ledges on the outer race are also used. If axial shaft fixation is required in the same direction, bearings with an extra ledge on the outer race are applied (Fig. 6.160b), and for axial fixing in two directions there are structures with an extra ledge and a thrust washer (Fig. 6.160c).

The double-row radial bearing with short cylindrical rollers and a conic hole (Fig. 6.160d) is used for high-speed shafts, which require precise rotation (mainly for spindles of metal-cutting machines). A high accuracy of the bearing in operation is reached on account of the structure workability, the possibility of adjusting the radial clearance by means of the inner race thrust, and the high rigidity caused by a large number of solids of revolution.

The roller radial spherical double-row bearing with ledges on the inner race (Fig. 6.160e) is intended for

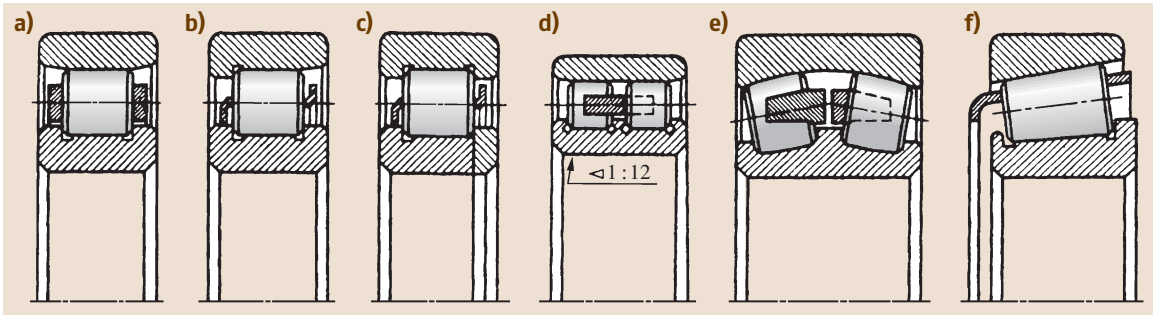

Fig. 6.160a–f Roller bearings. **(a)** Radial with short cylindrical rollers, **(b)** with shoulders on the inner race and an additional shoulder on the outer race, **(c)** with shoulders on the outer race and an additional shoulder on the inner race and a planar thrust washer, **(d)** radial double-row, **(e)** radial double-row spherical, **(f)** radial-thrust tapered

bearing radial and axial forces of any direction and allows considerable warp (0.5–2.5°) of the inner race (of the shaft) relative to the outer race (of the case). A rolling path of the outer race is made along the spherical surface. The rollers have the form of an asymmetrical or symmetrical barrel. This bearing differs from the ball radial spherical double-row bearing in its higher dynamic load rating, lower specific speed, and higher manufacturing complexity.

The roller radial-thrust tapered bearing with a contact angle of $\alpha = 10–16°$ (Fig. 6.160f) is intended for bearing radial and one-sided axial loads acting together.

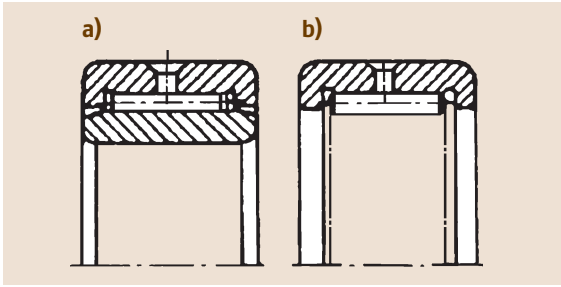

Fig. 6.161a,b Needle bearings. **(a)** With an outer and an inner race, **(b)** without inner race

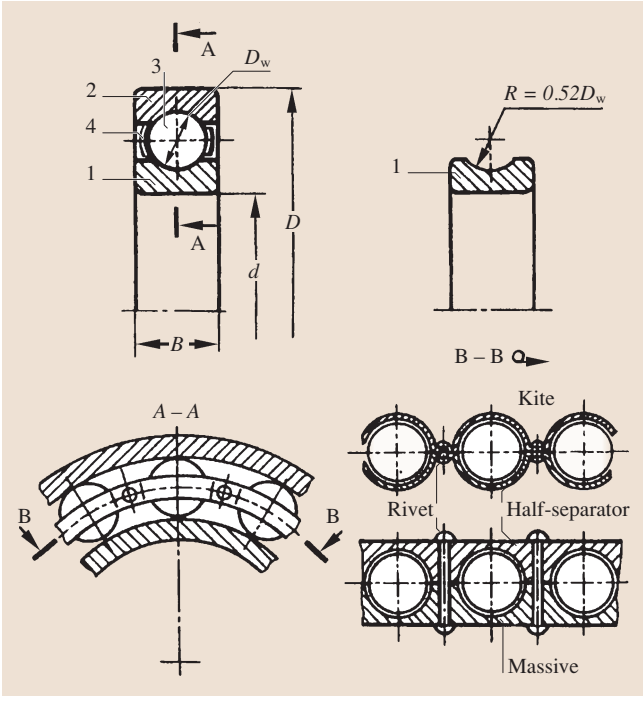

Fig. 6.162 The main components of a bearing

It differs from the ball radial-thrust bearing through its higher dynamic load rating, lower limit rotation frequency, and lower obtainable accuracy of the shaft rotation. The possibility of adjusting the axial bearing clearance must be considered in units with roller tapered bearings. Split assembly of the outer race and the inner race with a roller set is permissible.

This bearing has a rather wide application in mechanical engineering. It is remarkable for its convenient assembly, dismantling, and clearance adjustment. To provide pure rolling the tips of the tapered surfaces of the rolling paths of the races and the rollers must coincide. The rollers are aligned in the direction along the face from the side of the major diameter to avoid axial displacement. Bearings intended for particularly high axial loads are made with a contact angle of $\alpha = 20–30°$.

Tapered and cylindrical roller bearings are designed with a modified contact (rollers and rolling paths are made with a convex generatrix of different configuration), which means that the unfavorable effect of race axis warps can be decreased.

The roller radial needle bearing (Fig. 6.161a) is remarkable for its large radial dynamic load rating with small radial dimensions. It cannot bear axial forces and does not maintain axial shaft position.

Most of these structures are manufactured without cages. They are recommended for application in units running with hobbing motion or at low rotational frequencies. Needle bearings with cages can work with comparatively high rotational frequencies. They are sensitive to mutual warps of the races. Bearings with a profile modification allow insignificant mutual warps of the races.

To reduce size, a needle set is widely used in a cage without races or with one race (Fig. 6.161b). The surfaces of the shaft or the case for the needles must be quenched to high hardness, ground, and polished.

6.11.4 Functions of the Main Bearing Components

Figure 6.162 shows an axial section of a ball radial single-row bearing. The main components of the rolling bearing are 1 – the inner race, d – the hole diameter, 2 – the outer race, D – the outer diameter of the bearing, 3 – the solid of revolution – a ball, D_w – the diameter of the solid of revolution; 4 – the cage, which covers the solids of revolution and moves together with them.

The races of the bearings have grooves, which serve as guides for the solids of revolution.

A cage (see sections A–A and B–B in Fig. 6.162) is intended for direction, retention of the solids of revolution in a certain position (with the provision purpose of race coaxiality), and for separation of the solids of revolution from direct contact (with the objective of decreasing wear and friction losses). For low rotational frequencies and hobbing motion, bearings without cages are used (e.g., bearings of universal joint crosses).

The main application of a kite cage is in the configuration of two sinuous ring-shaped half-cages connected with rivets. Massive cages (unbroken or composite) are applied in fast-rotating units and high-accuracy bearings; they provide more precise positioning of the solids of revolution relative to the races of the bearings.

6.11.5 Materials of Bearing Components

In Russia races and solids of revolution are manufactured from special ball-bearing high-carbon chromium steels of various grades (100Cr6, 100CrMn6), as well as from carburized alloy steels (20MnCr5G, 17CrNiMO) (Appendix 6.A Table 6.95). The races have hardness 61–65 HRC, while the hardness of the solids of revolution is 63–67 HRC. Races and solids of revolution for bearings running at increased temperatures (up to 500 °C) or in corrosive mediums are produced from temperature-resistant or corrosion-resistant steels. For bearings that are to meet increased requirements in terms of lifetime and safety, steels subjected to special refining to decrease inclusion content, as well as double refining (electroslag and vacuum-arc refining), are used. In high-speed units bearings with balls made from silicon nitride Si_3N_4 are used.

In most cases cages are produced from soft carbon steel (Appendix 6.A Table 6.95). The rivets of the cages are manufactured from steel grades 15 and 20 (GOST) [6.89, 104, 106–115]. The cages of high-speed bearings are made massive from textolite, teflon, brass, and bronze, listed in ascending order of specific speed.

The surface roughness of the solids of revolution and rolling paths is $Ra = 0.04–0.08\ \mu m$.

6.11.6 Nomenclature

The reference designation of a bearing is mostly marked on the race face. The main reference designation can consist of seven figures, indicating the diameter of the bearing hole, the dimensional series, the type, and the design philosophy. Zeros to the left of the least significant figure are not filled in. In this case, the number of figures in the reference designation is fewer than seven, e.g., 7208.

The first two figures to the right form a number that indicates the diameter, d, of the bearing hole. For bearings with $d = 20–495$ mm the hole diameter is determined by multiplication of this number by 5. Thus, bearing 7208 has $d = 40$ mm. Diameter designations of bearing holes from 10 to 17 mm are given in Table 6.76.

The third digit to the right indicates a diameter series and, together with the seventh digit designating a width series, determines the dimensional bearing series (Fig. 6.163). In ascending order of bearing outer diameter (with the same inner one) the series are designated as: 0, 8, 9, 1, 7, 2, 3, 4, 5, and 6. Thus, bearing 7208 has diameter series 2.

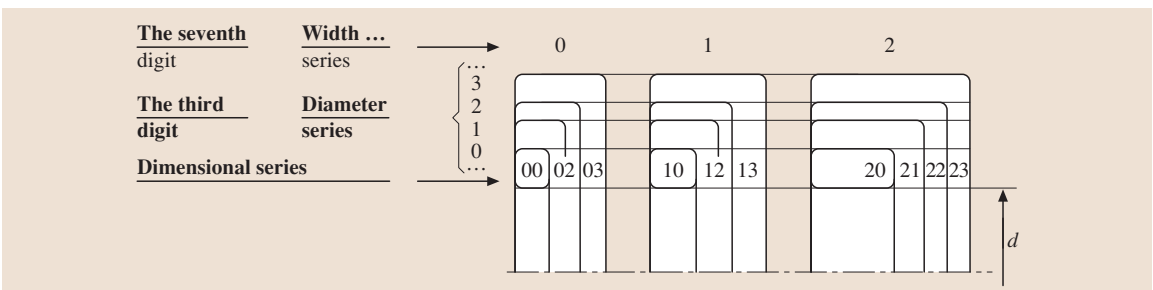

Fig. 6.163 Dimension series of bearings

The fourth figure to the right indicates a bearing type:

Table 6.77 Bearing type designation

Bearing type	Designation
Ball radial single-row	0
Ball radial spherical double-row	1
Roller radial with short cylindrical rollers	2
Roller radial spherical double-row	3
Roller needle or with long cylindrical rollers	4
Roller radial with spiral rollers	5
Ball radial-thrust single-row	6
Roller tapered	7
Ball thrust, ball thrust-radial	8
Roller thrust or thrust-radial	9

The example bearing 7208 is therefore roller tapered.

The fifth or the fifth and sixth digits to the right indicate a structural modification of the bearings (the value of the nominal contact angle in radial-thrust bearings, the presence of seals or a groove on the outer race for the thrust washer, etc.). The fifth and sixth digits in the bearing designation 7208 are absent; this is therefore the bearing with the main embodiment (base dimension type).

The seventh digit to the right indicates a width (height) series and with the third figure, which designates a diameter series, determines the dimensional series of the bearing. In ascending order of bearing width (height) the series are identified as: 7, 8, 9, 0, 1, 2, 3, 4, 5, and 6 (Fig. 6.163). The example roller-tapered bearing 7208 is of dimensional series 02.

Bearings of different types and series have dissimilar dimensions, mass m, dynamic load rating C_r, and limit rotation frequency $[n]$ (Fig. 6.164). In Fig. 6.164 most high-speed bearings are radial ball bearings from the dimensional series 02. The bearings in dimensional series 04 are not applicable for such high speeds, but their dynamic load rating is higher. Roller tapered bearings are characterized by a higher dynamic load rating than ball bearings with the same dimensions and lower limit rotation frequency.

Besides the digits of the main designation there may be additional alphabetic and numeric characters to the left or to the right, which define special manufacturing conditions of the given bearing.

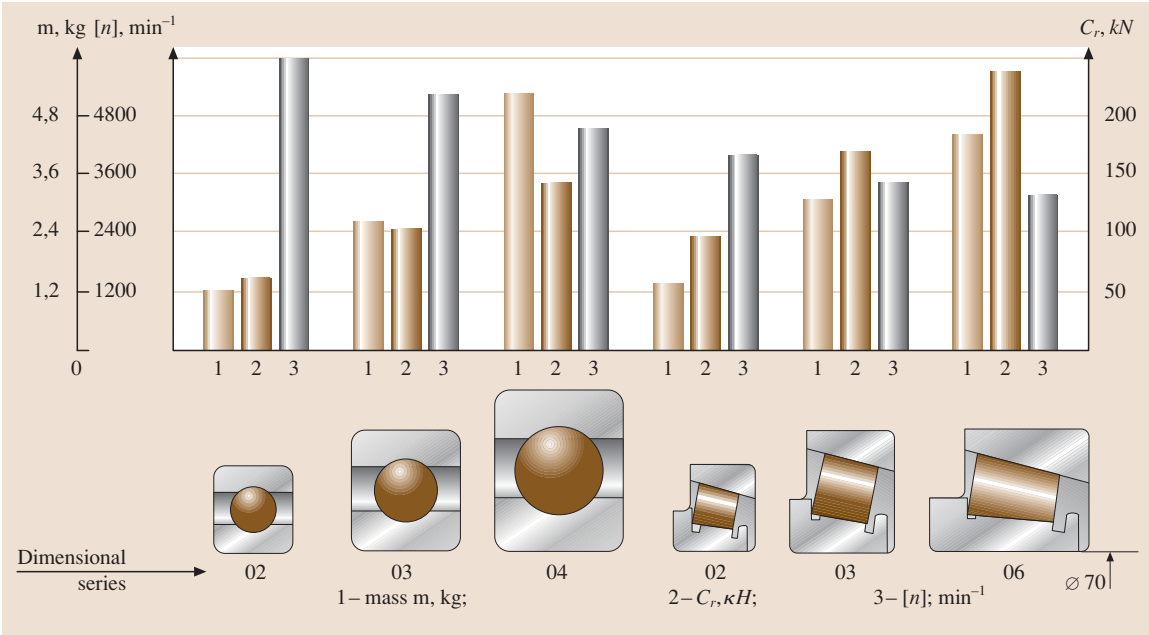

Fig. 6.164 Comparative parameters of radial ball and radial-thrust roller bearings of different dimension series

The characters defining an accuracy rating (0, normal, 6*X*, 6, 5, 4, *T*, 2, Appendix 6.B), a group for radial clearance (0, 1, 2–9; for radial-thrust ball bearings the grade of preinterference is indicated by 1, 2, and 3), a row for the frictional moment (1, 2–9) and a bearing class (A, B, and C) are marked to the left of the main designation.

The accuracy ratings are listed in ascending order of accuracy. In general engineering bearings of the accuracy ratings *normal* and 6 are used. In products with high accuracy or running with high rotational frequency (spindle units of high-speed machines, high-speed motors, etc.) bearings of classes 5 and 4 are applied. Bearings of accuracy rating 2 are used in gyroscopic devices.

The characters are located in recitation order right-to-left from the main designation of the bearing and are attached to it by a dash, e.g., A125-3000205, where 3000205 is the main designation, 5 is an accuracy rating, 2 is the group for radial clearance, 1 is a row of frictional moment; and A is the bearing class.

For all bearings except tapered ones the character "0" is used to designate the normal accuracy rating. For tapered bearings the character "0" is used to designate accuracy rating 0, the character "N" is for the normal accuracy rating, and the character "X" is for accuracy rating 6X. In our example the bearing 7208 has accuracy rating 0.

Depending on the presence of extra requirements for vibration level, deviations of shape and rolling surface position, frictional moment, etc., there are three bearing classes: A, increased regulated standards; B, regulated standards; and C, without extra requirements.

Possible characters to the right of the main designation are the following: A – increased dynamic load rating; E – the cage is made of plastic materials (polymers, textolite); P – the components of the bearing are made from heat-resistant steels; C1–C28 – closed class for filling with a lubricant; T (T1–T5) – temperature requirements of tempering of the bearing components, etc.

An example of the reference designation of a bearing with extra characters is A75-3180206ET2C2, i.e., a ball radial single-row bearing (0) with a double-sided seal (18) and a hole diameter of 30 mm (06), a diameter series 2, a width series 3, an accuracy rating 5, a radial clearance according to group 7, in the case of a requirement failure in the frictional moment, class A, with a cage made from plastic material (E), and the temperature of the regulating race tempering is 250 °C (T2), filled with a lubricant by the manufacturer (C2).

6.11.7 The Nature and Causes of Failure of Rolling Bearings

1. Fatigue flaking of the work surfaces of the races and solids of revolution in the form of bubbles or flaking-off under the action of fluctuating contact stresses. Nonmetallic inclusions in the steel, deep grinding marks, and microasperities are the main sources of crack nucleation. Fatigue flaking is the main fracture mode of bearings with good lubrication and ingress protection of the abrasive particles. It is usually observed after a long operation time.
2. Bearing of the work surfaces of the rolling paths and solids of revolution (formation of dimples and hollows) as a consequence of local plastic strains under the action of vibrational, impact, or considerable dead loads.
3. Abrasion owing to poor protection of the bearing from penetration of abrasive particles (construction-site engines, road and agricultural machines, looms). Application of perfect seal structures in bearing units decreases wear of the work-bearing surfaces.
4. Cage fracture due to the action of centrifugal forces and the influence of solids of revolution with different dimensions on the cage. This fracture mode is a principal cause of efficiency loss in high-speed bearings.
5. Fracture of the races and solids of revolution as a consequence of race warp and impact overloads (chipping of the ledges, splitting of the races, etc.). In the case of qualitative assembly and correct operation, component fracture of the bearings should not take place.

Outward signs of abnormal operation are the following: loss of rotational accuracy, increased noise and vibration, increased rotation, and temperature resistance. The main efficiency criteria for rolling bearings are contact fatigue strength and static contact strength.

6.11.8 Static Load Rating of Bearings

At initial point contact (ball bearings) touching of the bodies under load occurs along an elliptic area; at initial linear contact (roller bearings) it is along a rectangular area. The corresponding values of the contact stresses are determined from Hertz's formulas for point and linear contact.

The ratio of the curvature radii at the contact points is such that the contact stresses σ_h in the contact of the

solid of revolution with the inner race are higher than in the contact zone of the solid of revolution with the outer race for all bearing types (except spherical ones).

Thus, e.g., contact stresses σ_H (N/mm^2) for ball radial single-row bearings in contact with the inner race are

$$\sigma_H \approx 1035\sqrt[3]{F_0/D_w^2} \approx 1035\sqrt[3]{5F_r/\left(zD_w^2\right)}\,, \quad (6.22)$$

while for the outer race

$$\sigma_H \approx 827\sqrt[3]{F_0/D_w^2} \approx 827\sqrt[3]{5F_r/\left(zD_w^2\right)}\,,$$

where F_0 is a force acting on the most heavily loaded solid of revolution by the loading of the bearing with the radial force F_r (N), z is the number of solids of revolution, and D_w is the diameter of the solid of revolution (mm).

The basic static load rating of the bearing is a static load in N, which corresponds to the rated contact stress in the center of the most heavily stressed contact zone of the solid of revolution and the rolling path of the bearing.

According to the relevant ISO standard the following are assumed as design contact stresses σ_H for bearings:

Radial and radial-thrust ball (except self-installed):	$\sigma_H = 4200\,\mathrm{N/mm^2}$
Radial ball self-installed:	$\sigma_H = 4600\,\mathrm{N/mm^2}$
Radial and radial-thrust roller:	$\sigma_H = 4000\,\mathrm{N/mm^2}$
Thrust and thrust-radial ball:	$\sigma_H = 4200\,\mathrm{N/mm^2}$
Thrust and thrust-radial roller:	$\sigma_H = 4000\,\mathrm{N/mm^2}$

The total residual strain in the solid of revolution and the rolling path of the race arising by these contact stresses is approximately equal to 0.0001 of the diameter of the solid of revolution.

The static load rating for radial and radial-thrust bearings corresponds to the radial force F_r causing purely radial displacement of the races relative to each other. For thrust and thrust-radial bearings this corresponds to the central axial force F_a. The basic static load rating is designated in the following way: radial – C_{0r}, axial – C_{0a}.

With static loading, damage of the bearings appears in the form of the working surface plastic strain. In strength analysis the acting contact stress σ_H should be limited to

$$\sigma_H \le [\sigma]_H\,,$$

where $[\sigma]_H$ is the allowable contact stress.

The derivation of this formula is shown for the calculation of the basic static load rating using the example of a ball single-row radial bearing.

The strength condition for the most loaded point on the inner race of the bearing is, according to (6.22),

$$\sigma_H = 1035\sqrt[3]{5F_r/\left(zD_w^2\right)} \le [\sigma]_H\,.$$

From this the allowable radial load is

$$[F]_r = \left[\frac{1}{5}\left(\frac{[\sigma]_H}{1035}\right)^3\right] zD_w^2\,.$$

Designating the expression in square brackets on the right-hand side by f_0 and writing $[F]_r = C_{0r}$ we obtain the formula to calculate the basic static load rating C_{0r} (N), for radial and radial-thrust ball bearings:

$$C_{0r} = f_0 i z D_w^2 \cos\alpha\,,$$

where f_0 is a coefficient depending on the bearing class, material, and geometry of the bearing components, their manufacturing accuracy, and the assumed value of the design contact stress (Table 6.78); i is the number of rows of the solids of revolution, z is the number of solids of revolution in a row, D_w is the ball diameter (mm), and α is the nominal contact angle (degrees).

Design dependencies for the calculation of the static load rating for other bearing classes are given in the standard [6.111].

The values of the basic static load rating C_{0r} (C_{0a}) for all bearings are calculated in advance and given in the manufacturer's catalog.

6.11.9 Lifetime Testing of Rolling Bearings

The lifetime is the running time of the bearing until the appearance of signs of material fatigue on the solids of revolution or the races. The bearing lifetime is designated by L (life) and is expressed in terms of the number of millions of revolutions of one race relative to another or in terms of working hours. The main design dependencies for matching of bearings are obtained on the basis of a pilot study of specimen and full-scale bearings.

Figure 6.165 shows a contact stress-cycle diagram of specimens manufactured according to the standards of the bearing industry technology. The ordinate axis shows contact stresses σ_H, which were determined according to Hertz's theory; the abscissa shows the lifetime, expressed by the number N of stress change cycles to fracture. Stress-cycle diagrams are plotted for the different probability levels Q of fracture: 0.01, 0.10, 0.30,

Table 6.78 Values of the coefficient f_0 for ball bearings. The values f_0 are determined from Hertz's formulas obtained from the condition of initial point contact with a modulus of elasticity of 2.07×10^5 N/mm^2 and Poisson's ratio of 0.3. The values of f_0 are calculated for the case of common external force distribution between the solids of revolution, when the load on the most loaded ball in ball radial and radial-thrust bearings is equal to $5F_r/(z \cos\alpha)$, and in ball thrust and thrust-radial bearings it is $F_a/(z \sin\alpha)$. f_0 for the intermediate values $D_w \cos\alpha / D_{pw}$ is calculated by linear interpolation

0.50, and 0.70. The equation for the curve in the stress-cycle diagram is $\sigma_{Hi}^q N_i = \text{const}$. The exponent is $q = 9$ for point contact and $q = 20/3$ for linear contact.

According to the test results of 20–30 specimens the lifetime exhibits considerable dispersion at the same stress level. The maximum value can differ from the minimum value by 50–100.

Dispersion of the testing results occurs as a consequence of the static nature of the fatigue failure process, which is caused by microstructure discontinuities in the metal: different dimensions, forms, and metal grain orientation, the presence of different structural phases, nonmetallic inclusions, different orientation of the crystal lattice, as well as occasional changes in microgeometry and the structure of the surface layer, etc.

The load P on the specimen or the bearing corresponds to the contact stresses σ_H. For a point contact

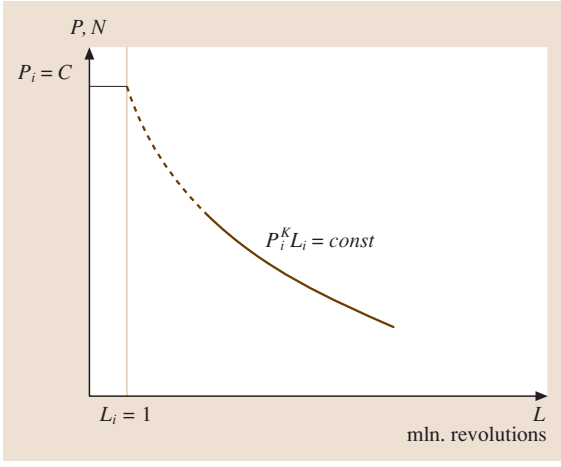

Fig. 6.166 Dependence of the bearing lifetime L on the acting load P

P is proportionate to σ_H^3, for a linear contact $P \sim \sigma_H^2$. On the basis of pilot studies the following dependence is fixed between P acting on the bearing load and its lifetime L_i (Fig. 6.166)

$$P_i^k L_i = \text{const.}\,, \tag{6.23}$$

where k is the exponent of the stress-cycle diagram ($k = 3$ for ball bearings and $k = 10/3$ for roller bearings).

Theoretically, the stress-cycle diagram, which is obtained experimentally, can be extrapolated to the area of higher loads – hatch in Fig. 6.166. Assuming the lifetime of the bearing to be $L_i = 1$ million revolutions and indicating the load P_i, which corresponds to this lifetime, through C, it can be written in accordance with (6.23) for the stress-cycle diagram as

$$P_i^k L_i = C^k 1\,.$$

Omitting the index i, we obtain formula for calculation of the lifetime L, in millions of revolutions, depending on the bearing load P (N), in a general form as

$$L = (C/P)^k\,. \tag{6.24}$$

The load C (N) is called the *dynamic load rating*. The design dependence (6.24)) is correct when $P \le 0.5C$.

In view of the considerable dispersion in the fatigue characteristics, the testing results are handled with a statistical method. The distribution of bearing failure is described according to Weibull's two- or three-parameter distribution.

Based on estimation of the test results the value of the lifetime L_{10} that corresponds to the probability $Q = 10\%$ of bearing fatigue failure is used.

6.11.10 Design Dynamic Load Rating of Bearings

The basic dynamic radial (or axial) design load rating represents a radial (or axial) load in N, which the rolling bearing can theoretically support for the base design lifetime constituting 1 million revolutions.

The basic design lifetime L_{10} is the lifetime in millions of revolutions that corresponds to 90% safety for a specific bearing or a group of identical rolling bearings manufactured from a common material with the application of standard technology and running under the same standard operating conditions, i.e., the bearing is installed correctly, lubricated, protected from the penetration of foreign bodies, and the load corresponds to the bearing dimension type, and the bearing is not

subjected to excessive changes of temperature and rotational frequency.

The basic dynamic design load rating is designated in the following way: radial – C_r, axial – C_a. The values C_r (C_a) for each bearing are calculated in advance and indicated in the manufacturer's catalog. The development of the formula for calculation of the basic dynamic radial load rating is shown by using the example of a ball radial single-row bearing.

The calculation is based on the use of experimental stress-cycle diagrams (Fig. 6.165) described by a dependence

$$\sigma_{Hi}^{q} N_i = \text{const.} , \tag{6.25}$$

where $q = 9$ for ball bearings, and const. is a constant that corresponds to the experimental environment.

With bearing loading with a radial force F_r and inner race rotation and a nonrotating outer race, the number of loading cycles for L million revolutions is

$$N = 0.5 \times 10^6 z K_1 K_{ef} L ,$$

where z is the number of solids of revolution, $K_{ef} < 1$ is an equivalence coefficient taking into account the uneven load distribution between the solids of revolution, and $K_1 = 0.5(D_{pw} + D_w \cos\alpha)/D_{pw}$. Here D_{pw} is the diameter of the circle going through the centers of the solids of revolution, D_w is the ball diameter, and α is the contact angle.

In accordance with (6.25) we have

$$\left[1035 \sqrt[3]{5F_r/\left(zD_w^2\right)}\right]^9 0.5 \times 10^6 z K_1 K_{ef} L = \text{const.}$$

The left- and the right-hand sides of this expression are raised to a power of one-third and, after transformation, we have

$$F_r L^{1/3} = \left[\frac{\text{const}^{1/3}}{1035^3 \times 5 \left(0.5 \times 10^6 K_1 K_{ef}\right)^{1/3}}\right] \times z^{2/3} D_w^2 .$$

The expression in square brackets is designated f_c. In accordance with (6.24) for $P = F_r$ we have $F_r L^{1/3} = C_r$. After appropriate changes and some corrections we obtain the formula for the calculation of C_r (N), the basic dynamic radial design load rating for ball radial and radial-thrust bearings

$$C_r = b_m f_c (i \cos\alpha)^{0.7} z^{2/3} D_w^{1.8} ,$$
$$\text{by} \quad D_w \le 25.4\,\text{mm} ;$$
$$C_r = 3.647 b_m f_c (i \cos\alpha)^{0.7} z^{2/3} D_w^{1.4} ,$$
$$\text{by} \quad D_w > 25.4\,\text{mm} ,$$

where b_m is a coefficient characterizing the behavior of steel, taking into account its method of manufacture and depending on the bearing class and structure; f_c is a coefficient depending on the geometry of the bearing components and their production accuracy; i is the number of rows of solids of revolution; and z is the number of solids of revolution in a row.

Design dependencies for the calculation of the dynamic load rating are given in standards for other bearing classes. By definition, the basic dynamic load rating represents a very large load corresponding to the theoretical area of the stress-cycle diagram, that is not achievable in practice.

6.11.11 Design Lifetime of Bearings

The basic design lifetime L_{10} in millions of revolutions is determined by 90% safety (as indicated by the figure 10 in the designation; i.e., $10 = 100 - 90$)

$$L_{10} = \left(\frac{C}{P}\right)^k , \tag{6.26}$$

where C is the base dynamic load rating of the bearing (radial C_r or axial C_a) (N), P is the equivalent dynamic load (radial P_r or axial P_a) (N), and k is an exponent that is chosen in accordance to the outcomes of experiments to be $k = 3$ for ball bearings and $k = 10/3$ for the roller bearings.

The formula for the lifetime calculation is correct if P_r (or P_a), and for varying loads $P_{r\,max}$ (or $P_{a\,max}$), does not exceed $0.5C_r$ (or $0.5C_a$). The applicability of this formula is also limited to rotational frequencies from $10\,\text{min}^{-1}$ to the limiting values stated in the manufacturer's catalog.

From the given formula the basic design lifetime L_{10} for bearings that are produced from standard bearing steels according to standard technology and exploited under common conditions is calculated.

For different material properties or operating conditions from the standard ones, as well as for increased safety requirements and to take into account special bearing properties, the *corrected design lifetime* L_{sa} is determined in millions of revolutions as

$$L_{sa} = a_1 a_2 a_3 L_{10} , \tag{6.27}$$

where a_1 is a coefficient correcting the lifetime depending on the *safety* P_t (Table 6.41), a_2 is a coefficient adjusting the lifetime depending on the special bearing properties, and a_3 is a coefficient correcting the lifetime depending on the operating conditions of the bearing.

The corrected design lifetime of the bearing in operating hours is

$$L_{sah} = 10^6 L_{sa}/(60n) ,$$

where n is the rotational frequency of the race (min^{-1}).

Sometimes it is more convenient to express the bearing lifetime of vehicles (the bearings of wheel hubs and half-axes) in units of distance. The corrected design lifetime in millions of kilometers is

$$L_{sas} = (\pi D/1000) L_{sa} ,$$

where D is the wheel diameter in meters.

The rolling bearing calculation for an increased probability of nonfailure during operation is carried out for important units by using a safety factor of 91–99%. Instead of the index s, the value of the difference $(100 - P_t)$ is written in the lifetime designation, where P_t is the safety used for the lifetime determination. Thus, for 90% safety one writes L_{10a} (L_{10ah}) and for 97% safety one writes L_{3a} (L_{3ah}).

The bearing can obtain special properties, resulting in a different lifetime, following the application of special materials (e.g., steels with a particularly low content of nonmetallic inclusions) or special production processes, or are of a special structure. The values of the coefficient a_2 are fixed by the bearing manufacturer.

Working conditions, which are additionally taken into account with the help of the coefficient a_3 – it is a conformity of the lubricant viscosity with the required value (taking into account rotational frequencies and temperatures), the presence of foreign particles in the lubricant, as well as conditions causing material property change of the bearing components (e.g., high temperature causes hardness to decrease).

Calculation of the basic lifetime is built upon the fact that the thickness of the oil film in the contact zones rolling element race is equal to or a little more than the total roughness of the contact surfaces; Therefore $a_3 = 1$. The bearing producer provides recommendations concerning the values of the coefficient a_3 for other conditions.

For the choice of the bearing dimension and the calculation of the corrected lifetime for specific operating conditions it is supposed that the bearings correspond to the required accuracy grade and that the required strength and rigidity of the shafts and cases are provided.

Application of the values $a_2 > 1$ and $a_3 > 1$ in the formula of the corrected lifetime will be valid.

6.11.12 The Choice of Bearing Classes and Their Installation Diagrams

Each bearing class has particular features due to its structure. For the choice of bearing class a few different comparative factors must be appreciated. Thus, it is impossible to formulate a general law for bearing choice. The most significant factors are given below:

- Value and direction of the load (radial, axial, combined)
- Load conditions (constant, varying, vibrational, impact)
- Rotational frequency of the bearing race
- Required lifetime (in hours or millions of revolutions)
- Environmental conditions (temperature, humidity, dust level, acidity, etc.)
- Particular requirements for the bearing, which are made with a unit structure (the necessity for bearing self-installation into the support for warp compensation of the shaft or the case; the ability to allow shaft displacement in the axial direction; bearing assembly directly onto the shaft, on the clamping or clamping-tightening sleeve; the necessity to adjust the radial and axial clearance of the bearing, increase of support rigidity and accuracy of the shaft rotation, decrease of the frictional moment, noisiness; desired overall dimensions of the unit, requirements for safety; price of the bearing and of the entire unit)

With the choice of bearing type the common practice in machine design and operation of the fixed machine class can be headed for. Thus, for example, ball radial bearings are mostly used for shaft supports of spurs and helical wheels, reduction gears, and gearboxes. Tapered roller bearings are applied as shaft supports of spur gears where the dimensions of the ball bearings are excessively large.

Bevel and worm wheels must be precisely and rigidly fixed in the axial direction. Ball radial bearings are characterized by low axial rigidity. Thus, in power trains, tapered roller bearings are used for shaft supports of bevel and worm wheels.

For the shaft supports of the bevel pinion tapered roller bearings are applied from the same considerations. For high rotational frequency of the gear shaft ($n > 1500\,\mathrm{min}^{-1}$) ball radial-thrust bearings are used.

Worm supports in power worm gears are loaded with considerable axial forces, which is why tapered roller bearings are mainly applied as supports for worm

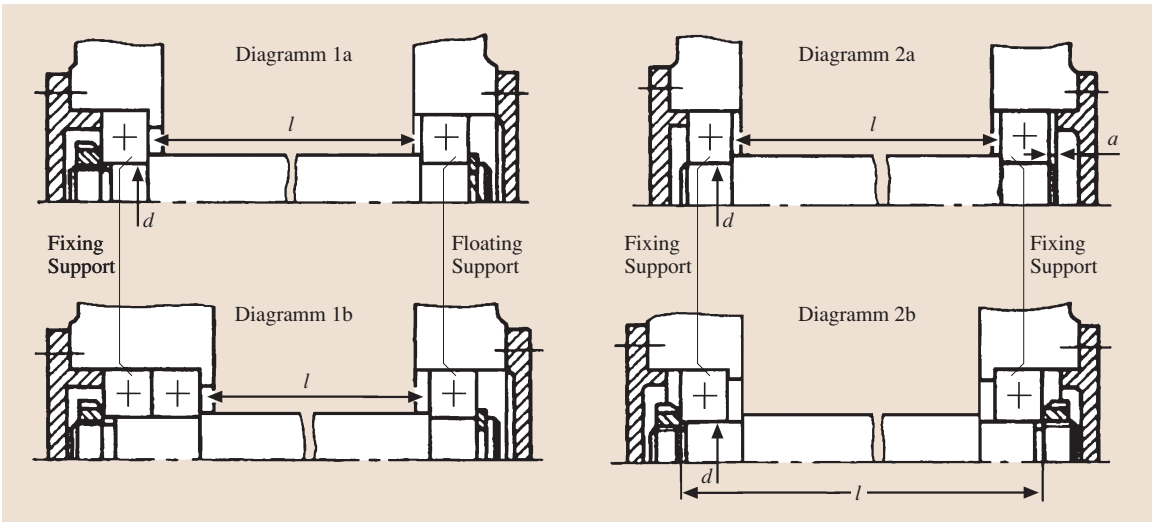

Fig. 6.167 Methods of axial fixation of the shafts

shafts. Under continuous operation of the worm gear ball radial-thrust bearings are also used in order to reduce heat generation.

For the supports of floating shafts of herring-bone gears, radial bearings with short cylindrical rollers are used.

Bearings of the normal accuracy degree are usually used. Bearings of higher accuracy are applied for shaft supports that require increased rotation accuracy or run at particularly high rotational frequencies. Application of bearings with higher accuracy degrees increases product value.

After class, structural modifications and the installation diagram of the bearings are outlined, the bearing is chosen from the catalog, and the lifetime calculation and/or static load rating calculation are performed for the required safety level. Depending on the operating rates and working conditions, the lubrication method, lubricant type, its protection from contamination, and outflow from the bearing are then chosen.

Installation diagrams

In most cases the shafts should be fixed to the supports to avoid axial displacements. The shafts are divided into fixing and floating types according to their ability to fix the axial position of the shaft. Axial shaft displacement is restricted in fixed supports in one or both directions. In a floating support axial shaft displacement is not limited in any direction. A fixing support is loaded only with radial and axial forces, whereas a floating support is only loaded with radial forces.

In some structures so-called *floating* shafts are used. These shafts allow axial displacement in both directions; they are installed on the floating supports. Fixation of the axial shaft is not carried out in the supports, but by some other structural components, e.g., with the component faces or the teeth of chevron gears.

Figure 6.167 shows the main methods of axial shaft fixation. In diagrams 1a and 1b (Fig. 6.167) the shaft is fixed in a (left-hand side of the figure) support: in 1a a bearing is used, whereas in 1b two single-row bearings are used. Radial bearings are usually applied in a floating support. These diagrams can be used for any distance l between the shaft supports. The diagramm 1b (Fig. 6.167) is characterized by high rigidity of the fixing support, especially in the case of the application of two radial-thrust bearings with large contact angles in one support.

By combining a fixing support and a floating support, the aim is to provide approximately even loading of the bearing and the lowest frictional forces in the floating support.

With fluctuations in temperature the floating bearing moves in the axial direction due to the extension (shortening) of the shaft. Then displacement can take place under load, and the hole surface of the case wears out. This is why, under the action of only radial forces on the shaft supports, the less loaded support is chosen as the floating one. If the output shaft end is connected to the shaft of another unit by means of a sleeve, the support at the output shaft end is assumed to be fixed.

In diagrams 2a and b (Fig. 6.167) the shaft is fixed in two supports, with each support in one direction. These diagrams are used with certain limitations on the distance between the supports, which results from the change in clearance at the bearings as a consequence of component heating during operation. With heating of the bearings the clearances in them decrease; with shaft heating its length increases.

Due to the increase of the shaft length the axial clearances in the bearings of diagram 2a (Fig. 6.167) are also reduced. The axial clearance a is designed for the supports at assembly so that shaft jamming does not occur. The value of the clearance must be slightly higher than the expected thermal deformation of the bearings and the shaft. Depending on the unit structure and operating conditions one uses $a = 0.15–1.0$ mm.

Installation diagram 2a (Fig. 6.167) is physically the simplest. It is widely used with relatively short shafts. On assembly of the radial bearings in the supports the ratio is $l/d \approx 8–10$, and no higher.

In the supports in diagram 2a (Fig. 6.167) radial-thrust bearings can also be used. As these bearings are more sensitive to changes in axial clearances, more exacting requirements are made on the ratio l/d, i. e., $l/d \leq 6–8$. Lower values are used for roller bearings, whereas higher values are used for ball radial-thrust bearings. It is not recommended to apply radial-thrust bearings with a contact angle of $\alpha = 25 - 40°$ according to this diagram.

With the shaft installation according to diagram 2b (Fig. 6.167) the probability of the bearings jamming as a consequence of thermal deformations is lower, because the axial clearance in the bearings increases with shaft length extension. The distance between the bearings can be larger in diagram 2a (Fig. 6.167): for ball radial bearings $l/d = 10–12$, for ball radial-thrust bearings $l/d \leq 10$, and for tapered roller bearings $l/d \leq 8$.

It is not recommended to install longer shafts according to diagram 2b (Fig. 6.167), as large axial clearances can occur due to thermal deformations, which are inadmissible for radial-thrust bearings.

6.11.13 Determination of Forces Loading Bearings

Determination of Radial Reactions

The shaft on the bearings installed one at a time in the support is conditionally considered as a bar on hinged movable supports or as a bar with one hinged movable support and one hinged immovable support. The radial reaction F_r of the bearing is regarded as being applied to the shaft axis at the crossing point of the lines normal to it, drawn through the centers of the contact areas. For radial bearings this point is located in the center of the bearing width. For radial-thrust bearings the distance a between this point and the bearing face can be determined graphically (Fig. 6.168) or analytically as:

- For ball bearings: $a = 0.5[B + 0.5(d + D)\tan\alpha]$
- For tapered roller bearings: $a = 0.5[T + (d + D)e/3]$

where B is the bearing width, T is the mounting height, d is the hole diameter, D is the outer diameter, α is the nominal contact angle, and e is the coefficient of axial loading. The values of the listed parameters are taken from the manufacturer's catalog.

Supporting forces are determined from the equilibrium equation: the total moment of external forces relative to the relevant support and the reaction moment in another support is equal to zero.

In a number of cases, the rotational direction can vary or be uncertain, and the change in rotational direction can result in modification of not only the direction but also the values of the supporting forces. With installation of a joint sleeve on the shaft ends the direction of the force on the shaft due to the the sleeve is unknown. In such cases, the most dangerous situation is considered by the reaction calculation. In order to create favorable working conditions for ball and roller bearings, they must be subject to a certain minimum continuously. This is especially so if they run at high rotational frequencies, in which case the inertial forces of

Table 6.79 Formulas for the calculation of the coefficients X, Y, and e for ball radial and radial-thrust bearings. For single-row bearings with $F_a/F_r \le e$ it is assumed that $X = 1$ and $Y = 0$. In the formulas given in the table C_{0r} is a static load rating of the bearing; for the double-row bearings C_{0r} is a static load rating of a row (half of the static load rating of the double-row bearing)

the solids of revolution and the cage, as well as friction in the lubricant, can negatively influence rolling conditions in the bearing and cause creep of the balls and rollers along the rolling path.

As a general recommendation it is assumed that the loads that affect the roller bearings must be $0.02C$ and those on the ball bearings must be $0.01C$, where C is the dynamic load rating. The weight of the components supported by the bearing with the external forces often exceeds the required minimum load. Otherwise the bearing must be loaded by an extra radial or axial force. It is easier to provide such a force, e.g., in systems with radial and radial-thrust ball bearings, and tapered roller bearings, by means of prior axial loading made by adjustment of the relative position of the inner and outer races with spacing racers, pads, or springs. Extra radial force can be applied in the same way, e.g., by means of increased belt tension.

Determination of Axial Reactions

By the installation of a shaft on two nonadjustable radial ball or radial-thrust bearings the axial force F_a loading the bearing is equal to the external axial force F_A acting on the shaft. The force F_A supports the bearing, which limits the axial displacement of the shaft under the action of this force.

By determination of the axial forces loading adjustable radial-thrust bearings the axial forces that arise under the action of the radial load F_r as a consequence of the tilt of the contact area with respect to the hole axis of the bearing should be taken into account. The values of these forces depend on the bearing class, contact angle, and the radial forces, as well as on how the bearings are adjusted. If the bearings are assembled with a large clearance, only one or two balls or rollers take the whole load. The axial load component equals $F_r \tan\alpha$ for transmission through only one solid of revolution. The working conditions of the bearings are unfavorable with large clearances, so such clearances are not permissible. Bearings are usually adjusted in such a way that the axial clearance is about zero under fixed temperature conditions. In this case, about half of the solids of revolution are under the action of the radial load F_r, and the total axial component for all the loaded

Single-row	1.0	0	0.4	$0.4\cot\alpha$	$1.5\tan\alpha$

solids of revolution is equal to $e' F_r$ as a consequence of the tilt of the contact area and represents a minimum axial force, which must act on the radial-thrust bearing with the set radial force

$$F_{amin} = e' F_r \,, \tag{6.28}$$

where e' is a coefficient of the minimum axial load.

For ball radial-thrust bearings with contact angle $\alpha < 18°$, one has $F_{amin} = e' F_r$. In such bearings the actual contact angle differs from the initial (nominal) one and depends on the radial load F_r and basic static load rating C_{0r}. Thus, the coefficient e' is determined depending on the ratio F_r/C_{0r} from the following formulas:

- For bearings with contact angle $\alpha = 12°$

$$e' = 0.57(F_r/C_{0r})^{0.22} \,.$$

- For bearings with contact angle $\alpha = 15°$

$$e' = 0.58(F_r/C_{0r})^{0.14} \,.$$

- For ball radial-thrust bearings with contact angle $\alpha \geq 18° e' = e$ and $F_{amin} = eF_r$. The values of the coefficient e for axial loading are taken from Table 6.79.
- For tapered roller bearings $e' = 0.83e$ and $F_{amin} = 0.83eF_r$. The values of the coefficient e are taken from Table 6.80 or from the manufacturer's catalog.

In order for normal working conditions to be guaranteed, the axial force loading the bearing must not be lower than the minimum one, $F_a \geq F_{amin}$. This condition must be met for every support.

If $F_a \geq F_{amin}$, more than half or all of the bearing solids of revolution are under load. The support rigidity increases with increasing axial load, which is why in some supports, e.g., for work spindles, assembly with prior interference is applied.

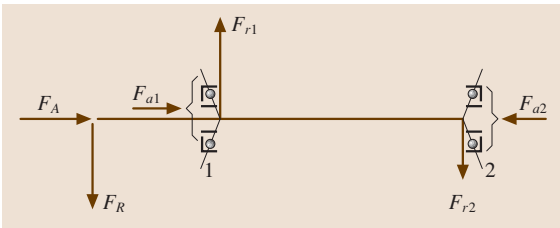

Fig. 6.169 Loading diagram of the shaft and supports with radial-thrust adjustable bearings

Under normal operation of radial-thrust bearings it is necessary that the axial force loading the bearing is above the minimum force in all supports

$$F_{a1} \geq F_{a1\,min} \quad \text{and} \quad F_{a2} \geq F_{a2\,min} \,.$$

Moreover, the equilibrium condition of the shaft must be met, i.e., the sum of all the axial forces acting on the shaft must be zero; for example, for the configuration shown in Fig. 6.169 we have

$$F_A + F_{a1} - F_{a2} = 0 \,.$$

Example of the Determination of Axial Supporting Forces

In the design model represented in Fig. 6.169 it is indicated that F_A and F_R are external axial and radial loads acting on the shaft, F_{r1} and F_{r2} are radial supporting forces, and F_{a1} and F_{a2} are axial supporting forces.

The solution can be obtained from joint satisfaction of three equations:

- From the condition that $F_a \geq F_{amin}$ in every support, and taking into account (6.28), it follows that:

$$F_{a1} \geq e'_1 F_{r1}, \; F_{a2} \geq e'_2 F_{r2} \,.$$

- From the equilibrium condition of the shaft under the action of the axial forces it follows that:

$$F_A + F_{a1} - F_{a2} = 0 \,.$$

The method of attempts is applied, previously assuming that the axial force in one of the supports is equal to the minimum value.

1. Let, for example, $F_{a1} = e'_1 F_{r1}$. Then from the equilibrium condition of the shaft we have

$$F_{a2} = F_A + F_{a1} = F_A + e'_1 F_{r1} \,.$$

   Check the condition fulfillment $F_a \geq F_{amin}$ for the second support. If $F_{a2} \geq e'_2 F_{r2}$, the axial forces F_{a1} and F_{a2} have been determined correctly. If $F_{a2} < e'_2 F_{r2}$ (which is inadmissible), the initial assumption was false. A second attempt should be made.
2. It should be assumed that $F_{a2} = e'_2 F_{r2}$. Then from the equilibrium condition of the shaft we have

$$F_{a1} = F_{a2} - F_A = e'_2 F_{r2} - F_A \,.$$

The condition $F_{a1} \geq e'_1 F_{r1}$ will then certainly be met.

6.11.14 Choice and Calculation of Rolling Bearings

Let us assume that the type and configuration of the bearing installation have been chosen previously. The dimensions of the bearing selected for the application can be chosen on the basis of estimation of its loading rate in accordance with the corresponding acting loads, rotational frequency, required lifetime, and safety. The values of the dynamic and static load ratings are given in the manufacturer's catalog. Calculations on the static and/or dynamic load ratings are now to be performed.

The static load rating is not only used to calculate the parameters for nonrotating bearings or those rotating with low rotational frequencies ($n < 10\,\mathrm{min}^{-1}$), or those performing slow oscillatory rotations, but also for bearings rotating with frequency $n \geq 10\,\mathrm{min}^{-1}$ and those subjected to the action of short-term impact loads or substantial overloads. The static load rating of bearings that run with low rotational frequencies and are designed for a short lifetime are also checked in this way.

Calculations *of the dynamic load rating* (specified lifetime calculation) are performed for the entire load range. Testing is additionally carried out under the assumption of the application of the highest loads.

Calculation of the Static Load Rating of Bearings

A static load rating calculation checks whether the equivalent static load P_{0r} (P_{0a}) on the bearing exceeds the static load rating C_{0r} (C_{0a}) given in the manufacturer's catalog

$$P_{0r} \leq C_{0r} \quad \text{or} \quad P_{0a} \leq C_{0a} \,.$$

The equivalent static radial (or axial P_{0a}) load P_{0r} is a static radial (or axial) load that causes the same contact stress in the most heavily loaded contact zone as in the conditions of actual loading.

The static equivalent radial load for ball radial and radial-thrust, and roller radial-thrust ($\alpha \neq 0°$) bearings is equal to the greater of the two values determined from the expressions

$$P_{0r} = X_0 F_r + Y_0 F_a \,;$$
$$P_{0r} = F_r \,,$$

where F_r and F_a are, respectively, the radial and axial loads on the bearing (N), and X_0 and Y_0 are, respectively, the coefficients of the static radial and static axial loads (Table 6.81).

For roller radial bearings $\alpha = 0°$, which supports only a radial load, $P_{0r} = F_r$. The static equivalent axial load for ball and roller thrust-radial bearings ($\alpha \neq 90°$) is determined from

$$P_{0a} = 2.3 F_r \tan\alpha + F_a \,.$$

For ball and roller thrust bearings ($\alpha = 90°$) one has $P_{0a} = F_a$. For the calculation of the static equivalent radial load for two identical single-row radial ball, radial-thrust ball, and roller bearings installed together on the same shaft positioned with the wide or narrow faces towards one other, making a mutual bearing unit, the values X_0 and Y_0 for double-row bearings are used, and the values F_r and F_a are assumed to form a combined load acting on the whole set.

For the choice and calculation of the bearings it should be borne in mind that the allowable static equivalent load P_0 can be lower than, equal to, or higher than the basic static load rating. The value of this load depends on the requirements of run smoothness (e.g., of

the machines), noise level (for electric motors), constancy of the friction moment (for measuring apparatus and test equipment), or the value of the initial friction under load (for cranes), as well as on the actual geometry of the contact surfaces. The higher the listed requirements, the lower the value of the allowable static equivalent load.

If a high run smoothness is not needed, a short-term increase P_{0r} (P_{0a}) up to $2C_{0r}$ ($2C_{0a}$) is possible. With increased requirements of run smoothness, noise level, and constancy of the friction moment it is recommended that the allowable static equivalent load P_{0r} (P_{0a}) be reduced to C_{0r}/S_0(C_{0a}/S_0). The safety factor $S_0 = 1.5$ for thrust bearings of crane hooks and brackets, $S_0 = 2$ for precise instrumental equipment, and $S_0 = 4$ for important heavily loaded supports and turntables.

Specified Lifetime Calculation of Bearings

The basic data for this calculation are: F_{r1} and F_{r2}, the radial loads (radial reaction) of every support of the double-seat shaft (N); F_A, the external axial force acting on the shaft (N); n, the rotational frequency of the race (as a rule the rotational frequency of the shaft) (min^{-1}); d the diameter of the mounting shaft surface, which is taken from the layout diagram (mm); L'_{sa} and L'_{sah}, the required lifetime during which the probability of bearing operation failure is less than the appropriate probability, in millions of revolutions or hours, respectively; and the loading and operating conditions of the bearing unit (possible overload, working temperature, etc.).

Working conditions of the bearings are rather varied and can differ in terms of short-term overloads, working temperature, rotation of the inner or outer race, etc. The influence of these factors on the bearing efficiency is taken into account by means of the insertion of the equivalent dynamic load into the calculation.

As an equivalent dynamic radial (or axial P_a) load P_r one assumes a constant value that results in the same lifetime under the actual loading conditions.

The equivalent dynamic load is:

- *Radial*, for ball radial and ball or roller radial-thrust bearings

$$P_r = (VXF_r + YF_a)K_{dy}K_t \tag{6.29}$$

- *Radial*, for the roller radial bearings

$$P_r = F_r V K_{dy} K_t \tag{6.30}$$

- *Axial*, for ball and roller thrust bearings

$$P_a = F_a K_{dy} K_t \tag{6.31}$$

- *Axial*, for ball and roller thrust-radial bearings

$$P_a = (XF_r + YF_a)K_{dy}K_t \tag{6.32}$$

Here F_r and F_a are radial and axial loads on the bearing (N), X and Y are coefficients of the radial and axial dynamic loads, V is a coefficient of rotation ($V = 1$ for rotation of the inner race relative to the vector direction of the radial load, or $V = 1.2$ for rotation of the outer race), K_{dy} is a dynamic coefficient (Table 6.85); K_t is a temperature coefficient, its values are assumed depending on the operating temperature t_{oper} of the bearing: For operation under increased temperatures

bearings with a special stabilizing heat treatment or produced from heat-resistant steels are applied. The quality of the operation of the bearing under increased temperatures also depends on whether the lubricant used retains its properties, and on whether the materials of the seal and the retainer are chosen correctly.

The values X and Y depend on the class and structural features of the bearing, as well as on the ratio of the axial and radial loads. The limit value of the ratio F_a/F_r is a coefficient e of the axial loading.

For ball bearings with contact angle $\alpha < 18°$ the values of e are determined from the formulas given in Table 6.79 depending on the ratio $f_0 F_a/C_{0r}$. The values of the coefficient f_0 depending on the geometry of the bearing components and on the stress levels used in the calculation of the basic static radial load rating are given in Table 6.78 for ball radial and radial-thrust bearings.

The values of the coefficients X, Y, and e are assumed according to the data given in Table 6.79 for the

ball radial and radial-thrust bearings, in Table 6.80 for roller radial-thrust bearings ($\alpha \neq 0°$), in Table 6.82 for ball thrust-radial bearings, and in Table 6.84 for roller thrust-radial bearings ($\alpha \neq 90°$).

For bearings running under varying loading conditions, which are set with a load sequence diagram and with the loads corresponding to these rotational frequencies (Fig. 6.170), the equivalent dynamic load is calculated for the varying loading conditions using

$$P_E = \sqrt[3]{\frac{P_1^3 L_1 + P_2^3 L_2 + \ldots + P_n^3 L_n}{L_1 + L_2 + \ldots + L_n}} ,$$

where P_i and L_i are, respectively, the constant equivalent load (radial P_{ri} or axial P_{ai}) in the i-th mode of operation and the period of its action in millions of revolutions. If L_i is set in operating hours (L_{hi}), it is converted to millions of revolutions. Taking into account the rotational frequency n_i (min^{-1})

$$L_i = 60 n_i L_{hi} / 10^6 .$$

If the load on the bearing changes according to a linear law from $P_{\min}$ to $P_{\max}$, the equivalent dynamic load is

$$P_E = (P_{\min} + 2P_{\max})/3 .$$

It is known that the rates of machines with a varying load can be classified into six typical loading conditions (Sect. 6.2.8): 0 (constant), I (heavy), II (average equiprobable), III (average normal), IV (easy), and V (especially easy).

For bearings of shaft supports for toothed and worm gears running under typical loading conditions it is convenient to perform calculations with the help of the equivalence coefficient K_E:

Mode of operation	K_E
0	1.0
I	0.8
II	0.63
III	0.56
IV	0.5
V	0.4

The equivalent loads are calculated by means of the known maximum long-term forces $F_{r1\,max}$, $F_{r2\,max}$, and $F_{A\,max}$ (corresponding to the maximum value of the long-term acting torques)

$$F_{r1} = K_E F_{r1\,max} , \quad F_{r2} = K_E F_{r2\,max} ,$$
$$F_A = K_E F_{A\,max} ,$$

according to which the bearing calculation is performed as though under constant load.

Matching of the rolling bearings is carried out in the following order:

1. The class and installation diagram of the bearing is set in advance.
2. For the appointed bearing the following data are written down from the manufacturer's catalog:
   – The values of the basic dynamic C_r and static C_{0r} radial load ratings for ball radial and radial-thrust bearings with contact angle $\alpha < 18°$; the main geometry: hole diameter d, outer diameter D, ball diameter D_w.

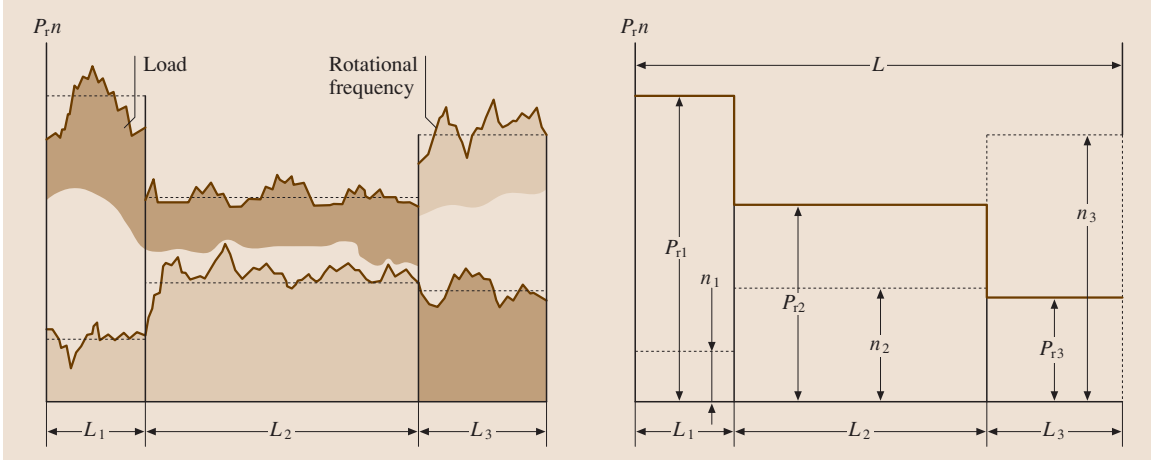

Fig. 6.170 Approximation of loads and rotational frequencies

- The value C_r for ball radial-thrust bearings with contact angle $\alpha \geq 18°$, and the values of the coefficients of the X radial, Y axial loads, the coefficient e of the axial loading from Table 6.79.
- The values C_r, Y, and e for tapered roller single-row bearings; $X = 0.4$ is also assumed (Table 6.80).

3. The axial forces F_{a1} and F_{a2} are determined from the equilibrium condition of the shaft and that of the minimum level of the axial loads on radial-thrust bearings.
4. For ball radial bearings, as well as for ball radial-thrust bearings with contact angle $\alpha < 18°$ the values X, Y, and e are determined according to Table 6.79, depending on the ratio $f_0 F_a / C_{0r}$. The values of the coefficient f_0 are given in Table 6.78 depending on the ratio $D_w \cos\alpha / D_{pw}$, where D_w is the ball diameter, α is the contact angle (for radial bearings $\alpha = 0°$), D_{pw} is the circle diameter of the center ball position: $D_{pw} = (d + D)/2$. In the absence of tabulated values the ball diameter can be calculated according to the height of *the effective cross-section* $H = (D - d)/2$:
   - For bearings from series 200, 300, and 400 for $d \leq 40$ mm for the *especially easy* series $D_w = 0.6H$.
   - For bearings from series 200, 300, and 400 for $d > 40$ mm $D_w = 0.635H$.
   - For compact and high-speed bearings $D_w = 0.55H$.
   - For bearings of increased load rating $D_w = 0.64H$.
5. The ratio F_a/F_r is compared with the coefficient e, and the values of the coefficients X and Y are finally assumed: for $F_a/F_r \leq e$ it is assumed that $X = 1$ and $Y = 0$, for $F_a/F_r > e$ for ball radial and radial-thrust, and roller bearings the earlier (under points 2 and 4) values of the coefficients X and Y are finally assumed.
6. The equivalent dynamic load is calculated ((6.29)–(6.32)).
7. The design lifetime of the bearing, which has been corrected according to the safety level and use conditions, is determined (h)

$$L_{sah} = a_1 a_{23} \left(\frac{C}{P}\right)^k \frac{10^6}{60n},$$

where C is a basic dynamic load rating of the bearing (radial C_r or axial C_a) (N), P is an equivalent dynamic load (radial P_r or axial P_a, and under varying loading conditions P_{Er} or P_{Ea}) (N), k is an exponent that takes on the value $k = 3$ for ball bearings and $k = 10/3$ for roller bearings, n is the rotational frequency of the race (min^{-1}), a_1 is the coefficient adjusting the lifetime depending on the required safety (Table 6.41), and a_{23} is a coefficient adjusting the lifetime depending on special properties of the bearing, which it obtains, e.g., as a consequence of the application of special materials or special production processes or special structure, as well as its working conditions (conformity of the lubricant characteristics with the required ones, the presence of the foreign particles causing behavioral changes of the material).

The basic design lifetime is confirmed based on the test results of the bearings on special machines and in certain conditions characterized by the presence of a hydrodynamic oil film between the contact surfaces of the races and the solids of revolution and by the absence of increased warp of the bearing races. Under real operating conditions deviations from these conditions are possible, which are approximately estimated by using the coefficient a_{23} (Table 6.40).

With the choice of the coefficient a_{23} the following use conditions of the bearing are distinguished:

a) Common (material of usual fusion, presence of the race warps, absence of a safe hydrodynamic oil film, and presence of foreign particles)
b) The presence of the elastic hydrodynamic oil film in the contact between the races and the solids of revolution, the absence of increased warps in the unit; standard production steel.
c) The same as in item (b), but the races and the solids of revolution are manufactured from steel of electroslag or vacuum-arc refining.

Design formulas for lifetime are correct for rotational frequencies over $10\,\text{min}^{-1}$ to the limit frequencies according to the manufacturer's catalog, and also if P_r (or P_a), and with varying loads $P_{r\,max}$ (or $P_{a\,max}$) does not exceed $0.5C_r$ (or $0.5C_a$).

In some cases, the allowable load P_r (or P_a) is determined from the formula for the lifetime calculation. For bearings running with low rotational frequencies and those intended for a short lifetime the allowable load calculated in such a way can exceed the static load rating, which is inadmissible. Thus, adaptability of the formulas is restricted by the condition $P_r \leq C_{0r}$ (or $P_a \leq C_{0a}$).

8. The fitness of the planned dimension type of the bearing is estimated. The bearing is suitable if the design lifetime L_{sah} is more than or equal to the

required one

$$L_{sah} \geq L'_{sah} \, .$$

In some cases, two identical radial or radial-thrust single-row bearings are installed together in one support. If the bearings are manufactured precisely and assembled so that they run as a unit, this pair is considered as one double-row bearing. For the lifetime determination from the formula of item (7) the basic dynamic radial load rating $C_{r\,sum}$ of the set of two bearings is substituted for C_r, taking the value $C_{r\,sum} = 1.625C_r$ for ball bearings and $C_{r\,sum} = 1.714C_r$ for roller bearings. The basic static radial load rating of this set is equal to twice the nominal load rating of a single-row bearing $C_{0r\,sum} = 2C_{0r}$.

For the determination of the equivalent load P_r the values of the coefficients X and Y are assumed as for double-row bearings: for ball bearings according to Table 6.79; for roller bearings according to Table 6.80.

If the bearing unit comprises two self-contained bearings, which are substituted independently of each other, these premises are not applicable.

The recommended values of the bearing lifetime of different machines and equipment are given in Table 6.87.

6.11.15 Fits of Bearing Races

Bearing races can be classified into the following categories: local, circulating, and oscillatory.

Local loading applies when when the resulting radial load acting on the bearing is always supported by the same limited section of the rolling path of the race and is transmitted to a corresponding part of the mounting surface of the shaft or the casing.

Circulating loading applies when the resulting radial load acting on the bearing is supported and transmitted through the solids of revolution to the rolling path in a rotational process in sequence along its whole length and, therefore, along the whole mounting surface of the shaft or the case.

Oscillatory loading applies when the fixed race of a bearing is subjected to the influence of the resulting radial load, which therefore performs periodic oscillatory motion.

For circulating loading the connection of the races with the shaft or the case should be made through interference, which prevents turning and running of the mated component with the race and consequently beading of the mounting surfaces, contact corrosion, galling, decrease of rotational accuracy, and imbalance.

Under local loading, fits that allow small clearance are used. Running of the components mated with the races does not occur under such loading, and casual turning of the nonrotary race is useful, as the position of its loading zone changes. Furthermore, this mating facilitates axial displacements of the races in assembly, clearance adjustment in the bearings, and thermal deformations.

Races under oscillatory loading and with clearance of the mated component also exhibit relative motion, as in the case of circulating loading. Displacement occurs only over a certain surface area. This also causes contact corrosion and wear, which is why races subjected to oscillatory loading are installed using interference.

Bearing fits can differ from standard fits in terms of the position and the values of the tolerance ranges for the mating surfaces of the races. The required fits in the connections of rolling bearings are obtained by setting the appropriate tolerance ranges for the shaft diameters and the holes in the case. Figure 6.171 shows the position of the most commonly used tolerance ranges relative to the bearing hole and its outer surface. One peculiarity consists of the fact that the tolerance range for the hole diameter in rolling bearings is not positioned from the zero line (not *on the positive side*), but down (*on the negative side*). In this way interferences are guaranteed in the connections of the inner race with the shafts, with the tolerance ranges k, m, and n. The tolerance range for the diameter of the outer race is positioned as usual *on the negative side* or *in the component body*.

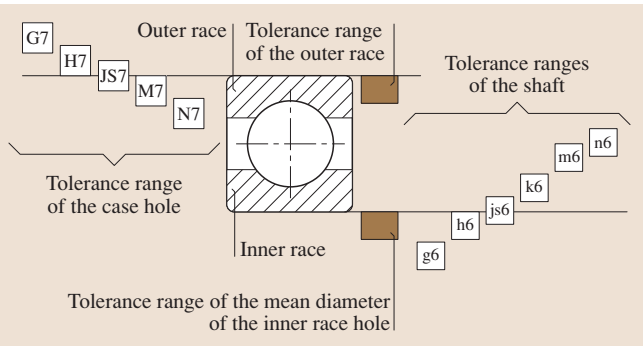

Fig. 6.171 Position of the tolerance ranges relative to the hole of the bearing and its outer surface

The value of the equivalent dynamic load P also influences the choice of the fit. In accordance with this we have the following loading conditions

$$\begin{aligned} &\text{Light :} && P \le 0.07C \\ &\text{Normal :} && 0.07C < P \le 0.15C \\ &\text{Heavy :} && P > 0.15C \end{aligned}$$

where C is the dynamic load rating of the bearing. The heavier the conditions, the tighter the fit. As a rule, roller bearings run under high loads, so the fits of roller bearings are tighter than those of ball bearings. In Russia the fits of the races on the shaft and in the case are determined according to the recommendations of [6.89]. The fit is often chosen by an analog method to obtain analogous long-working checked components similar in structure, function, and operating conditions.

6.12 Design of Bearing Units

6.12.1 Clearances and Preloads in Bearings and Adjustment of Bearings

General radial or axial displacement of one race of bearings relative to another is considered a radial or axial clearance. The optimal values of the radial and axial clearances for given operating conditions of the bearing allow for efficient load distribution between the solids of revolution, and between the required displacement of the shaft and the case in the radial and axial directions, as well as improve and increase the vibroacoustic stability and reduce friction losses.

In nonadjustable bearings classes there are three kinds of radial clearances: initial, setting, and operating. The setting clearance is always less than the initial one because of race deformations in the radial direction after installation of the bearing at the work site. During operation of the bearing unit and under steady temperature conditions the operating clearance forms, which can be more or less than the set value depending on the installation configuration of the bearings, taking into account the load and temperature differences applied to the shaft and case.

In Russia, in accordance with [6.114], values of the radial and axial clearances for a rolling bearing as delivered, and reference designations of the clearance groups *normal and additional* (with lower or higher clearance values) are specified.

Nonadjustable bearing classes are produced with comparatively small clearances after installation on the shaft when they can run without additional adjustment.

Table 6.88 provides the dimensions of the radial clearances for ball radial single-row bearings with a cylindrical hole as an example.

Bearings intended for regular operating conditions (temperature difference between the outer and inner races of 5–10 °C, temperature of the inner race usually higher than the temperature of the outer one) should have a clearance corresponding to the basic, normal group.

The application field of bearings with increased clearances is supports with substantial operating temperature fluctuations, as well as supports where the races of the bearing are assembled on the shaft, and the case with considerable fit interference, because of the expected high dynamic loads, or supports where warps of the inner races relative to the outer races are possible as a consequence of manufacturing errors, assembly, or insufficient shaft rigidity. Radial single-row ball bearings being loaded only with axial forces should also have increased radial clearance, which allows the contact angle in the bearing to be increased, i. e., its axial load rating increased. Radial non-self-installed bearings with increased radial clearance are also used under deviation from slots coaxiality.

Bearings with a cut clearance are installed in supports with high requirements for the radial or axial runout of shafts operating with moderate rotational frequency with efficient cooling, as well as in supports where greater heating of the outer races than of the inner ones is expected as a consequence of particular heat sources.

The axial and radial clearances of adjustable bearings can be fixed in certain ranges only by assembly in the machine unit. The required axial clearance in thrust bearings is settled the same way as for assembly.

The optimal value of the clearances is fixed experimentally for each particular unit. If the bearings are assembled with a large clearance, then the whole load is taken by one or two balls or rollers (Fig. 6.172a). The working conditions of bearings with large clearances are not favorable, which is why these clearances are not admissible. A decrease in clearances results in a more even load distribution between the solids of revolution, reduces vibrations, and increases rigidity of the support. The presence of some axial clearances positively influences the reduction of the antitorque moment. Standard radial-thrust bearings are adjusted in such a way that the axial clearance is about zero under steady tem-

perature conditions. In this case, about one-half of the solids of revolution are under the action of the radial load (Fig. 6.172b).

In some units, e.g., in the machine tool industry, assembly of the bearings with a preload is used to increase support rigidity and the rotational accuracy of the shaft, and to improve the vibroacoustic feature of the unit. In this case, more than one-half or all the solids of revolution of the bearing are under loading (Fig. 6.172c).

The nature of the preload consists in the fact that a pair of bearings has previously been loaded by the axial force, which removes the axial clearance in the set making an initial resiliency at the contact points of the working surfaces of the races with the solids of revolution. If the working axial force is then applied to the bearing, the relative displacement of its races will be lower, as a consequence of the extra deformation of the working surfaces, than before the preload. The preload causes an identical deformation in both bearings. With too great an interference the bearings run under hard usage, as the loads on the solids of revolution, antitorque moment, and wear increase, and the bearing lifetime is therefore reduced.

The influence of the clearance interferences on the lifetime L is shown in Fig. 6.173.

Ball radial, radial-thrust, and roller tapered bearings are installed with a preload. This is also so with bearings with short cylindrical rollers mountable on a conic shaft journal with interference, which is able to cause an extension of the inner race and completely remove radial clearance in the bearing.

The recommended axial clearances for single-row radial-thrust ball and roller tapered bearings are given in Tables 6.89 and 6.90, respectively. The values in these tables correspond to the standard operating conditions, when the temperature of the inner races of the bearings does not exceed that of the outer races by more than 10 °C, and the differential temperature of the shaft and the case amounts to ≈ 10–20 °C.

By assembling the bearing with a flare for a conical shaft journal the initial radial clearance decreases as a consequence of the extension of the inner race. The axial displacement of the inner race with a hole having a taper of 1:12 relative to the shaft journal or the clamping sleeve causes a reduction of the initial radial clearance, being approximately 1/15 of the displacement value.

Adjusting Methods

Adjustment is the installation of the inner clearance in the bearing or installation of the preload in the bearing unit. The radial and axial clearances in the bearing are mutually dependent. With a clearance change in one direction (e.g., in the axial direction) the clearance also changes in the other (radial) direction. The clearances in the bearings are made and changed on assembly of

the product most often by means of axial displacement of the outer and inner races or (rarely) by means of radial deformation of the inner race by its fit onto the cylindrical or bevel surface of the shaft.

A radial preload is usually used in roller bearings with cylindrical rollers, double-row radial-thrust ball bearings, and sometimes in radial ball bearings. For example, the preload is applied with the help of the interference fit of a sufficient size of one or two races of the bearing, where the initial radial inside clearance in the bearing decreases to zero. As a result in operation the clearance becomes negative, i. e., a preload appears. Bearings with a flare are the most convenient for applying a radial preload, as the force of the preload can be adjusted rather exactly by moving the bearing along its bevel mounting surface (on the shaft journal, clamping sleeve, or tightening bushing).

The axial force of the preload required for single-row radial-thrust ball bearings, tapered roller bearings, and radial ball bearings is made by means of the displacement of one of the races relative to the other along the axis by a distance corresponding to the required force of the preload.

Two fundamentally different main adjusting methods are applied: individual and combined adjustment.

With individual adjustment each bearing unit is regulated separately with the help of nuts, washers, spacing, deformable sleeves, etc.; changing and checking allow the nominal value of the preload force to be maintained with the lowest possible deviations. The following measuring procedures of the preload are used:

- According to displacement, which is determined by means of the component measurement of the bearing unit, taking into account the thermal expansion of the components in operation and a certain force loss of the preload during some operation time, i. e., taking into account the resiliency in the system.
- According to the frictional moment with the use of the known ratio between the bearing load and frictional moment in it. This method is universal, requires little time, and can be easily automatized.
- According to the directly measured force, which can be made or changed by adjustment.

In practice, the first two methods are used more often due to their simplicity and availability.

For combined adjustment all of the components of the bearing unit must be completely interchangeable, which in the end results in a tightening of their dimensional tolerances.

The advantage of individual adjustment is that single unit components can be manufactured according to free tolerances (e.g., corresponding to the 9th–14th accuracy degree) and the preload is applied with a comparatively high degree of accuracy.

6.12.2 Principal Recommendations Concerning Design, Assembly, and Diagnostics of Bearing Units

Design Recommendations

The design of a product should be adapted for convenient assembly, and precise installation and dismantling of the bearing units.

The mounting surfaces of shafts and cases should have hollow chamfers or contact lead-ins with a small taper angle to guarantee precise prior centering, decrease shearing and bearing microasperity, and a smooth insertion force increase with assembly.

The hollow chamfer radii of the shafts and the cases at the mounting sites must provide a reliable fit of the race face to the supporting shoulder surface of the shaft or the case. It is also necessary that perpendicularity of the supporting shoulder surface of the shaft or the case to the common axis be ensured.

The race of the bearing cannot be installed with interference, but should be applied without a thrust block into the mated component, otherwise the runout of the face appearing in the pressing process may substantially exceed the allowable values. Shoulders or spacer rings of insufficient height cannot be used. In Russia the shoulder dimensions must conform to the [6.113].

The dimensions of the elements of the shaft and the case mated with the bearings must guarantee reliable support of the bearing races when subjected to axial forces and the possibility of using a press or mechanical removers that grab the extension of the race above the shaft shoulder or the case hole to dismantle them must be available.

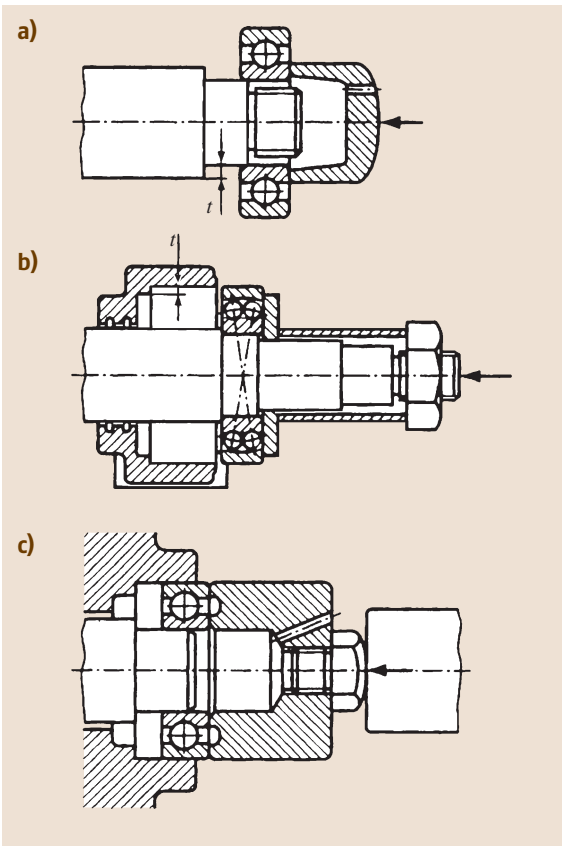

Fig. 6.174a–c Installation of the bearings **(a)** onto the shaft, **(b)** into the case, **(c)** simultaneously onto the shaft and into the case

Assembly and Dismantling of Bearings

Upon installation (or dismantling) of the bearings on the shaft and into the case the condition that the axial force must be applied directly to the race that is being built up (or dismounted) must be met. The force must not be transmitted through the solids of revolution (balls and rollers) upon assembly and dismantling of the bearing. Otherwise, hollows may appear on the rolling paths and solids of revolution. It is impossible to apply the assembly forces to the cage.

Figure 6.174 shows some installation methods of the bearings on the shaft (Fig. 6.174a), into the case (Fig. 6.174b), and simultaneously on the shaft and the case (Fig. 6.174c). The bearing races have low rigidity. For correct installation the race should be inserted up to the stop in the shoulder. The height t of the shoulders on the shafts and in the holes of the cases or the sleeves (Figs. 6.174 and 6.175) defines the dimension r of the race bevel. The shoulder height must form a sufficient supporting surface for the faces of the bearing races. The minimum height t of the shoulders is assumed as:

Table 6.91 Recommended minimum height t of the shoulders

r (mm)	t (mm)
0.5	1.0
1.0	1.8
1.5	2.5
2.0	3.0
2.5	4.0
3.0	4.8
3.5	5.5
4.0	6.5

The shoulder height is usually assumed to be equal to half of the race width. The holes in the assembly sleeves (Fig. 6.174a,c) are intended for the outlet of air from the inner hollow of the sleeve by the bearing insertion on the shaft.

For the assembly of bearings, mechanical erection tools (spanners, impact, socket wrenches), and hydraulic (hydraulic nuts, thrusts) or heating (inductive, electric ovens with thermostat, oil reservoir) units can be used as well as presses.

Figure 6.176 shows an installation diagram for a bearing with a conical hole on the shaft using hy-

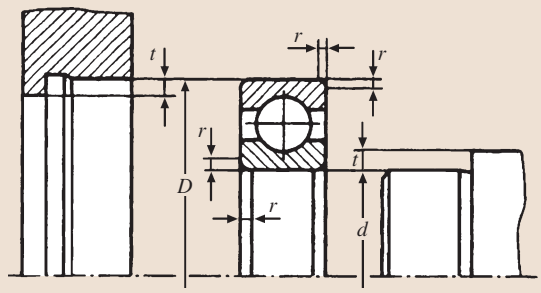

Fig. 6.175 Determination of the collar height

draulic thrust. Oil under pressure is supplied with a plunger pump through the hole into the shaft groove under the inner race, which is burst opened. By means of rotation of the nut the bearing is moved in the axial direction to the installation site. Bearings with a cylindrical hole are mounted in the same way. However, for assembly of a bearing on a cylindrical area they are necessarily inserted up to the stop in the shaft shoulder.

It is evident from this figure that, on assembly of bearing with hydraulic thrust, the following must be considered in the shaft structure: a threaded section for the nut, a threaded hole for the connecting pipe of the oil-duct (M6 by $d \leq 100$ mm), a hole ⌀2.5 mm, and a groove (width 3 mm, depth 0.5 mm) for the oil supply.

For assembly of bearings of the open *class* with a cylindrical hole on the shaft with interference it is advisable that the bearing be heated first. The required differential temperature Δt between the bearing race and the shaft or the case depends on the interference value of the fit and on the bore diameter of the race. The

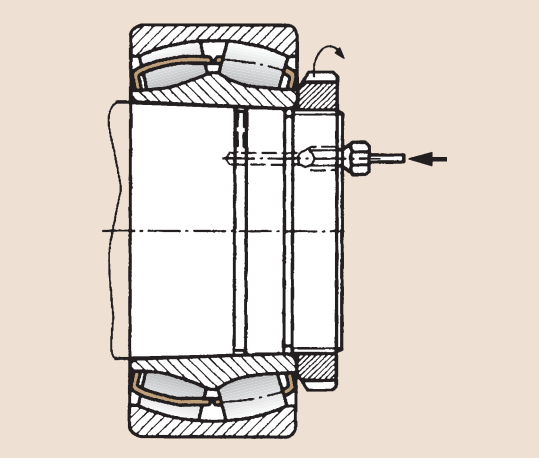

Fig. 6.176 Installation of the bearing using hydraulic thrust

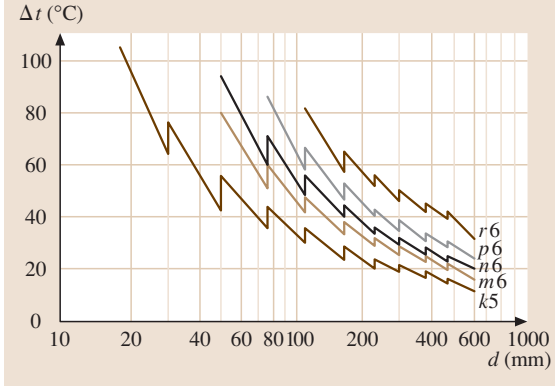

Fig. 6.177 Approximate values of the differential temperature Δt between the bearing race and the shaft for the most commonly used tolerance ranges depending on the inner diameter d

approximate values of the differential temperature Δt for the most widely used tolerance ranges depending on the hole diameter d can be determined from Fig. 6.177. It is inadmissible to heat the bearings to a temperature above 125 °C, as otherwise changes of the material structure of the bearing may occur.

Uniform heating can be achieved with the help of electric heat boosters, heating furnaces, and oil reservoirs. In the latter case, the bearing is dipped into the reservoir with clean mineral oil, which has a high flash point, heated, e.g., up to 80–90 °C and held for 10–15 min. For assembly of bearings with safety washers and permanently laid lubricant heating is carried out in a thermostat.

For bearing installation into the case with interference it is recommended that the bearing be cooled previously to a temperature of −70 to −75 °C in a thermostat by using dry ice or to heat the case to 20–50 °C higher than the temperature of the bearing.

For dismantling of small ($d < 80$ mm) and average ($d = 80$–200 mm) bearings *spiral removers* are used: with two (Fig. 6.178a) or three folding rods (Fig. 6.178b,c) (the maximum dismantling force is 6–50 kN, and with a hydraulic booster up to 80 kN).

The remover in (Fig. 6.178c) also allows the use of two rods for dismantling, which are mounted in two large bosses. The installation sites of the bearings must be physically designed in such a way to that the removers can be operated with convenience.

When being removed from the case, the bearing must be grabbed by the outer race (Fig. 6.179a, and by dismounting off the shaft, by the inner race Fig. 6.179b).

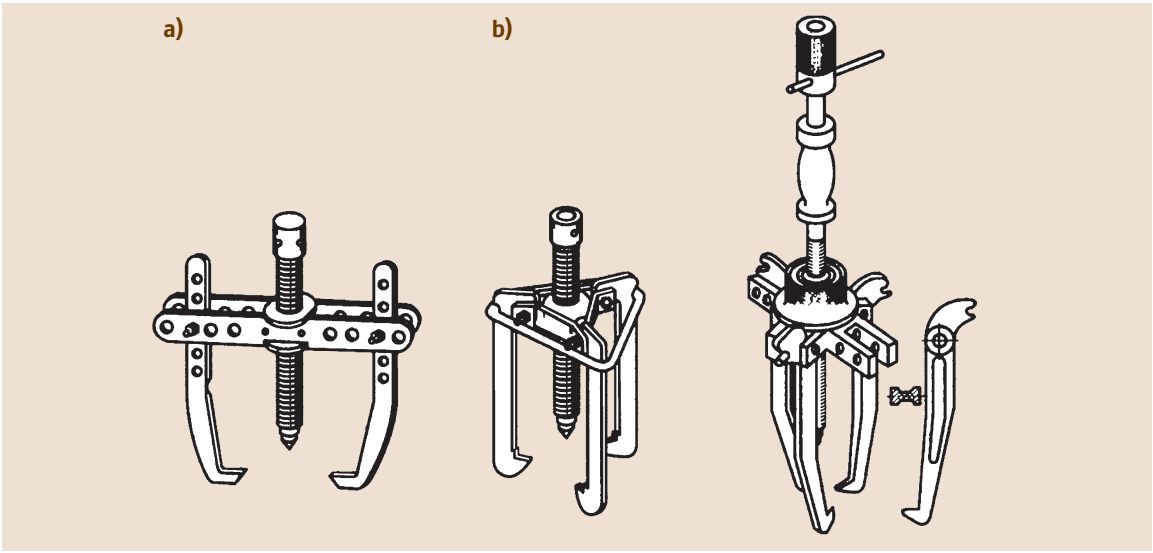

Fig. 6.178a,b Screw removers with (a) two and (b) three rods

In order for the bearing race to be grasped by the rods, the height of the remover t of the shoulder (Fig. 6.179a) must not be too high. The minimum dimension of the t_1 inner face and t_2 outer face extension of the bearing race intended for dismantling is as follows:

Table 6.92 Recommended minimum dimensions, t_1 – inner face and t_2 – outer face

Shaft diameter (mm)	$t_1 = t_2$ (mm)
< 15	1
15–50	2
> 50–100	3.5

With high shoulders it is necessary to foresee grooves for the position of the remover rods (Fig. 6.179b – a remote element A).

For location of the remover rods (Fig. 6.179a) a free space $a \approx (0.4–0.5)C$ is included, where C is the width of the bearing race on removal of the outer race from the blind hole.

Diagnostics of the rolling bearing state during operation and planning of their maintenance is gaining increasing importance. If damage of the bearings can be determined in the initial stage, they can be replaced in time by carrying out a scheduled repair of the machine, and thus extraordinary machine lockup can be prevented.

For estimation of the current status of the running bearing units without lockup and dismantling of the product, and for timely detection of the first features of beginning fracture (flaking on the working surfaces of the races and the solids of revolution) various systems and devices are used; most of them are based on the measurement and analysis of vibrations.

However, in practice not all machines or machine units are controlled by means of modern devices. The machine operator must pay attention to the indirect features of possible damage, e.g., increased noise, temperature, or vibration of the bearing units.

Noise control. The most common method of assessing the status of bearings is listening. With the help of an ascultoscope (most commonly, by means of a wooden stick) increased noise can be detected, and the experienced operator can determine its source. In a faultless state the bearings generate a quiet buzzing noise. Clattering, hissing, or any unusual noise indicates improper status of the bearings.

Temperature control. The integrated indicator of the quality and work stability of the bearing unit is its temperature. Increased temperature indicates abnormal operation of the bearing and, moreover, has a negative influence on the lubricant characteristics and its intake into the bearing. Continuous running at a temperature over 125 °C can result in a decrease in the lifetime of the bearing.

The reason for the higher temperature or its constant change can be insufficient lubrication and excess lubrication, increased loads, lubricant contamination, too little clearance in the bearing, excessive interference, in-

creased frictional moment as a consequence of higher mutual race warp, low-quality manufacture of the mating components, or heightened friction in the seals.

6.12.3 Design of Bearing Units

Figure 6.167 shows the main diagrams for axial shaft fixation. It is more convenient to consider the designs of the bearing units for each diagram separately for the fixing support and the floating support.

Fixing Support in Diagram 1a (Fig. 6.167)

With the axial fixing of the shafts according to diagram 1a, the bearing classes shown in Fig. 6.180 are used in the fixing supports.

Fastening of the Bearings on the Shafts

Figure 6.181 shows methods of fastening bearings on the shaft, which are applied with shaft loading with a substantial axial force in both directions.

Reliable fastening of the bearing is carried out with a round slotted nut (Fig. 6.181a), which is stopped from spontaneous breakout with a multitab washer. The retainer has one inner jut and six outer jut tabs. The inner jut of the washer gets to a specially made groove on the shaft, and one of its outer juts is turned back into the slot of the washer.

Fastening with an end plate is simple and reliable (Fig. 6.181b). In this case, the pin fixes the washer from turning relative to the shaft. So that the end plates do not cause unbalance under high rotational frequencies, they

are centered according to the bearing hole (Fig. 6.181c) or to the shaft (Fig. 6.181d). In all variants it is necessary to consider stopping of the screws, which fix the washer to the shaft face, from self-unfastening. In Fig. 6.181b,c stopping of the screw is carried out by means of a retainer with a toe, and in Fig. 6.181d by means of a deformable washer, installed under both screws at once. The ends of the washer are turned back on the panes of the screw heads.

Fastening of the bearings with a spring thrust planar outer ring is finding increasing application (Fig. 6.182c).

The races of the rolling bearings are manufactured in width b (Fig. 6.182a) with rather great deviations. Thus with a hole diameter of over 30–50 mm the width tolerance is 0.12 mm, and with a diameter of over 50–80 mm it is 0.15 mm. The shaft dimension e performs with approximately the same accuracy. The thickness of the spring ring s has a tolerance of 0.12 mm. The clearance z between the thrust ring and the bearing is $z = e - s - b$.

The presence of the clearance z, which can vary in range from 0 to 0.3 mm for bearings with a hole diameter, e.g., over 50–80 mm, is a disadvantage of the given fastening. To avoid this effect, it is advisable to install a compensatory ring (2) between the bearing and the spring thrust ring (1) (Fig. 6.182b). The clearance is minimized by means of matching of this ring according to the thickness or extra machining in compliance with measuring results during assembly.

The ends of special tongs, with which the rings are opened, are placed into the holes of the spring rings (Fig. 6.182b) on their removal from the shaft. The thickness of the spring rings is small, so the tongs do not

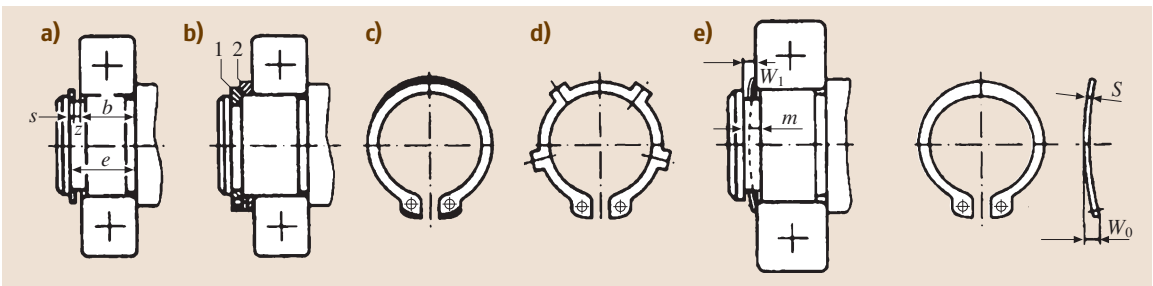

Fig. 6.182a–e Fastening of the bearing with a spring ring. **(a–c)** Planar, **(d)** tab, **(e)** bent

penetrate the hole very deeply and often come off. In order to avoid this, the groove is milled on the ring face (2) (Fig. 6.182b).

It should be borne in mind that the spring thrust ring projects lightly above the shaft surface. Thus, the eccentric ring overlaps a chamfer of the bearing only on a small surface (shaded area in Fig. 6.182c). On the greater part of the circle the spring planar ring does not touch the race face of the bearing at all, which is why the compensatory ring not only decreases the axial clearance, but also improves the contact of the bearing with the spring ring.

The firm SEEGER (Germany) and others use tab spring rings (Fig. 6.182d), which make contact with the race of the bearing at six points. The same firms apply bent spring thrust bearings for tightening of the bearings to the face of the shaft shoulder (Fig. 6.182e) that exclude application of other compensators. Compensative abilities of such rings are characterized by the following data (mm):

Table 6.93 Main parameters of the bent spring rings

d (mm)	40 – 100
s (mm)	1.75 – 3.0
m (mm)	3.4 – 6.3
W_0 (mm)	3.5 – 6.9
W_1 (mm)	$2.1^{+1.2} - 3.3^{+2.4}$

It should be taken into account that spring thrust planar rings can transmit considerable axial forces. Thus, for example, the allowable axial force for the spring thrust planar ring amounts to 17.1 kN with a shaft diameter of 30 mm.

Making of the Thrust Collars on the Shaft

A structural peculiarity of the rolling bearing is the fact that its inner race is a rather compliant component. The inner race has to be tightened by assembly to the shaft collar or the face of the component, which is mounted on the shaft, to be installed precisely on the shaft without warp. The race of the bearing must fit to the thrust collar with its flat face. On the one hand, the height of the shaft collar must be higher than the coordinate of the bearing chamfer, while on the other hand, it must be chosen taking into account the possibility of removal of the bearing from the shaft. The required information concerning the height of the shaft collar is given above.

If, for some reason, a shaft collar of the required height cannot be made, then one of the following variants is used:

- The spacing washer of the required height is mounted between the shaft collar and the bearing race (Fig. 6.183a).
- The collar is made by means of installation of the spring thrust planar ring into the shaft groove (Fig. 6.183b).
- The extra ring (1) is mounted, which improves contact of the bearing with the spring ring (Fig. 6.183c).
- Two half-washers of hooked type or of rectangular cross-section are installed in the groove on the shaft, which the inner race of the bearing (Fig. 6.183d),

the spring ring (Fig. 6.183e), and the nondetachable ring 2 (Fig. 6.183f,g) prevent from falling out.

Fastening of the Bearings in the Case

Figure 6.184 shows the most frequently used methods for fastening the bearings in the case. A simple and reliable method of fastening the bearing in the case *with a cap* is widely used, either clamped (Fig. 6.184a) or inserted (Fig. 6.184b). It is simpler to fix bearings that have a groove for the thrust ring on the outer race of the bearing. The spring thrust planar ring (Fig. 6.184c) or two half-washers (Fig. 6.184g) are installed into the groove and fastened on the case with screws. The advantage of these methods is the fact that the hole of the case does not have a ledge to complicate its machining.

In (Fig. 6.184d) the bearing is fixed with a spring thrust planar ring (1). To fasten the race of the bearing in the case without clearance the compensatory ring K is sometimes installed between the thrust ring and the bearing. To improve contact with the bearing, race tab spring rings are used (Fig. 6.184e). A compensator is not needed to fasten the bearing with a spring bent retaining ring (Fig. 6.184f), which tightens the outer bearing race to the case collar.

Figure 6.184h shows fastening of the bearing with the help of three set screws and a ring (1). To apply this method it is necessary to have the possibility to position three screws evenly along the case circle. The lock ring (2) prevents the screws from self-unfastening.

In lightly loaded supports fastening is done with the help of plates with adjustable ends in the absence of axial forces (Fig. 6.184i). Two plates are usually installed at 180° along the circle. The plates are placed into the axial grooves on the mounting hole of the case. The ends of the plates are bent in pairs onto the case and the outer race of the bearing.

All of these fastening means for the bearing in the case are more or less equivalent.

Making of the Thrust Collar in the Case

For precise installation the outer races of the bearings are tightened to the collar of the housing part. According to Fig. 6.185a the thrust collar is made directly in the case. However, the presence of a ledge in the hole of the housing part presents certain problems with hole boring. Hole machining of the housing part can be simplified by making a collar in the sleeve (Fig. 6.185b). However, incorporation of an additional laborious and precise component – a sleeve – can be avowed only in the case that the sleeve helps to solve another design problem, e.g., simplification of assembly or making of the free-standing assembly unit.

Execution of the collar by means of erection of a spring thrust planar inner ring (Fig. 6.185c) is easier. It should be taken into account that the spring rings can transmit substantial axial forces. Thus, e.g., the allowable axial force for the spring thrust planar ring becomes 74.7 kN with a hole diameter of 62 mm.

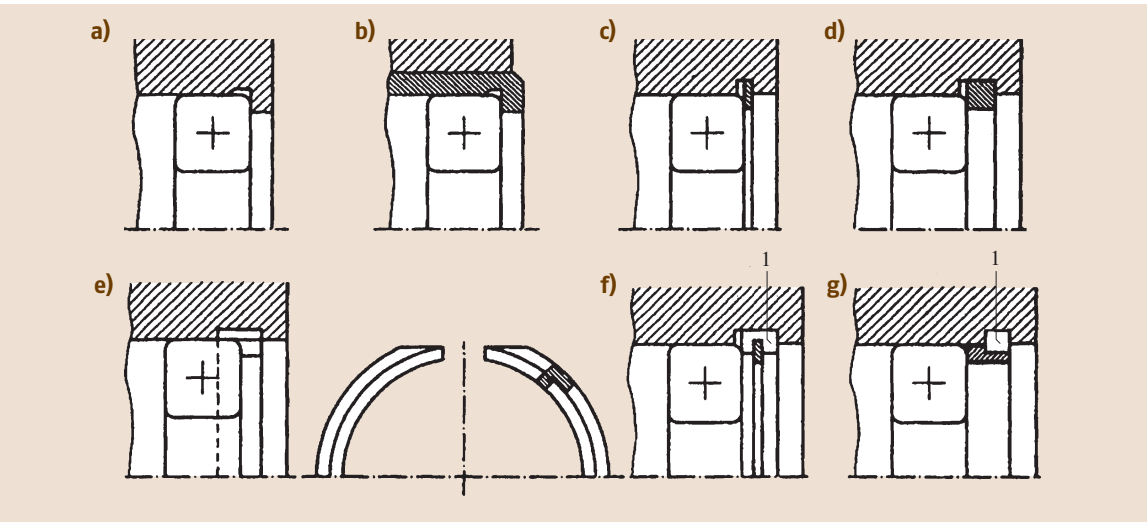

Fig. 6.185a–g Methods of making the collars in the case. **(a)** With a shoulder in the case, **(b)** with a shoulder in the sleeve, **(c)** with a planar spring ring, **(d)** with an unbroken ring in a split frame, **(e)** with two semirings of L-type section, **(f)** two semirings secured with a spring ring, **(g)** with a one-piece L-type ring

In the case with a split along the shaft axis the thrust collar can be made with *an unbroken ring*, which is put into the groove of the case hole (Fig. 6.185d).

In Fig. 6.185e the thrust collar is made with *two semirings* of hooked-type cross section. Semirings are placed into the groove of the case hole. The chamfers on the semirings enable their installation into the hole groove of a one-piece case. The outer race of the bearing prevents the semirings from falling out. The collar shown in Fig. 6.185f is made with two semirings, which are prevented from falling out of the case groove by a spring thrust ring. Two semirings forming a thrust collar in the variant illustrated in Fig. 6.185g are kept from falling out by the one-piece ring of hooked-type cross section. All the thrust collars made according to Fig. 6.185 are able to support substantial axial forces and can be used with any of the fastening means of the bearings shown in Fig. 6.184.

Adjustment of Axial Clearances in Bearings

When a shaft fixing in a support with one bearing (diagram 1a in Fig. 6.167) adjustment is not carried out. The axial clearance is made when the bearing is manufactured.

A fixing support is shown in diagram 1b (Fig. 6.167). When the axial shaft is clamped as shown in diagram 1b, the bearing classes are applied in the fixing supports, which are given in Fig. 6.186a–i. The thrust collars on the shafts and in the holes of the housing parts are designed according to one of the variants shown in Figs. 6.183–6.185.

The angular rigidity of the fixing supports, where the bearings are positioned in compliance with the variants in Fig. 6.186b,d,f,h, is higher than that of supports with positioning of the bearings according to the variants in Fig. 6.186a–c,e,g.

In some bearing classes (e.g., radial, radial-thrust ball, radial spherical ball, and roller bearings) the axial clearances between the rings and the solids of revolution are made by production of the bearings. In others (tapered roller bearings) the axial clearances are set on assembly.

Clearance adjustment of radial or radial-thrust bearings of the fixing support in diagram 1b (Fig. 6.167) is carried out by means of the axial displacement of the outer and inner races.

Adjustment of Bearings by Means of Axial Displacement of the Outer Races

Figure 6.187a shows the adjustment with a gasket package (1), which is installed under the flange of the bearing cap. A package of thin (thickness ≈ 0.1 mm) metallic gaskets is applied to it. It is also convenient to adjust with a gasket package of different thicknesses. The Timken firm (USA) delivers the following gasket package: three pieces with thickness 0.127 mm, three pieces with thickness 0.179 mm, or one piece with thickness 0.508 mm. Rather precise adjustment

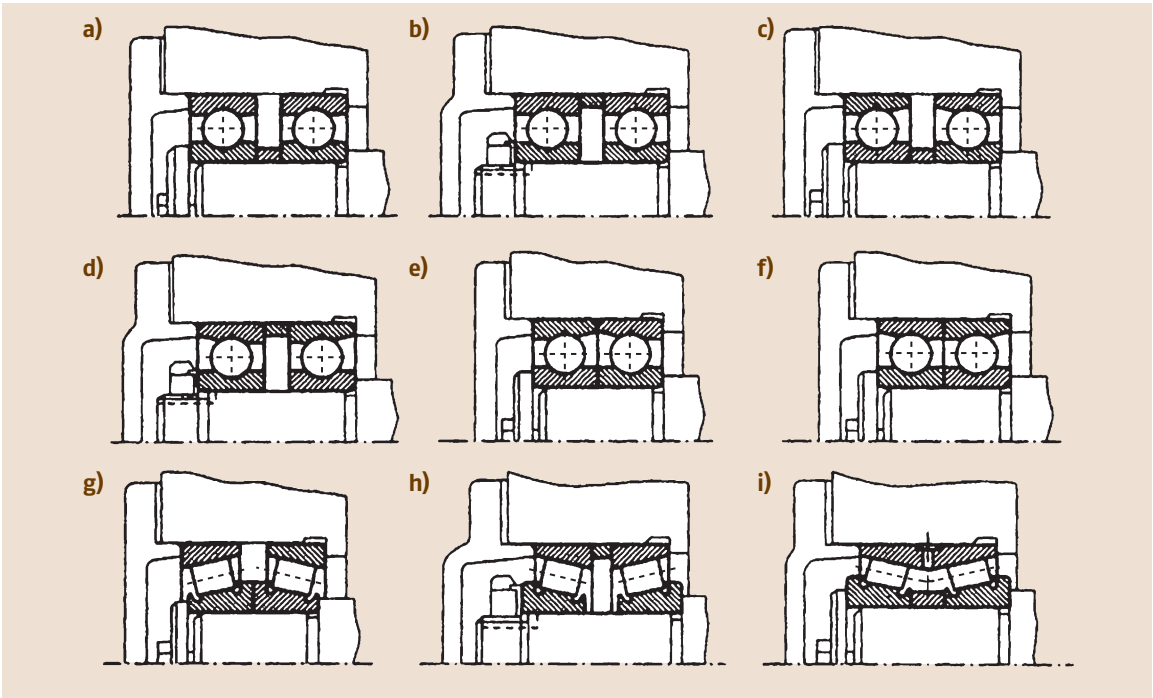

Fig. 6.186a–i Design of the fixing support in diagram 1b (Fig. 6.167) using the following types of bearings: **(a,b)** ball radial, **(c–f)** ball radial-thrust, **(g,h)** roller tapered, **(i)** roller-tapered double-row

can be obtained with a gasket package with the thickness series: 0.05, 0.1, 0.2, 0.4, and 0.8 mm. Calculation of the required adjustment with the gasket package is performed by means of a probability-theoretical method. Sometimes, instead of using the gasket package, adjustment is carried out with two semirings that are installed under the flange without removal of the cap.

Adjustment of the bearings can be carried out with a stud screwed into the case (Fig. 6.187b). It should be taken into account that, in this case, the positioning accuracy of the bearing is decreased. The positioning accuracy can be increased with the help of the influence of the screw (1) on the washer (2) (Fig. 6.187c). The washer self-installs along the face of the outer bearing race due to the presence of the spherical surface on the screw face (1). In this design the washer (2) should be stiff, and the diameter of the adjusting screw should be as large as possible. For smaller diameters of the screws there have been cases of screw extraction from the bearing cap under the action of axial forces. Adjustment accuracy in the configuration shown

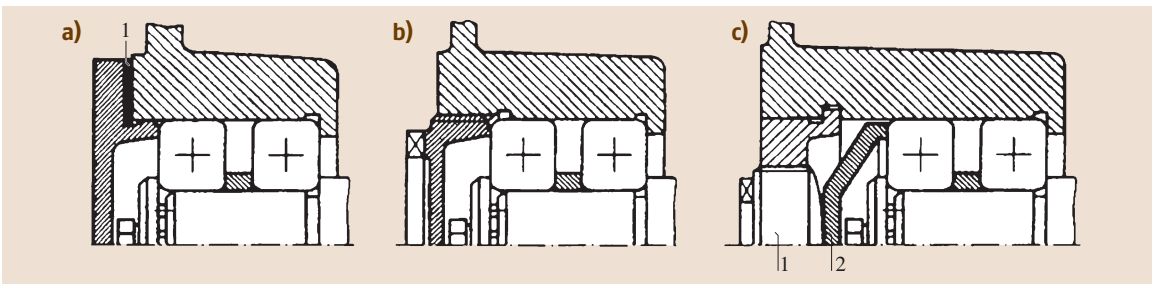

Fig. 6.187a–c Adjustment methods of bearings with axial displacement of the outer races. **(a)** With metallic gaskets, **(b)** with a stud screwed into the case, **(c)** with a screw and a self-installed washer

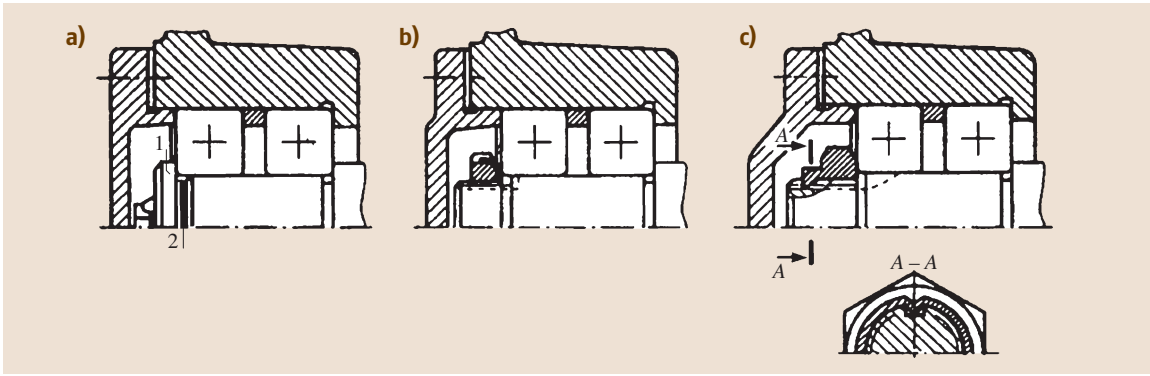

Fig. 6.188a–c Adjustment methods of bearings with axial displacement of the inner races. **(a)** With metallic gaskets, **(b)** with a round slotted nut, **(c)** with a nut with deformable shoulder

in Fig. 6.187c can be increased by decreasing the thread pitch. Thus, in these structures threads with a fine pitch are used.

Adjustment of Bearings with Axial Displacement of the Inner Races

In Fig. 6.188a adjustment of the bearings is carried out by means of tightening the face washer (1). A package (2) of thin metallic gaskets is installed between the faces of the shaft and the washer. The washer is fixed to the shaft face with a screw and locked.

In Fig. 6.188b the bearings are adjusted with a nut. After making the required clearance in the bearings the slotted nut is locked with a multitab washer. To this end the nut must be installed in such a way that the slot on it coincides in position with one of the bending ledge tabs of the retainer. In some cases, this condition results in degradation of accuracy of the adjustment. Adjustment with a nut with a special circular deformable shoulder (Fig. 6.188c) does not suffer from such a disadvantage. Two grooves are made (at 180°) on the thread shaft. After making the required clearance in the bearings the nut is locked, pressing the edges of the deformable shoulder into the shaft grooves.

Practice indicates that it is not necessary to loosen the fit under a moving inner race for adjustment. Adjustment of the bearing is an important operation. The quality of the adjustment depends on the professional skills of the assembler. Bearings can easily be undertightened or overtightened. Thus, on some plants the required rigidity is obtained by means of matching and grinding of the spacing washers (1 and 2), which are installed between the bearings on the shaft and in the case (Fig. 6.189). Then both the inner and outer races of the bearings are fixed on the shaft and in the case. This method is very reliable, but requires precise measuring of the bearing dimensions and thorough fitting of the races.

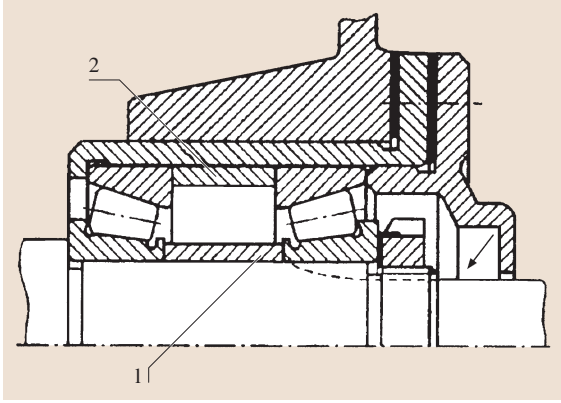

Fig. 6.189 Adjustment of bearings with spacing washers

Floating Supports in Diagrams 1a and 1b (Fig. 6.167)

For axial fixation of the shaft according to diagrams 1a and 1b the bearing classes given in Fig. 6.190a–h are used in the floating supports. The clearance b is included between the faces of the outer bearing race and the cap in the floating support. The value of the clearance in the supports designed according to Fig. 6.190a–c can be assumed to be $b \geq 0.01l$, where l is the distance between the faces of the bearing races (mm) (Fig. 6.167). In a support designed according to Fig. 6.190e it is assumed that $b \approx 0.5–0.8$ mm. To fasten the races on the shafts or the housing parts the methods given in Figs. 6.181–6.185 can be used.

Fig. 6.190a–h Design of the floating supports in diagrams 1a and 1b using the following bearings: **(a)** ball radial single-row, **(b)** ball radial spherical double-row, **(c)** roller radial spherical double-row, **(d,e)** with short cylindrical rollers, **(f,h)** needle ▶

Adjustment of the Bearings

The rigidity of the floating support can be increased by means of special design methods. Figure 6.191a,b shows floating supports where permanent interference is provided with the installation of the race (1), with a large number of springs positioned along the circle.

The firm SKF (Sweden) recommends that interference in the bearings be made with both coil and disk springs (Fig. 6.191a–c). In the latter case, the springs guarantee a constant force. The required radial stiffness of the floating support in the bridge mill (Fig. 6.191d) is obtained by straining of the inner race on the bevel neck.

Supports with a Preload

Preloading of the bearings is usually carried out by means of mutual axial race displacement (shown schematically in Fig. 6.192). The forming diagram of the preload is similar in the case of the installation of gaskets, springs, or races of unequal thicknesses. The preload is used to increase the stiffness of both fixing and floating supports.

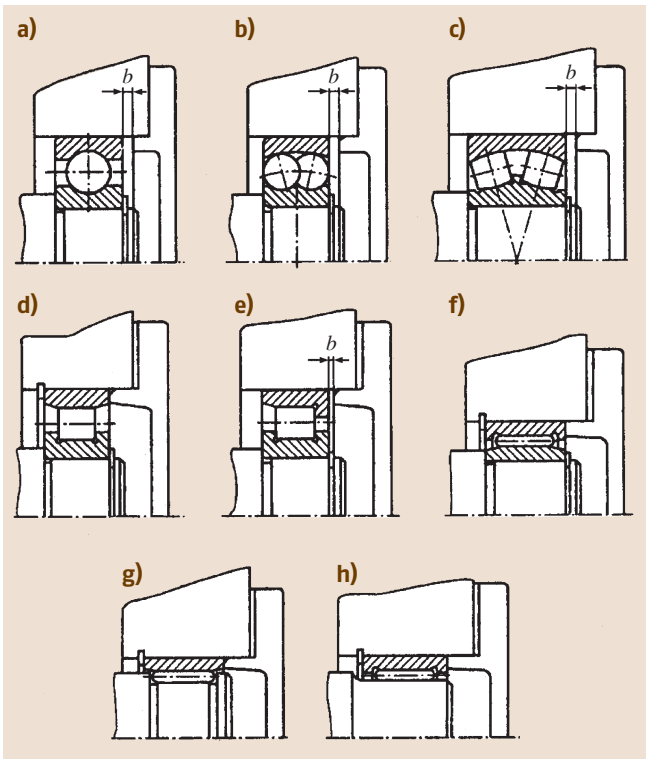
Preload of Bearings of Fixing Supports

Figure 6.193 shows the principal methods of preload making in the bearings of the fixing supports in diagram 1b. The preload is made by means of face grinding of the inner races (Fig. 6.193a) by the value required for obtaining the set interference after axial compression of the outer and inner races with each other; with the help of gaskets (Fig. 6.193b) or races of different thicknesses (Fig. 6.193c); as well as springs (Fig. 6.193d).

The preloading of the bearings of the floating supports can be applied with compression rings (Fig. 6.194a), the application of rings with different thickness (Fig. 6.194b), grinding of the faces of the inner races (Fig. 6.194c), and by a specially matched ring (1) (Fig. 6.194d).

Supports According to Diagram 2a (Fig. 6.167)

With the axial shaft fixation according to diagram 2a both supports are designed equally. Figure 6.195a–h shows examples of the embodiment of one shaft support; other supports are designed in a similar manner.



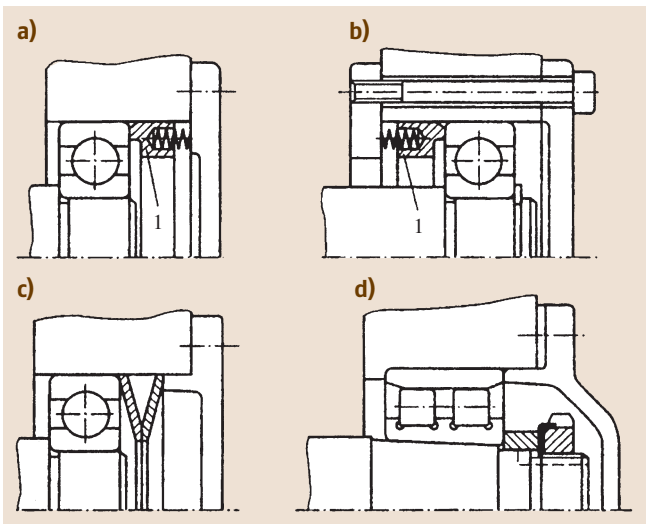


Fig. 6.191a–d Methods of increasing the stiffness of the floating support. **(a,b)** With a ring with a large number of coil compression springs, **(c)** disk springs, **(d)** with deformation on the cone of the inner bearing race

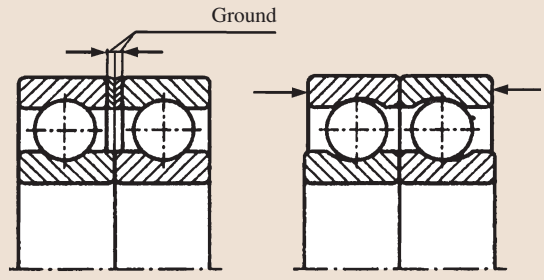

Fig. 6.192 Forming diagram of the preload

Clearance adjustment in the bearings is carried out by means of axial displacement of the outer races. In Fig. 6.196 adjustment with the help of a package of thin metallic gaskets (1) is shown, which are installed under the flanges of the caps of the clamped-on bearings. To adjust the bearings the package of gaskets can be installed under the flange of one of the caps. If it is further necessary to adjust the axial shaft position, the entire package of gaskets is halved, and then each of them is mounted under the flange of the corresponding cap. Adjustment with a package of metallic gaskets guarantees a rather high accuracy; this method is used for the installation of both radial and radial-thrust bearings.

Through the application of inserted caps, adjustment of the radial bearings can be carried out by means of the installation of the compensatory ring (1) between the faces of the outer race and the inserted cap (Fig. 6.197a). For convenience of assembly the compensatory ring is mounted from the side of the blind bearing cap. Upon mounting of the radial ball bearings a clearance $a = 0.2–0.5$ mm is left between the face of the outer race and the face of the bearing cap to compensate for thermal deformations (Figs. 6.196 and 6.197a). This clearance is not shown in the drawings of the assembly units in view of its insignificance.

Adjustment of radial-thrust bearings in the case of the application of inserted caps is carried out according to Fig. 6.197b, operating the screw (1) on the self-installed washer (2). To increase the adjustment accuracy threads with a fine pitch are used.

When the operating mode of the product is modified, the temperature changes and, therefore, so does the clearance in the bearings and their rigidity. After a time, the adjustment of the bearings carried out during assembly gradually disintegrates due to wear and crumpling of microridges. Thus, periodic readjustment of the bearings is needed.

More or less permanent support rigidity is obtained with the help of the application of resilient members

(Fig. 6.198), which compensates for wear. The springs are positioned along the circle and mounted in the ring (1) (Fig. 6.198a,b). In the bearings of the firm Game (France), as well as in Russian bearings, the outer race is joined with a ring (1) (Fig. 6.198c). The width of the outer race is increased, which increases the positioning accuracy of the bearing along the hole surface of the housing part.

The resilient members are incorporated into the support on which the axial force does not have any in-

fluence (or the value of which is not high). The force applied by the springs must exceed the sum of the axial component from the radial load and the external axial force in radial-thrust bearings.

Supports According to Diagram 2b (Fig. 6.167)

In the axial shaft fixation according to diagram 2b both supports are designed equally according to Fig. 6.199a–f. The axial shaft is fixed with case collars, in which the faces of the outer races are set. The collars for the bearing thrust can be designed in compliance with one of the variants in Fig. 6.185.

The most successful application is represented in Fig. 6.199e. In this variant there are no ledges or grooves in the case. Tapered roller bearings with a ledge on the outer race are currently widely used in the engineering industry.

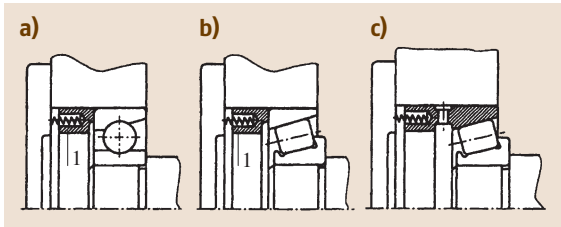

Fig. 6.198a–c Methods to maintain the required stiffness of the supports with the help of a greater number of compression springs installed in **(a,b)** the additional ring, **(c)** in the outer ring of the bearing

Clearance adjustment in the bearings is carried out with the help of the axial displacement of the inner races on the shaft with nuts. It is not necessary to loosen the fit under the moving inner race of the bearing. One nut on one of the shaft ends is enough to adjust the bearings (Fig. 6.200a). If it is additionally necessary to adjust the axial shaft position, nuts are included on both ends (Fig. 6.200b).

The positioning accuracy of the inner races depends on the thread manufacturing accuracy of the shaft and the nut, and the deviation from perpendicularity of the mounting nut face. To increase the accuracy of positioning for the bearings fixed according to diagram 2b (Fig. 6.167) the thread of the shaft is ground in quality products, and the mounting nut face is ground on the threaded arbor.

The firm Timken recommends screwing the adjusting nut (1) onto the shaft thread and locking it at the appointed position (Fig. 6.201). With a ground shaft the mounting nut face (1) is also ground. Some plants provide a permanent axial interference in tapered roller bearings by means of installation of the ring (1) with a large number of springs positioned around the circle (Fig. 6.202a). The firm Game recommends the same solution (Fig. 6.202b).

Mounting of resilient members improves the operating conditions of bearings, as even for this relatively inexact adjustment the axial clearance in the bearings is removed by any thermal shaft extension. Resilient members can be built into the supports not only for tapered roller bearings, but also with ball radial (Fig. 6.202c) and radial-thrust (Fig. 6.202d) bearings.

6.12.4 Design of Shaft Supports of Bevel Pinions

The diagrams of the axial shaft fixation of bevel pinions are shown in Fig. 6.203. In bevel gearing units cantilever fastening of the pinion shaft is widely used (Fig. 6.203a–c). In this case, the structure of the unit is simple, compact, and convenient to assemble and adjust. The disadvantage of the cantilever pinion position is the higher stress accumulation along the tooth of the pinion. If the pinion is positioned between the supports (Fig. 6.203d), stress accumulation is lower as a consequence of a decrease in the shaft flexure and the rotary angle of the section at the installation site of the bevel pinion, but design of the supports according to these diagrams results in a substantial structure meshing of the housing parts and the gear wheel, which is why it is relatively rarely used in practice. The diagram according to Fig. 6.203a (diagram 2b in Fig. 6.167) is primarily applied.

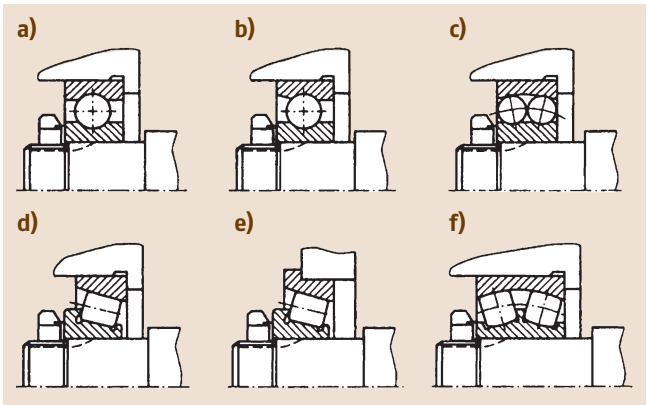

Fig. 6.199a–f Methods of executing the fixing support in diagram 2b using the following bearings: ball radial single-row **(a)**, ball radial-thrust **(b)**, all radial double-row spherical **(c)**, tapered roller **(d,e)** roller radial double-row spherical **(f)**

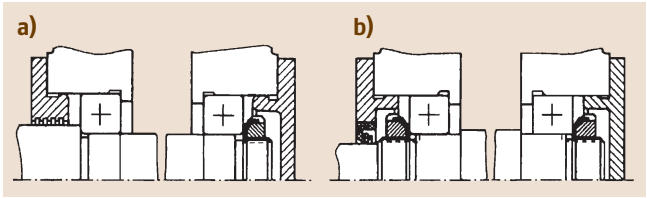

Fig. 6.200a,b Adjustment of clearances in bearings (diagram 2b) **(a)**, with a nut, **(b)** with two nuts

The shafts of bevel pinions are short, so thermal axial deformations do not play such an important role as in long shafts. The distances between the bearings are relatively small, and the forces acting on the shaft and its supports are large. Load accumulation at the cantilever position of the pinion can be decreased by increasing the rigidity of the unit. Higher rigidity requirements are required for high accuracy of the axial position of

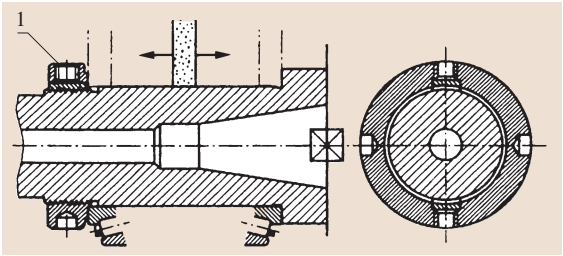

Fig. 6.201 Grinding of the mounting face of the adjustment nut

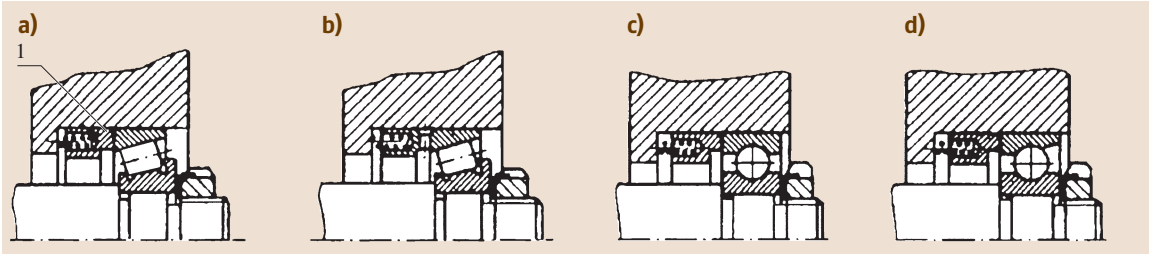

Fig. 6.202a–d Methods of maintenance of the required stiffness of the supports with greater number of compression springs installed in **(a,c,d)** the additional ring (1) **(b)** in the outer ring of the bearing

the bevel pinion, which is necessary according to the working conditions of bevel gearings.

In the unit design, the directions of the tooth dip and of the pinion rotation are chosen equal to the axial force in the toothing, directed from the vertex of the pitch cone of the pinion. In the unit structures of bevel pinions radial-thrust bearings are used, mainly tapered roller ones, because they have greater load-carrying capability and are cheaper, which ensures greater rigidity of the supports. More expensive ball radial-thrust bearings are applied for relatively high rotational frequencies ($n > 1500\,\mathrm{min}^{-1}$) for loss enhancement in the supports, as well as when required for high rotational accuracy.

As indicated, the bearing installation according to the diagram in Fig. 6.203a finds primary application in bevel power trains. Figure 6.204 shows a typical shaft structure of the bevel pinion fixed according to this diagram. The forces acting in the bevel gearing cause a radial reaction of the supports. The radial reaction is considered to be applied to the shaft at the cross point of its axis with the normal lines drawn through the centers of the contact areas on the races of the bearings. Let us designate b as the distance between the reaction points, a as the size of the console, d as the shaft diameter at the installation site of the bearing, and l as the distance from the reaction point of the pinion support closest to the vertex of the pitch point. During design it should be assumed that $d \geq 1.3a$, and that b is the greater of $b \approx 2.5a$ and $b \approx 0.6l$. Engineers aim to obtain the minimum dimension a for reduction of the bending moment acting on the shaft. After this dimension has been determined, the distance b is assumed according to the given ratios. Then the unit is rather compact. The bearing positioned closer to the bevel pinion is loaded with a greater radial force and furthermore takes an axial force. Thus, in a number of structures this bearing will have a larger hole diameter.

The typical shaft structure of the bevel pinion fixed according to the diagram of Fig. 6.203b is given in Fig. 6.205. This installation diagram of the bearing has substantial unit dimensions in the axial direction due to adherence to the required ratio between b and a according to the conditions of stiffness. It is not recommended for use in power trains.

The shaft structure of the bevel pinion fixed in the diagram of Fig. 6.203c is shown in Fig. 6.206. For convenience of adjustment of the axial pinion position the

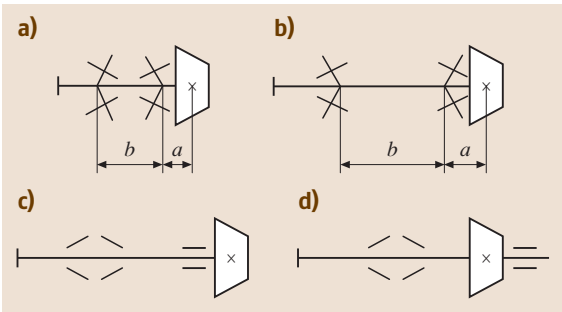

Fig. 6.203a–d Diagrams of the axial fixation of the shafts of bevel pinions. **(a)** Stretched out (diagram 2b), **(b)** end thrust (diagram 2a), **(c,d)** diagram 1b

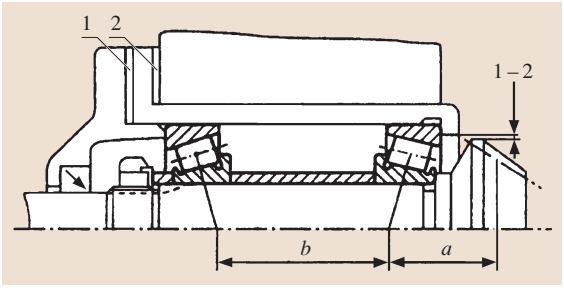

Fig. 6.205 Axial fixation, end thrust (diagram 2a)

fixing support is enclosed in the sleeve. The bearing closest to the pinion is mounted directly in the case hole, which increases the accuracy of the position of the radial pinion.

The floating support can be positioned in one sleeve with the fixing support (Fig. 6.207) by location of the bevel pinion between the supports as shown in Fig. 6.203d in order to simplify the case structure. The disadvantage of structures designed according to this diagram is overdesign of the mating with the pinion bevel wheel.

For the design of the shaft units of bevel pinions, adjustment of the bearing clearances of the fixing supports and of the bevel gearing (of the axial position of the shaft-pinion) is foreseen.

For axial fixation according to Fig. 6.204 the clearances in the bearings are adjusted with a round slotted nut (1), and the axial position of the pinion shaft is adjusted with a package of thin metallic gaskets (2). For axial fixation according to Figs. 6.205–6.207 clearance adjustment in the bearings is carried out with the package of gaskets (1), and the gearing is adjusted with the gasket package (2).

To guarantee the standard (GOST 16984-79) wrench application for screwing, the round slotted nut must be beyond the bounds of the sleeve flanges

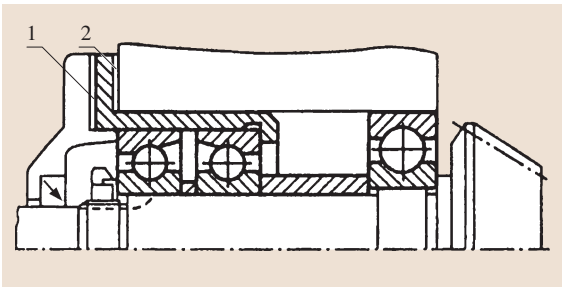

Fig. 6.206 Axial fixation according to diagram 1b with the cantilever position of the pinion

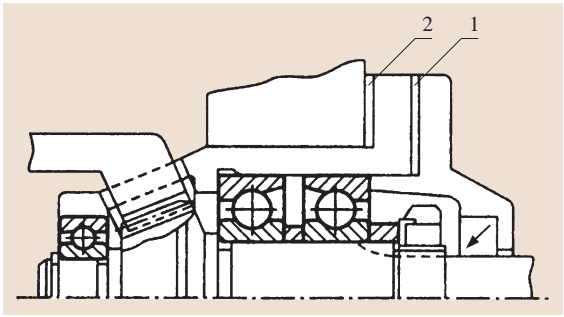

Fig. 6.207 Axial fixation according to diagram 1b with the noncantilever position of the pinion

(Fig. 6.207), which extends the axial unit dimensions and complicates the form of the bearing cap. By application of a nonstandard wrench these disadvantages can be eliminated (Fig. 6.204). To exclude the possibility of damage to the bearing cage by straining with the multitab washer a *joint sealant* can be used to stop the round slotted nut.

Examples of Embodiment of Shaft Units of Bevel Pinions

Figures 6.208 and 6.209 show structures of the bevel pinion input shafts with installation of the bearings according to diagram 2b (Fig. 6.167). Adjustment of the axial clearance in the radial-thrust bearings (Fig. 6.208) is carried out with axial displacement along the shaft with the help of the round slotted nut of the inner bearing race. By adjustment of the toothing the pinion shaft is moved in the axial direction by means of a thickness change in the package of thin metallic gaskets (1) between the case and the flange of the sleeve. In the unit shown in Fig. 6.208a, tapered roller bearings are applied with a thrust ledge on the outer race. The sleeve has a very simple structure.

The bearing positioned closer to the bevel pinion is loaded with a higher radial force and, furthermore, takes an axial force from the toothing side. Thus, in a number of structures this bearing is chosen with a large outer diameter (Fig. 6.208b) or with a large hole diameter (Fig. 6.208c). The bearing is installed directly in the hole of the case. This increases the positional accuracy of the radial pinion.

In the unit of Fig. 6.208d a sleeve with a collar in the hole is used for the positioning of the shaft bearings of the bevel pinion. The installation accuracy of the outer rings in the sleeve depends on the manufacturing accuracy of the collar faces. The presence of the collar in the hole of the sleeve complicates its machining.

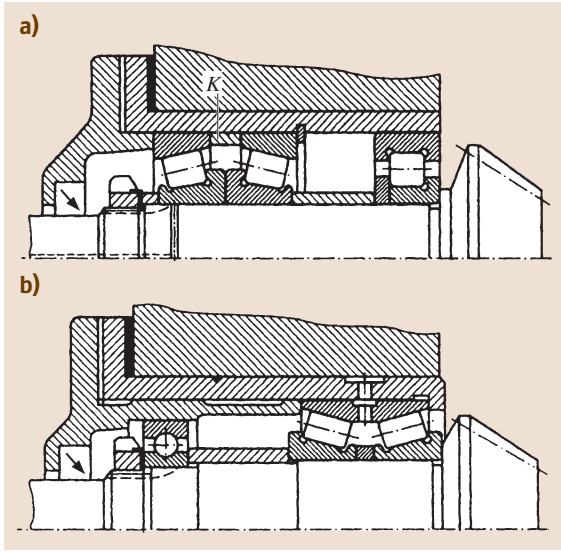

Fig. 6.210a,b Axial fixation of shafts of bevel pinions according to diagram 1b with position of the fixing support **(a)** at the outlet of the shaft, and **(b)** next to the pinion

A peculiarity of the described structures of the sleeves is the fact that their position in the case is not determined by an external cylindrical surface, but rather by a developed flange. This is why the cylindrical surface used only for centering can be substantially reduced (Fig. 6.208c).

Figure 6.209a,b shows unit structures of bevel pinions used in cars (according to information from the firm SKF). The inner race of the left bearing is tightened with a nut up to the stop to the face of the compensatory ring K or to the face of the compensatory bushing (1), which improves its positioning. In some structures there is a compliant steel bushing (1) between the faces of the inner bearing races (Fig. 6.209c). The required preload of the bearing is applied with a torque spanner by the application of a tightening torque determined based on experience.

Figures 6.210 and 6.211 show the structures of the input shafts of bevel pinions with a fixing support and a floating one (diagram 1b, Fig. 6.167). For convenience of adjustment of the axial pinion position both shaft supports, fixing and floating, are enclosed in the sleeve (Fig. 6.210a). Adjustment of the bearing of the fixing support is carried out by means of matching and grinding of the compensatory ring K. Sometimes (Fig. 6.210b) the fixing support is not located at the output shaft as usual, but near the bevel pinion.

In has been noted that a noncantilever position of the pinion is more efficient. However, such structures are more complicated. An additional support can be positioned in a special inner wall (Fig. 6.211a,b). Because the teeth of the bevel pinion are cut on the shaft, the bore diameter for the bearing is small. The mating wheel of the bevel gearing limits the radial dimensions of this support. The fixing support in Fig. 6.211a is adjusted with a cap (1) screwed into the sleeve. In Fig. 6.211b it is adjusted by matching and grinding of the compensatory ring K. The bevel meshing is adjusted with the package of metallic gaskets (2) installed under the flange of the sleeve.

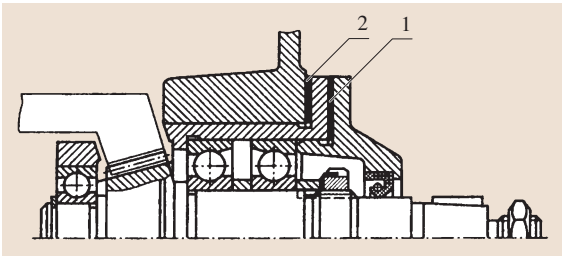

Fig. 6.212 Axial fixation of shafts of bevel pinions according to diagram 1b with adjustment of the ball radial-thrust bearings of the fixing support with metallic gaskets

There is a possible variant of the structure with extra support in the sleeve, as shown in Fig. 6.212. In this case, rigidity of the unit is rather high and for rotation loss enhancement ball radial-thrust bearings can be used in the fixing support, and the radial bearing can be used in the floating support. Bearing adjustment of the fixing support is carried out by means of thin metallic gaskets (1), and adjustment of the bevel meshing is applied with metallic gaskets (2).

6.12.5 Support Design of Worm Shafts

Diagrams for axial fixation of the worm shafts are given in Fig. 6.213. Fixation from the axial displacements according to diagram 2a (Fig. 6.167) is used with the expected differential temperature of the worm and the case being up to 20 °C and relatively short shafts (Figs. 6.213a and 6.214). Thus for shaft installation $d = 30–50$ mm and in ball radial-thrust bearings the ratio l/d is not more than 8, whereas in tapered roller bearings l/d is not more than 6.

Because the substantial axial force influences the worm, radial-thrust bearings are mounted in the supports. Mainly tapered roller bearings are used

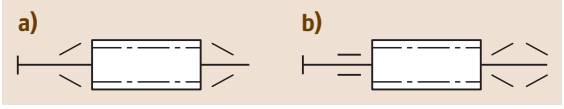

Fig. 6.213a,b Diagrams of the axial fixation of worm shafts. **(a)** Thrust (diagram 2a), **(b)** diagram 1b

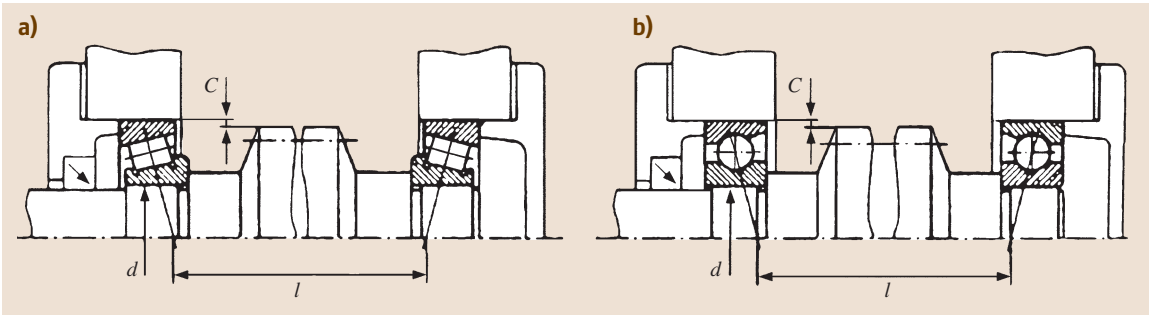

Fig. 6.214a,b Axial thrust fixation using (a) tapered roller bearings, (b) ball radial-thrust bearings

(Fig. 6.214a). Ball radial-thrust bearings are used in continuously operating gearings in order to reduce power loss and maintain heat generation in the supports, as well as for adherence to the manufacturing accuracy of the unit components (Fig. 6.214b). However, the dimensions of supports designed using radial-thrust bearings are larger than those of tapered roller bearings as a consequence of their lower load rating. Thus, the final choice of the shaft supports of the worm is sometimes made after comparative calculations and tracings. It should be taken into account that it is not recommended to install radial-thrust bearings with a large contact angle ($\alpha > 18°$) according to diagram 2a. The diagram with a fixing support and a floating support (Fig. 6.213b) is used because of the application requirements of these bearings, as well as the large expected thermal deformations of the shaft for fastening in the case of the worm shaft.

Figure 6.215 shows the most common variant of the fixing support of worm shafts. Due to the high axial force acting on the worm shaft, radial-thrust bearings, i. e., tapered roller bearings or ball bearings with a large contact angle, are used in the fixing support. Because radial-thrust single-row bearings are subjected to an axial force from only one direction, in the fixing support two such bearings are mounted for shaft fixation in both directions.

The clearances in the bearings of the fixing support are adjusted with the package of thin metallic gaskets (1), which are installed under the flange of the bearing cap. Instead of the adjusting gaskets a precisely longways fitting ring K (Fig. 6.215) is sometimes mounted between the outer bearing races.

A radial-thrust double bearing in combination with the radial one is used for substantial axial loads in the fixing support. Some structures of such supports are given in Fig. 6.216a,b. Installation of thrust bearings on the horizontal shaft is undesirable as the axial force loads one of the last rings and unloads another. In con-

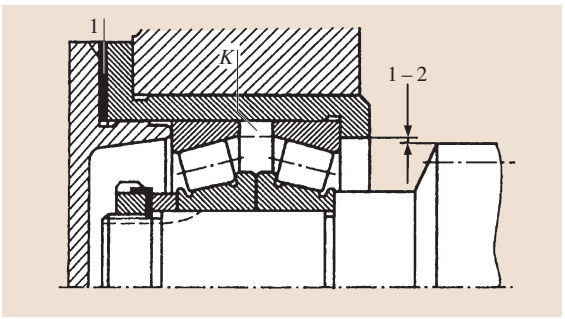

Fig. 6.215 Fixing support of a worm shaft using two tapered roller bearings

tact with the unloaded ring the balls creep under the action of inertial forces (the gyroscopic effect). This results in greater heat in the bearing and faster fracture. To avoid this increased creep the races of the thrust bearings are tightened with springs (Fig. 6.216b).

The axial fixation according to diagram 1a (Fig. 6.167) is seldom used. Figure 6.217 shows the structure of worm-shaft supports engineered by SKF. In the fixing support a very complicated and expensive ball radial-thrust double-row bearing is applied. To insert the worm shaft with the bearings into the sleeve or the case a clearance of $C \geq 1-2$ mm is foreseen (Figs. 6.214–6.217).

Examples of the Embodiment of Worm-Shaft Units

The minimum support dimensions in the radial direction, as well as the minimum distance between the bearings, can be obtained by installation of combined radial-thrust needle bearings (Fig. 6.218, according to information from the firm NADELLA, France). To position the flank of the combined needle bearing, housing parts must be machined. The seal on the input shaft end is positioned in a smooth hole, which is intended for installation of the bearing. The required clearance for the bearing operation is ensured with

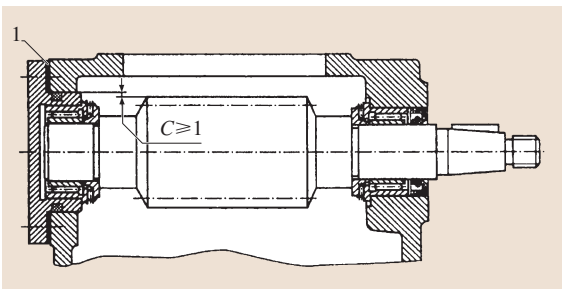

Fig. 6.218 Axial fixation of a worm shaft using combined radial-thrust needle bearings

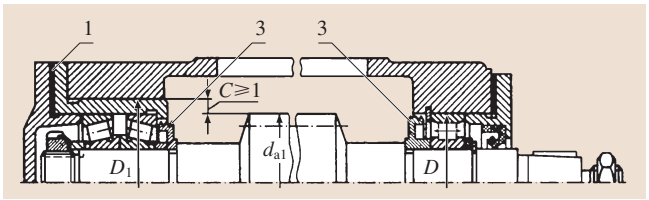

Fig. 6.219 Axial fixation of a worm shaft according to diagram 1b using roller bearings

the help of the metallic gaskets (1). Russian industry also produces similar bearings. On assembly the worm shafts are inserted into the case through the hole intended for installation of the bearings. Thus, the diametral dimensions of the worm or the components positioned on the shaft must be less than the hole diameter $2C$. If the worm diameter d_{a1} is more than the bearing diameter D, the bearing is mounted in the sleeve (Fig. 6.219).

Figure 6.219 shows an embodiment of the worm-shaft unit by mounting of the bearings according to diagram 1b (Fig. 6.167): the left support is fixing, the right one is floating. With such an installation configuration of the bearings the fixing support can support substantial axial forces, because tapered bearings with a large cone angle can be applied.

Possible variants of the fixing support of the worm shaft are given in Fig. 6.220. In Fig. 6.220a for fastening of the bearings a thrust collar is foreseen in the case, which however complicates machining of the mount-

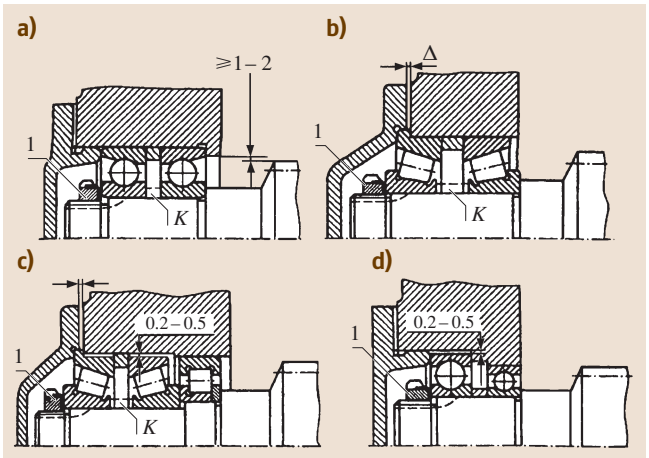

Fig. 6.220a–d Variants of design of the fixing support using **(a)** a thrust collar in the case, **(b)** a bearing with a thrust shoulder, **(c)** a roller, and **(d)** and ball bearings taking radial and axial loads separately

ing holes for the bearings. Application of bearings with a thrust ledge on the outer race (Fig. 6.220b) substantially simplifies a structure: there is a smooth hole in the case and there is no sleeve. In Fig. 6.220b tapered roller bearings are oriented towards each other with the wide faces of the outer races, and in Fig. 6.218 with the wide faces outwards. The variant shown in Fig. 6.220b is characterized by high angular rigidity.

The diametral dimensions of the support can be reduced as necessary if different bearings support the radial and axial forces. In the structure in Fig. 6.220c tapered roller bearings are mounted in the case with little clearance and therefore can take only axial force. By unloading the tapered bearings from the radial force their lifetime can be increased. The radial force is supported by the radial bearing with short cylindrical rollers. In order to bear the radial load radial bearings of other classes can be used. On the whole, the support in Fig. 6.220c is more expensive, e.g., than the support in Fig. 6.220b.

Figure 6.220d shows a structure of the fixing support of the worm, where ball, radial, and radial-thrust bearings with a split inner race, are applied. Here, as in Fig. 6.220c, clearance is included between the mounting hole and the bearing, so that the radial-thrust bearing only supports an axial force. The radial-thrust bearing is of the nonadjustable class; the required axial clearance is provided by production of the bearing. In other variants (Fig. 6.220a–c) the bearings of the fixing support are adjusted with a nut (1). Then the precisely fitting rings K (shown in the figures by hatch lines) are sometimes mounted between the races of the bearings. Attention should be paid to the fact how the bearing caps are installed in Fig. 6.220b,c. By tightening the fastening bolts the cap tightens a ledge on the outer bearing race to the case. A small clearance Δ must necessarily be present between the cap face and the mount of the case. This fastening guarantees transmission of axial forces in any direction from the bearing to the case.

6.12.6 Supports for Floating Shafts

Shafts are floating if both their supports are floating. In this case, the possibility of self-installation of the floating shaft relative to another shaft fixed from axial displacements is secured. This self-installation is required, e.g., in herring-bone or helical gearings representing a separated chevron. In the manufacture of the wheels of these gearings an error in the angular tooth position of one semichevron relative to the tooth of another semichevron is unavoidable. Due to this error first the teeth of only one semichevron engage. The axial force arising in the toothing works to move the wheel with the shaft along the shaft axis. If the supports allow, the shaft moves to such a position where the teeth of both semichevrons engage, and the axial forces arising in them are balanced. In this case, the axial fixation of the shaft is not carried out in the supports but by the teeth of the chevron gears.

Radial bearings are used as supports for floating shafts. Bearings with short cylindrical rollers are mostly applied. The construction diagrams shown in Fig. 6.221 are the most common.

Diagram in Fig. 6.221a

The inner races of the bearings are fastened on the shaft, and the outer ones are in the case. Axial floating of the shaft is ensured by the fact that the inner bearing races with a roller set can shift in the axial direction relative to the fixed outer races. Axial floating of the shaft occurs during its rotation. Then the force required for its displacement is very small, which is an advantage of this configuration.

Disadvantages of this approach are as follows:

- The necessity to apply very rigid shafts and guarantee of a high coaxiality grade of the mounting shaft and case surfaces as a consequence of the high sensibility of these bearings to race warps.

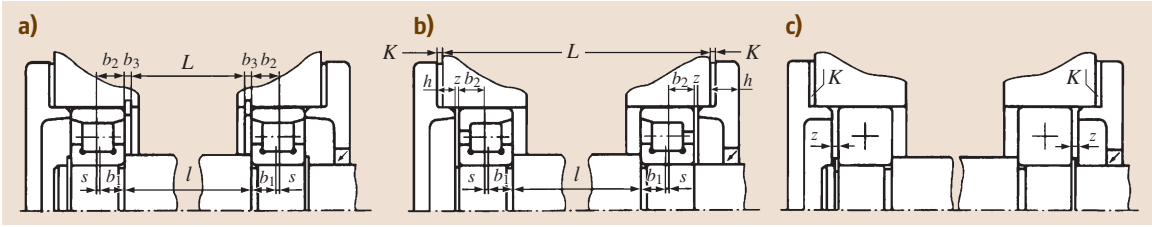

Fig. 6.221a–c Analytical models of floating shafts with installation of bearings with (a,b) short cylindrical rollers, (c) of other classes of radial bearings

- The possibility of substantial initial (after assembly) axial race displacement s, which is not compensated later. Errors in the dimensions l, L, b_1, and b_2 cause this displacement and also the fact that the axial shaft position depends on the axial position of the engaged wheels, which has an accidentally wide spacing in values.
- The need for comparatively precise production of the components according to the dimensions L and l. These dimensions (shown in Fig. 6.221a) along with other dimensions form a dimensional chain. The errors in the component manufacture according to these dimensions result in axial displacement of the bearing races.

Diagram in Fig. 6.221b

The outer races have some freedom from axial displacement. Displacement into the case is restricted to the ledges of both bearing races; towards the bearing caps it is restricted by a clearance z. The value of the clearance $z = 0.5–0.8$ mm depends on the unit dimensions and manufacturing accuracy of the teeth of the mated chevron gears, and their assembly accuracy.

With axial floating of the shaft the inner races of the bearings with roller sets shift relative to the outer races. At the start of axial shaft floating the rollers of the bearings displace the outer races towards the caps in such a way that the races find their place and are fixed later.

The advantages of this configuration are the following:

- Easy shaft floating because of the low axial force.
- The possibility of adjustment of the initial value of s – the axial displacement of the races – to the minimum. This is achieved by means of matching of the compensatory gaskets K mounted under the flanges of both bearing caps.
- The production of the components according to the dimensions l, L, and h in compliance with free tolerances (e.g., of accuracy degree 14). Possibly accumulated errors are eliminated with the compensatory gaskets K.
- The absence of stops for the outer bearing races in the case holes, which makes their machining easier.

The disadvantage of this configuration, as with the previous one, is that its application is limited to stiff shafts and high manufacturing accuracy of both the shafts and the case holes.

Diagram in Fig. 6.221c

In this configuration, in the supports radial ball single-row, ball, or roller double-row spherical bearings are applied. The choice of one or another bearing class is defined by the required load rating and shaft stiffness.

The inner bearing races are fastened onto the shaft, whereas the outer races are free and can move along the holes of the case. The displacement value is restricted by the clearances z set on assembly by matching the compensatory gaskets K. Axial shaft floating, if its value is not more than the axial clearance in the bearings, occurs at the expense of this clearance relative to the fixed outer bearing races. If the axial shaft displacement exceeds the axial clearance in the bearings, by floating of the shaft the outer bearing races slide in the holes of the case, which results in wear of the hole surface. To decrease this wear tempered-steel bushings are sometimes placed into the holes of the case.

The advantage of this configuration is than it can be applied for nonrigid shafts and low coaxiality grade of the mounting surfaces of the shaft and the case. The absence of stops for the outer bearing races in the holes of the case can also be considered an advantage.

The disadvantages of this configuration are the following:

- The presence of kinetic friction of the outer bearing races along the holes of the case.
- The necessity of the application of substantial axial force for realization of the shaft floating.
- The use of tempered-steel bushings makes the supports more expensive and reduces the positioning accuracy of the shaft.

Examples of the Embodiment of Floating Shaft Units

Figure 6.222 shows structures of the input shafts of a single-reduction gear unit with chevron gears made according to the configuration shown in Fig. 6.221a,b. The shafts are floating. The axial position of the floating shaft is determined by the teeth of the semichevrons, which are inclined in different directions. The conjugated shafts are fixed relative to the case.

The outer race of the bearing without ledges (Fig. 6.222a) is tightened with a face of the clamp-on cap to ring (1). This ring can be solid if the jointing plane of the case goes through the shaft axis. If the case is made without a split, (1) is a spring planar thrust inner ring. In the floating support shown in Fig. 6.222a it is recommended to fasten the inner bearing race from

two sides to prevent it from accidentally coming off the shaft. For compensation of unavoidable manufacturing inaccuracy the compensatory ring (3), the thickness of which is matched at assembly, is mounted for the length of the components between the spring ring (2) and the face of the inner bearing race.

By application of a bearing with one ledge on the outer race (Fig. 6.222b) the required axial position of the clamp-on caps is set on assembly by matching the thin metallic gaskets (4). The outer races are free from axial displacement for the value of the clearance z in the direction of the bearing cap. There is no need to fasten the inner bearing race onto the shaft.

At the start of axial shaft floating the rollers of the bearings displace the outer races by a certain value in the direction of the caps. Then the clearance z reduces and later, at the expense of thermal deformations of the shaft, it is completely removed. After the races find their position they become fixed (Fig. 6.222c). Then there is an axial clearance s between the rollers and the ledge of the outer race by the shaft floating. The clearance s changes during the working process over certain ranges, which are determined by the manufacturing accuracy of the teeth of the gear wheels. An important advantage of this configuration is the possibility of adjustment of the initial value of the axial displacement of the outer and inner bearing races.

6.12.7 Supports for Coaxial Shafts

These supports are designed, e.g., in the coaxial cylindrical double-reduction gear unit (Fig. 6.223), as well as in multiengine transmissions. In this case, on the inner case wall, bearings for the coaxial shafts (1 and 2), which have different overall dimensions, are located side by side. One of them is a support for the high-speed shaft, while another is a support for the low-speed one. As a rule, the shafts are fixed according to diagram 2a (Fig. 6.167). Figure 6.224 shows design versions of the support of coaxial shafts (remote element A, Fig. 6.223).

In Fig. 6.224a the holes for the bearings are made directly in the inner wall of the case. Machining of the holes is carried out from both sides, forming the collars for the bearings in both holes. This presents some machining problems; however with this design the greatest installation accuracy of the bearings can be achieved.

Boring of the hole can be simplified if it is done with a through diameter of D_2 (on the outer diameter of the bigger bearing, Fig. 6.224b). However, for installation of a bearing with a smaller outer diameter D_1 an additional component is used: the ring (3), which is fixed with a collar on the outer surface which goes into the groove of the split frame. The bearings are inserted up to the stop into the faces of the ring (3), which is why the manufacturing accuracy of the ring must be high. Thus simplified hole boring is achieved with the application of ring (3), execution of the groove in the case,

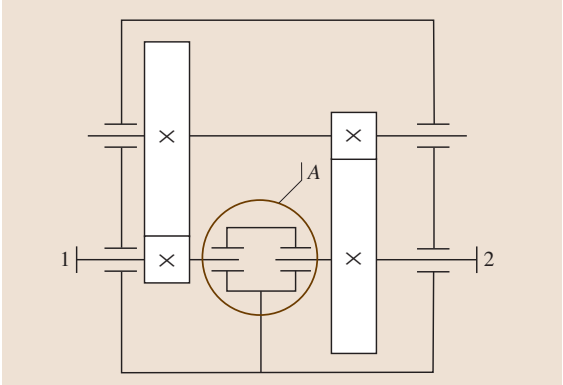

Fig. 6.223 Diagram of the coaxial cylindrical double-reduction gear unit

and the required use of the removable cap in the inner wall of the case.

In the version shown in Fig. 6.224c the ring (3) does not have a fixing flange and, therefore, the groove is not needed in this case. The structure of the ring is simpler and machining of the case hole is also simpler. However, here the shafts (1 and 2) form a general system. Adjustment of the axial clearance for four bearings of both shafts is carried out simultaneously. The main disadvantage of this version is that the axial forces acting on one shaft load the bearings of another shaft.

Depending on the version the points below can be followed:

- For the version shown in Fig. 6.224a the positional accuracy is higher, as there is no additional component with corresponding errors and no additional conjugation with the case.
- The version in Fig. 6.224c should be preferred to that in Fig. 6.224b as it is simpler and more economical due to the installation of the ring (3) when using radial ball bearings in the supports. It goes without saying that, by matching the bearings, the axial forces acting on both shafts (1 and 2) should be taken into account.

Examples of the embodiment of the supports of coaxial shafts are presented in Fig. 6.225 with a stop of the bearings into the collars either of the case (Fig. 6.225a) or the ring with flanges (Fig. 6.225b).

6.12.8 Lubrication of Bearings

Lubrication of bearings is carried out with the help of semisolid lubricants and liquid oils. In some cases solid lubricants are used. The choice of the lubricant type depends on operating conditions and, mainly, on the bearing temperature, rotational frequency, acting loads, and the structure of the bearing and the bearing unit.

For lubrication of rolling bearings running under normal conditions semisolid lubricants are predominantly used. These have the following advantages in comparison with oils: they do not need compound sealing devices, they have higher corrosion protection characteristics, they are more economical, they are retained better in the bearing unit, especially for an inclined or a vertical position of the shaft, and they better protect the bearing from moisture penetration and contamination from the environment. The service life of semisolid lubricants often exceeds the lifetime of the bearing, so the bearings do not require repeated lubrication.

However, application of liquid lubricants allows one to reduce the frictional moment and increase the limit rotation frequency by factor of 1.2–1.5. With the help of liquid lubricants, heat elimination and removal of wear debris occur.

Solid lubricants are applied for bearings running in conditions for which liquid and semisolid lubricants are unusable (vacuum, high and low temperatures, hostile environments, radioactive emission, equipment in the food and textile industries, and optical systems).

Semisolid lubricants consist mainly of a liquid base, thickener, and additives to improve their operational properties. The thickener, which comprises 8–25% of the total mass of the lubricant, forms a three-dimensional grid in the form of a fibrous frame whose cells retain oil. This is why, with low loads, the

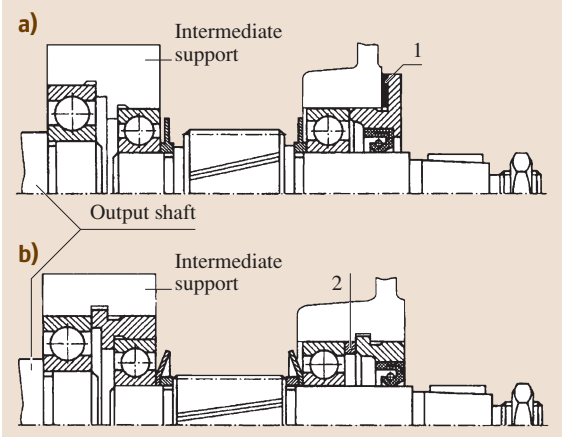

Fig. 6.225a,b Structures of the support of coaxial shafts: with stopping of the bearings **(a)** into the collars of the case, **(b)** into the collars of the ring with a ledge

semisolid lubricant behaves like a solid; it does not spread under its own weight and is retained on tilted and vertical surfaces.

Lubricants with calcium and lithium thickeners are used for bearings. Mineral and synthetic oils with a kinematic viscosity of 15–500 mm^2/s at 40 °C are applied as a dispersion medium. For the lubrication of rolling bearings semisolid lubricants of classes 2 (predominantly) and 3 according to the National Association of Lubricating Grease Institute (NLGI) standards are recommended. Most often lubricants with a lithium base are applied, which are resistant to water and are corrosion protected.

One type of lubrication method has a permanent quantity of lubricant that is intended for the entire lifetime of the bearing. The other requires periodic addition and changes of the lubricant. In the first case, the lifetime of the lubricant is equal to or greater than the lifetime of the bearings or the maintenance cycle of machines with built-in bearings. Closed bearings filled with a lubricant on manufacture with safety washers or with contact seals belong to this class. Bearings with built-in safety washers are applied in units where contamination is not high and water, vapor, etc., do not penetrate, or in units where the absence of friction in this noncontact seal in the case of high rotational frequencies or high temperatures is important.

Bearings with built-in contact seals are applied in units where it is impossible to ensure an external seal due to a lack of space, where the possibility of contamination is normal and ingress of moisture is possible, or if it is necessary to guarantee a long lifetime without maintenance.

As a liquid lubricant refined mineral (petroleum) oils are mostly used for bearings. Liquid synthetic oils (diether, polyalkylen-glycol, fluorine-carbonic, silicone) in comparison with mineral oils demonstrate better stability, viscosity, and pour point. They are used at high or low temperatures, and high rotational frequencies.

The choice of lubricating oil is determined by the viscosity required to ensure effective lubrication at the operating temperature. The dependence of the oil viscosity on the temperature is characterized by the viscosity index (VI). A higher VI indicates less viscosity dependence on temperature. The wider the range of operating temperatures, the greater the viscosity index of the oil used should be. For lubrication of rolling bearings oils with VI of 85 and higher should be used.

Table 6.94 shows a classification of kinematic viscosities in accordance with the recommendations ISO 3448.

To increase the performance characteristics of the oil various additives are used. The most common additives are antioxidants, anticorrosives, antifoams, antideterioration, and antiscoring.

Preference is given to oil used in the conjugate units (bearings and gear wheels are usually lubricated from a common oil reservoir). The use of oil with higher viscosity is advisable in the case of high loads and low velocities.

Efficiency of lubrication depends on the degree of separation of contact surfaces by the lubrication layer. To form an appropriate layer the lubricant must have a certain minimum viscosity, ν_1, at the operating temperature. The value of the minimum required kinematic viscosity ν_1 can be determined from the nomogram shown in Fig. 6.226, depending on the mean diameter d_m (mm) of the bearing and its rotational frequency n (min^{-1}). This nomogram corresponds to the results of the latest research in the field of the tribology of rolling bearings.

If the operating temperature of the bearing is known from field experience, or can be determined by other means, the kinematic oil viscosity ν at the base temper-

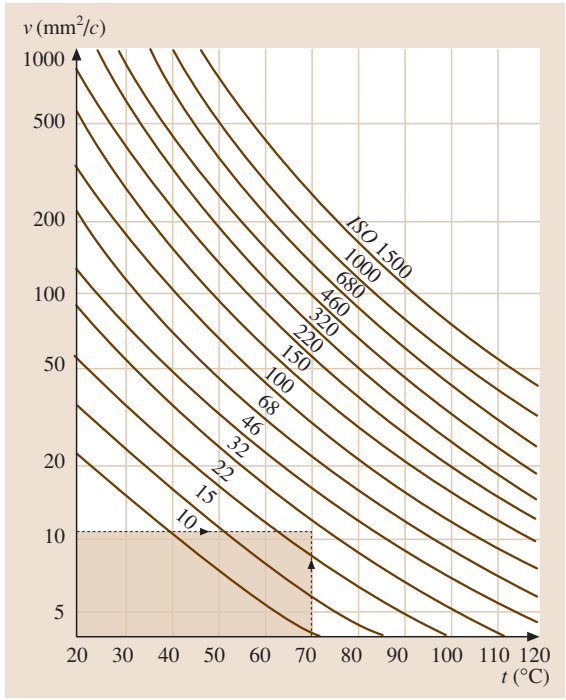

Fig. 6.227 Nomogram for defining kinematic oil viscosity ν of the base temperature 40 °C

ature of 40 °C can be determined from the nomogram shown in Fig. 6.227, depending on the required viscosity ν_1 and the operating temperature of the bearing. This nomogram is correct for oils with a viscosity index of VI 95. The higher the viscosity ν is at the base temperature, the higher the lifetime of the bearings, but with higher viscosity the operating temperature of the bearings increases.

The lubrication rate can be indirectly estimated by using the parameter of relative viscosity: $K = \nu/\nu_1$. With the relative viscosity $K < 1$ oil with antiscuffing additives (EP) is recommended, and with $K < 0.4$ the application of such oil is obligatory.

From the nomogram in Fig. 6.227 the kinematic oil viscosity ν at a base temperature of 40 °C can also be determined depending on the required viscosity ν_1 at the operating temperature of the bearing, i. e., the necessary viscosity class of oil can be determined.

Example

The viscosity class of oil for lubrication of a bearing with a hole diameter of $d = 340$ mm and an outer diameter of $D = 420$ mm, which is to run at the rotational frequency $n = 500\,\text{min}^{-1}$ and at an operating temperature of $t = 70$ °C, is to be determined.

Solution

The mean diameter of the bearing is $d_m = 0.5(d + D) = 0.5(340 + 420) = 380$ mm. From the nomogram in Fig. 6.226 it is determined that, for $d_m = 380$ mm and $n = 500\,\text{min}^{-1}$, the minimum kinematic oil viscosity ν_1 required for effective lubrication at the working temperature of the unit must not be lower than 11 mm²/s. From the nomogram shown in Fig. 6.227 we determine that, for a bearing operating at a temperature of 70 °C, oil with a viscosity of not less than 29 mm²/s at the standard temperature of 40 °C is necessary. Oil of the viscosity class ISO VG 32 is chosen (Table 6.94), the kinematic viscosity is $\nu = 32$ mm²/s at a temperature of 40 °C. Then from Fig. 6.227 the viscosity of the set oil at an operating temperature of 70 °C is determined as $\nu = 12.5$ mm²/s, and the relative viscosity parameter is calculated as $K = \nu/\nu_1 = 12.5/11 = 1.14$.

For most bearings with average dimensions (except roller spherical, tapered, and roller thrust bearings) that run under normal conditions oils with a kinematic viscosity of $\nu = 12$ mm²/s at working temperature are

recommended. For roller tapered and spherical bearings one uses $\nu = 20\,\mathrm{mm^2/s}$, and for roller thrust bearings one uses $\nu = 30\,\mathrm{mm^2/s}$. Oils with a viscosity of less than $12\,\mathrm{mm^2/s}$ are applied for high-speed compact bearings, especially when low starting moments are needed.

The most common oil supply methods in bearing units are the following: oil reservoirs, wicks and spraying, spiral grooves, cone nozzles, metering oilers, continuous flushing, periodic injection, oil mist, and air–oil mist.

For bearings running at moderate rotational frequencies and horizontal installation of the shaft the simplest lubrication methods are used, i. e., spray and oil reservoirs. In the latter case oil is filled into the case in such a way that its level is located in the center of the lower ball or roller (for a rotational frequency of up to $3000\,\mathrm{min^{-1}}$); for higher frequencies it is placed slightly lower.

Solid lubricants are used in the form of powders and thin coatings, or in the form of self-lubricated structural materials for the manufacture of retainers. Molybdenum disulfide, tungsten disulfide, graphite, fluorocarbon polymer, as well as composites made on their basis are the most often used solid lubricants. Solid lubricants are produced in the form of powders and pastes, or are colloid-dispersed or suspended in liquids and added to the lubricant materials or directly coated onto the components of the bearings, as well as in the form of briquette used for the manufacture of retainers. Metallic coatings of lead, silver, nickel, cobalt, indium, and gold are applied.

6.12.9 Position of the Adjacent with Bearing Components: Drawing of the Interior Structure

In a bearing unit, the contact of the component adjacent with the bearing needs to be foreseen only along the faces of the bearing races, in the height of the collar. Other surfaces of the adjacent components must be at a distance from the faces of the races of not less than in 2–3 mm (the dimension a in Fig. 6.228) for all bearing classes (except tapered roller bearings).

The design of mating components with a radial double-row spherical bearing must take into account that, in some dimension types of these bearings, the balls jut out of the faces of the races by 0.7–2.8 mm.

A peculiarity of the structure of the tapered roller bearing is the fact that the retainer juts out of the ranges of the outer race by distances m and n, as shown in Fig. 6.229a. This should be taken into account by installation of the adjacent components with the bearing, e.g., of slotted nuts (Fig. 6.229b) or by mounting of two bearings positioned side by side (Fig. 6.229c). The adjacent component must be at a distance from the face of the outer race of the tapered roller bearing of $b = 4$–6 mm. So that the cylindrical surfaces of the adjacent components do not touch the retainer, the heights h_1 and h_2 must not exceed the values

$$h_1 = 0.1(D-d); \quad h_2 = 0.05(D-d)\,.$$

For bearings with a larger cone angle one uses $h_1 = 0.08(D-d)$.

Therefore, a spacer ring (1) is mounted between the faces of the inner bearing race and the nut in the most common fastening of the tapered bearing with a round slotted nut (Fig. 6.229b). Approximately half of the length of the ring (1) overlaps with the shaft of diameter d made for installation of the bearing, and the rest of the length overlaps with the groove for the outlet of the tool for thread cutting.

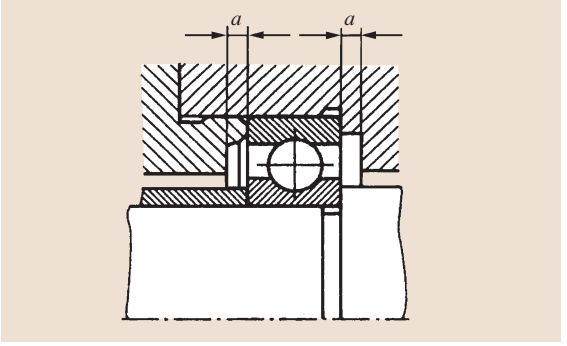

Fig. 6.228 Hookup of the adjacent components in the bearing unit

Drawing of the Interior Structure of Bearings

For the drawing of standard rolling bearings according to the overall dimensions d, D, and B the outer contour should be mapped with fine lines. Then for all bearing classes (except tapered roller bearings) the circle diameter $D_{pw} = 0.5(D+d)$ of the center position of the solids of revolution should be mapped. According to the formulas of Fig. 6.230a–e, the solids of revolution and rings are drawn.

Radial-thrust ball bearings (Fig. 6.230b) have only one ledge on the outer race. The second ledge is cut off. For sketching of the outer race from the side of the cut part an auxiliary vertical line is drawn to the intersection with the ball circle at point 1. The points 1 and 2

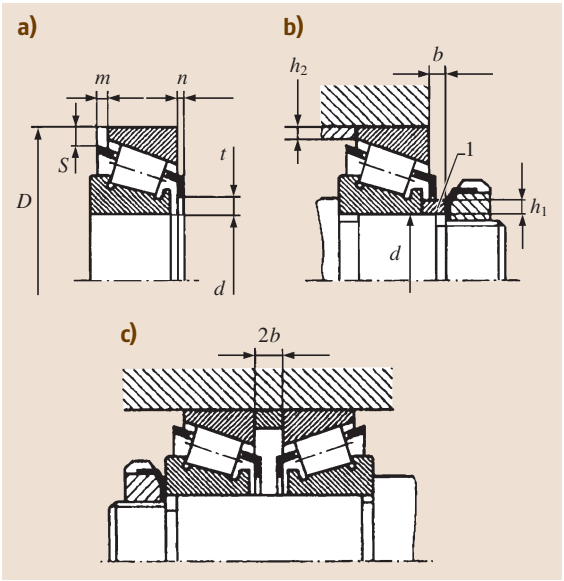

Fig. 6.229a–c Hookup of the adjacent components in the bearing unit with tapered roller bearings. **(a)** Peculiarities of the retainer structure, **(b)** allowable heights of the adjacent components, **(c)** allowable distance between two bearings

are joined. In ball radial double-row spherical bearings (Fig. 6.230c) the solids of revolution are represented in such a way that they do not touch the side lines of the outer contour. The spherical surface on the outer race is drawn as an arc of a circle with the center on the axis of the bearing hole.

For construction of tapered roller bearings (Fig. 6.230f) an auxiliary vertical line is drawn on the contour of the bearing that bisects the mounting height T of the bearing. Segment ab is divided by the points 1, 2, and 3 into four equal parts. From point 3 at an angle $\alpha = 15°$ the generating line of the cone is drawn up to its intersection with the pivot pin of the bearing at the point O. The lines O1 and O2 are drawn from this point. The segment $fk = 0.05(D - d)$ is mapped and the line fm is drawn transversely to the line O2. After the segment de is mapped, which is equal to fk, the line fm is drawn parallel to form a small face of the roller. To obtain the diameter d_2 of the ledge of the inner race a point

l is found that bisects the radius of the bigger face of the roller. The height h_1 of a small ledge of the inner race is $h_1 = 0.124D_w$, where $D_w = fm$ is the largest diameter of the roller. The retainers in the drawings of the bearings are not depicted [6.116–118].

Manufacturing is the set of activities converting raw materials into products in the most possible cost effective way, including design of goods, manufacturing parts and assembling them into products (subassemblies) using various production methods and techniques, the sale of products to customers, servicing, maintaining the product in good working order, and eventually recycling materials and parts. Whilst the design stage costs about 10–15% of all manufacturing costs, its effect on all other activities is enormous. The designed product has to be easy to make, easy to assemble, maintainable at a competitive cost level, and finally it should be economically recyclable. This is why concurrent engineering (CE) is a systematic approach integrating the design stage and manufacturing stage of products with a view to optimizing all elements involved in the life cycle of a product.

Due to the vast complexity of manufacturing engineering it can only be dealt with in a number of different chapters. The sections in this chapter illustrate the most important manufacturing processes from casting to assembly, from the first shape giving process to the last component integrative process. In between the reader will find a variety of manufacturing processes, including the most recent technologies, e.g. microbonding, nanotechnology, and others. Chapter 10 describes the front end of manufacturing, i. e. design, and Chap. 16 is allocated to quality assurance in manufacturing engineering. Finally, Chap. 17 is devoted to manufacturing logistics and manufacturing system analysis.

Manufacturing creates new wealth by its various value adding activities, including the addition of human knowledge and expertise to the products. Manufacturing provides products, which themselves are used to make other products and services, e.g. the machine tool industry is of vital importance for the well-being of a nation.

Manufacturing is the backbone of any industrialized nation contributing with approximately 20–30% of the value of all goods and services produced. However, it is increasingly difficult to meet customer demands and compete in the global market. Therefore manufacturing must be able to react speedily to changing market demands and to maximize the utilization of all resources, e.g. human (man), financial (money), equipment and buildings (machine), and time.

Manufacturing needs information on component parts to be produced (material, shape, features, size, accuracy/finish requirements, and batch size. This determines/affects the selection of most appropriate manufacturing technologies to be used, together with the selection of raw material, billets, etc., tool material (insert), tool life, tool assembly, tool type to be used together with the selection of type of machine tools (M/T) to be used, capabilities of M/T, work envelope, accuracy, power available, type of control, make of control, automatic tool change (ATC), pallet/workpiece changing facilities, swarf management, chip removal, tool interface type, tool holders, adapters required, accuracy, range of operational parameters (spindle speeds, feed rates, etc.), type of drive system, tool storage facilities, and others. This leads to process planning and manufacturing planning for the manufacturing sites. It is also very important to decide on part location and fixing and select or design the most suitable jigs, fixtures, and clamping.

Information related to all manufacturing activities is compiled in an integrated database with relevant access to any level of activity. However, it is of vital importance to verify data input and remove outdated information.

As manufacturing relies heavily on human involvement even in the case of fully automated systems, human ethics must not be violated or even overstretched due to the anatomy of the human, and thus requirements of ergonomics have to be met.

Not only must products fully meet design requirements and specifications, they have to be manufactured by the most economical methods in order to minimize costs.

Furthermore, quality must be manufactured into the product at each stage; the final testing is not enough. Therefore quality assurance (QA) plays a vital role in manufacturing from design through parts manufacture and assembly to after sales services. In a highly competitive market manufacturing methods must be sufficiently flexible to respond to changing market demands, types of products, production rates, production quantities, and on-time deliveries.

New developments in materials, production methods and computer integration of both technological and managerial activities in a manufacturing organization must constantly be evaluated with the view of imple-

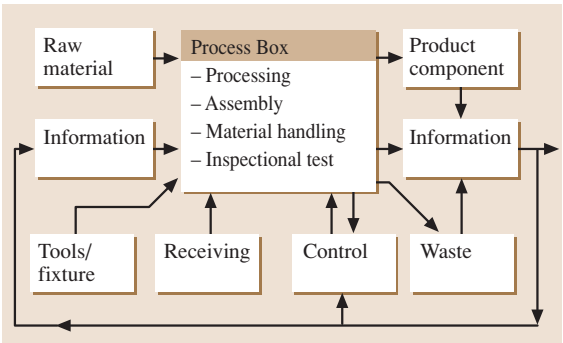

Fig. 7.1 A simplified process model for parts/product manufacturing

mentation. New materials meet new challenges at the design and parts manufacturing stages alike.

Manufacturing must be viewed as a system of activities and subsystems that are interrelated to others. These systems can be modeled to study the effect of various input factors.

A simplified process model can be used to illustrate parts/product manufacturing with input and output parameters as shown in Fig. 7.1.

It is important to note the role of information in the system and the number of feedback loops required to maintain the various functions in manufacturing.

7.1 Casting

7.1.1 The Manufacturing Process

Manufacturing is the production of workpieces of a geometrically defined shape. Unlike other production technologies, manufacturing technology produces products distinguished by material and geometric characteristics.

According to DIN 8580 [7.1] today's and tomorrow's many and varied manufacturing processes can be classified into six main groups (Fig. 7.2) according to the criteria *changing of material cohesion* (creation, preservation, increase, and reduction). These main groups are: primary shaping, forming, cutting, joining, coating, and changing of material properties. The main groups are subdivided into groups. Within these groups, the manufacturing processes themselves are distinguished by subgroups.

Casting is an important group of the main group *primary shaping*. The products of casting are so-called castings from metallic materials, so-called cast alloys. The foundry industry produces the castings.

7.1.2 The Foundry Industry

The foundry industry produces castings from metallic materials. Castings in various shapes and materials are to be found in all branches of engineering, such as in road and rail vehicles, machinery, the aerospace industry, electric power engineering, shipbuilding, pumps and fittings, electrical engineering, fine mechanics, architecture, electronics, medicine and optics, as well as office machines and cast art. Most technical products are not conceivable without castings.

Advantages of Casting Production

The following outlines the economical advantages resulting from the use of castings. It is based on two fundamental aspects: firstly, the overall consideration from melting to recycling, namely, recirculation of the metals within the framework of the national economy, and secondly, a comparison with other main groups of manufacturing such as forming, cutting and joining in accordance with DIN 8580 [7.1]. The advantages are the following:

- Exceptional freedom in the choice of shape
- Castability of all technically important metals
- Mechanical properties of cast materials that are no longer governed by those of the wrought materials
- Optimal components through the combination of material properties and shape
- Near net shape castings, i. e. reduced machining costs
- Integral castings, i. e. reduced assembly costs
- Tailored castings
- A high recycling rate, no down-cycling
- Material savings through the use of castings
- Ecological benefits
- When considered in overall terms, a lower specific use of energy on the whole

Production from the shapeless condition, i. e. the melt, and solidification in the prescribed cavity, i. e. sand or permanent mold, naturally enables great freedom in the choice of shape. It is possible to produce castings weighing less than 1 g and as much as 200 t, the weight only being restricted by handling and transport facilities.

There are very few restrictions with regard to the geometry of castings. All that can be drawn is also castable, but it is sometimes difficult to draw what is easy to cast.

High quality casting designs increasingly result from the incorporation of numerical simulation of mold filling and solidification, rapid prototyping, and simultaneous engineering. This takes place through close cooperation between foundrymen and designers. In the future it is expected that bionic and biological designing will provide new impulses for shaping. This will enable a large amount of freedom in the choice, thereby leading to full utilization of modern computer technology in the foundry industry.

Properties of Castings

Castings are produced from the following material groups: iron alloys (cast steel, cast iron), aluminum, magnesium, titanium, copper, zinc, tin, nickel, and cobalt alloys. All of these are cast alloys.

Independent of the type of production process, in the manufacture of metallic components by casting differentiation is always to be made between the material properties and the properties of the casting itself. In order to achieve a prescribed component characteristic the material and the geometry determine and complement each other in the properties of the component. These properties depend on the following:

- The geometry of the part
- The chemical composition of the cast material
- The treatment of the melted material (inoculation, modification, desulfurization, deoxidation, magnesium treatment, grain refinement, etc.)
- The type of molding and casting process
- The rate of cooling from casting to the ambient temperature
- The subsequent heat treatment
- The subsequent treatment of the outer layer (chemical-thermal process, surface deformation, surface alloying, surface remelting, etc.)
- Changes in the surface layer through machining
- The type of coating (painting, galvanizing, enameling etc.)

During the past decades the properties of cast alloys have also been further developed and considerably improved. For example, whereas in the 1950s only steel casting was able to achieve tensile strengths of more than 400 N/mm^2, today the designer has the choice of three higher strength groups of ferrous materials, i. e. spheroidal graphite cast iron, malleable cast iron, and cast steels. In many cases, this has enabled the highly economical substitution of forged and rolled steels.

There have also been further developments in nonferrous metal cast alloys, especially in the fields of aluminum and magnesium materials, which increasingly enable the use of these alloys in automotive manufacturing.

Consequently, the last decade has seen substantial rates of growth in the production of spheroidal graphite cast iron, as well as in aluminum and magnesium alloy castings. This is directly associated with the efforts towards light construction but also towards the reduction of total production costs.

The trend towards light construction is not only being realized with less dense cast materials, e.g. aluminum, but is also being achieved with higher density materials, e.g. spheroidal graphite cast iron. This is the result of the combined effect of material and shape as well as further development of casting technology.

In the selling of castings the material properties were traditionally (and often still are) taken as a basis for the contract, i. e. such material characteristics as yield strength, tensile strength, elongation at fracture, fatigue strength etc., which were determined from separately quasi simple geometrical samples. However, these samples only partially reflect the capabilities of the cast materials. Cast components are increasingly being designed on the basis of fracture mechanics. This shows that cast components are frequently unbeatable.

The Development of Casting Processes

The development of molding and casting processes during recent decades has led to the fact that the casting more and more approaches the shape of the finished part. The best results have been achieved with investment casting (lost wax molding process) and high pressure die casting, which can produce almost finished parts. These often require only minimum machining, e.g. fine machining of operating surfaces. Additionally, the development of weldable aluminum pressure die castings has enabled further possibilities of use.

Mechanical machining requires a relatively high amount of energy, the generation of 1 t of chips requiring the same amount of energy as that for the melting of 1 t of material.

The chips produced in machining the casting to the complete product, which can often result in a material utilization of less than 50%, should now be a thing of the past. The future lies in the production of near net shape castings with the resultant large savings in energy.

In many cases, groups of parts were and are being assembled from numerous individual components (turned, milled, and sheet metal components) by means of welding, riveting, bolting, etc. This type of assembly not only necessitates expensive manufacture of individual parts but also gives rise to considerable assembly costs.

The casting of integral components (one-piece-castings), through which the numerous previously necessary individual parts are combined in one casting, is an ideal way towards a new generation of parts. These integral castings can additionally better incorporate specific functional elements, resulting in considerable savings in material and energy.

Recycling is understood to be the return of material into the production process. In doing so, the aim is not to leave industrial production open-ended but, as with nature, to close the circuit, here material flows.

Recycling is in no way a new term for metallic materials but is rather a thousands of years old practice of returning metallic waste into the production process. Recycling of cast steel, cast iron, and cast nonferrous metals is a worldwide normal practice. Recycling of metallic materials leads to the saving of energy, preservation of our raw materials reserves, and thus to relief of our environment.

Development of the properties of the cast materials and the improvement of the molding and casting processes in the foundry industry have not only led to higher productivity but also material saving through:

- The reduction of wall thicknesses as a result of better pouring possibilities
- The use of higher strength materials
- Optimal casting design with, for example, ribbing or realization of hollow structures
- The reduction of machining allowances
- Material substitution, e.g. spheroidal graphite cast iron instead of forged steel and aluminum alloys instead of cast iron

These savings in materials reduce the weight of the components as well as the amount of machining. They also result in energy savings and thus preservation of the environment.

Overall consideration of component manufacture from the raw material to the finished part and taking account of recycling of metallic materials, i. e. an economic balance, illustrated that, by comparison with the other main production processes, the manufacture and use of castings results in substantial energy savings and thus ecological advantages, e.g. the reduction of CO_2.

From case studies, it is a well-known fact that, by comparison with other process variants, near net shape castings are clearly advantageous with regard to specific energy requirements for the finished components, especially with respect to machining from solid semiproducts. Component manufacture by casting is also clearly preferential when considering ecological aspects such as CO_2 emission.

Foundries pursue objective environmental management and confront public option with declarations of their achievements.

7.1.3 Cast Alloys

Cast alloys are metallic materials manufactured by primary shaping in a foundry. Cast alloys can be classified in two main groups: cast ferrous materials (cast irons and cast steels) and cast nonferrous materials (cast aluminum, cast magnesium, cast copper, and cast zinc alloys).

Cast Iron Alloys

Cast iron alloys can be classified into seven groups:

- Gray cast iron
- Spheroidal graphite cast iron
- Ausferrite spheroidal graphite cast iron
- Compacted graphite cast iron
- Malleable cast iron
- Austenitic cast iron
- Abrasion resisting alloyed cast iron

Cast Iron. The term *cast iron* designates an entire family of metallic materials with a wide variety of properties. It is a generic term like steel, which also designates a family of metallic materials. Steels and cast irons are both primarily iron with carbon as the main alloying element. Steels contain less than 2%, while all cast irons contain more than 2% carbon. About 2% is the maximum carbon content at which iron can solidify as a single phase alloy with all of the carbon in solution in austenite. Thus, the cast irons by definition solidify as heterogeneous alloys and always have more than one constituent in their microstructure.

In addition to carbon, cast irons also must contain appreciable silicon, usually from 1 to 3%, and thus they are actually iron-carbon-silicon alloys. The high carbon content and the silicon in cast irons make them excellent casting alloys. Their melting temperatures are appreciably lower than those of steel. Molten cast irons are more fluid than molten steel and less reactive with molding

materials. Formation of lower density graphite in cast iron during solidification reduces the change in volume of the metal from liquid to solid and makes production of more complex castings possible.

The various types of unalloyed cast irons cannot be designated by chemical composition because of similarities between the types. Unalloyed cast irons are designated by their mechanical properties. High-alloy cast irons are designated by their chemical composition and mechanical properties. These have a wide range in chemical composition and also contain major quantities of other elements.

The presence of certain minor elements is also vital for the successful production of each type of cast iron. For example, nucleating agents, called inoculants, are used in the production of gray cast iron to control the graphite type and size. Trace amounts of bismuth and tellurium in the production of malleable cast iron, and the presence of a few hundredth of a percent of magnesium causes the formation of spheroidal graphite cast iron.

In addition, the composition of a cast iron must be adjusted to suit particular castings. Small castings and large castings of the same grade of cast iron cannot be made from the same composition of alloy. For this reason, most cast iron castings are purchased on the basis of mechanical properties rather than composition. The common exception is for castings that require special properties such as corrosion resistance or elevated temperature strength.

The various types of cast iron can be classified according to their microstructure. This classification is based on the form and shape in which the major portion of carbon occurs in the cast irons. This system provides for five basic types of gray cast iron, spheroidal graphite cast iron, malleable cast iron, compacted graphite cast iron, and white cast iron. Each of these types may be moderately alloyed or heat treated without changing its basic classification. The high-alloyed cast irons, generally containing over 3% of added alloying element, can also be individually classified as gray or spheroidal graphite cast iron or white cast iron, but the high-alloyed cast irons are classified as a separate group.

Gray Cast Iron. When the composition of a molten cast iron and its cooling rate are appropriate, the carbon in the cast iron separates during solidification and forms separate graphite flakes that are interconnected within each eutectic cell (EN 1561). The graphite grows edgewise into the liquid and forms the characteristic flake shape. When gray cast iron is broken, most of the fracture occurs along the graphite, thereby accounting for the characteristic gray color of the fractured surface.

Because the large majority of iron castings produced are of gray cast iron, the generic term is often improperly used to mean gray cast iron specifically.

The properties of gray cast iron are influenced by the size, amount, and distribution of the graphite flakes, and by the relative hardness of the matrix metal around the graphite. These factors are controlled mainly by the carbon and silicon contents of the metal and the cooling rate of the casting. Slower cooling and higher carbon and silicon contents tend to produce more and larger graphite flakes, a softer matrix structure, and lower strength. The flake graphite provides gray cast iron with unique properties such as excellent machinability at hardness levels that produce superior wear-resisting characteristics, the ability to resist galling, and excellent vibration damping.

The amount of graphite present, as well as its size and distribution, are important to the properties of the cast iron. Wherever possible, it is preferable to specify the desired properties rather than the factors that influence them.

Microscopically, all gray cast irons contain flake graphite dispersed in a iron-silicon matrix. How much graphite is present, the length of the flakes, and how they are distributed in the matrix directly influence the properties of the cast iron.

The basic strength and hardness of the cast iron is provided by the metallic matrix in which the graphite occurs. The properties of the metallic matrix can range from those of a soft, low-carbon steel to those of hardened, high-carbon steel. The matrix can be entirely ferritic for maximum machinability, but the cast iron will have reduced wear resistance and strength. An entirely pearlitic matrix is characteristic of high-strength gray cast iron, and many castings are produced with a matrix microstructure of both ferrite and pearlite to obtain intermediate hardness and strength. Alloying element additions and/or heat treatment can be used to produce gray cast iron with very fine pearlite or with an acicular matrix structure.

Graphite has little strength or hardness, so it decreases these properties of the metallic matrix. However, graphite provides several valuable characteristics to gray cast iron: the ability to produce sound castings economically in complex shapes, good machinability, even at wear-resisting hardness levels and without burring, dimensional stability under different heating, high vibration damping, and borderline lubrication retention.

The properties of gray cast iron primarily depend on its chemical composition. The lower strength grades of gray cast iron can be produced consistently by simply selecting the proper melting stock. Grey cast iron castings in the higher strength grades require close control of their processing and chemical composition.

The majority of the carbon in gray cast iron is present as graphite. Increased amounts of graphite result from an increased total carbon content in the gray cast iron. This decreases the strength and hardness of the gray cast iron, but increases other desirable characteristics.

An appreciable silicon content is necessary in gray cast iron because this element causes the precipitation of the graphite in the material. The silicon also contributes to the distinctive properties of the gray cast iron. It maintains a moderate hardness level, even in the fully annealed condition, and thus assures excellent machinability. Also, silicon imparts corrosion resistance at elevated temperature and oxidation resistance in gray cast iron.

Gray cast iron can be alloyed to increase its strength and hardness as-cast or its response to hardening by heat treatment.

A very important influence on gray cast iron properties is the effective section thickness in which it is cast. The thicker the wall and the more compact the casting, the lower the temperature at which liquid metal will solidify and cool in the mold. As with all metals, slower solidification causes a larger grain size to form during solidification. In gray cast iron, slower solidification produces a larger graphite flake size.

Gray cast iron is commonly classified by its minimum tensile strength or by hardness (Table 7.1). The mechanical properties of gray cast iron are determined by the combined effect of its chemical composition, processing technique in the foundry, and the solidification and cooling rates. Thus, the mechanical properties of the gray cast iron in a casting will depend on its shape, size and wall thickness as well as on the gray cast iron that is used to pour it. Five grades of gray cast iron are classified by their tensile strength in EN 1561. The grades of gray cast iron also can be specified by Brinell hardness only. The chemical composition and heat treatment, unless specified by the purchaser, shall be left in the direction of the manufacturer, who shall ensure that the casting and heat treatment process is carried out with the same process parameters.

Spheroidal Graphite Cast Iron. Spheroidal graphite cast iron or ductile iron (EN 1563) is characterized by the fact that all of its graphite occurs in microscopic spherolites. Although this graphite constitutes about 10% by volume of this material, its compact spheroidal shape minimizes the effect on mechanical properties.

The difference between the various grades of spheroidal graphite cast irons is in the microstructure of the material around the graphite, which is called the matrix. This microstructure varies with the chemical composition and the cooling rate of the casting. It can be slowly cooled in the sand mold for a minimum hardness as-cast condition or, if the casting has sufficiently uniform sections, it can be shaken out of the mold while still at a temperature above the critical and normalized.

The matrix microstructure and hardness can also be changed by heat treatment. The high ductility grades are usually annealed so that the matrix structure's ferrite is entirely free of carbon. The intermediate grades are often used in the as-cast condition without heat treatment and have a matrix structure of ferrite and pearlite. The ferrite occurs as rings around the graphite spheroids. Because of this, it is called bull-eye ferrite. The high-strength grades are usually given a normalizing heat treatment to make the matrix all pearlite, or they are quenched and tempered to form a matrix of tempered martensite. However, spheroidal graphite cast iron can be moderately alloyed to have an entirely pearlitic matrix as-cast condition.

The chemical composition of spheroidal graphite cast iron and the cooling rate of the casting directly affect its tensile properties by influencing the type of matrix structure that is formed. All of the regular grades of the spheroidal graphite cast iron can be made from the same cast iron provided that the chemical composition is appropriate so that the desired matrix microstructure can be obtained by controlling the cooling rate of the casting after it is poured or by subsequent heat treatment. For most casting requirements, the chemical composition of the spheroidal graphite cast iron is primarily a matter of facilitating production.

The common grades of spheroidal graphite cast iron differ primarily in the matrix structure that obtains the spheroidal graphite. These differences are the result of differences in the chemical composition, in the cooling rate of the casting, or the result of heat treatment.

13 grades of spheroidal graphite cast iron are classified by their tensile properties or hardness in EN 1563 (Table 7.2). The common grades of spheroidal graphite cast iron also can be specified by only Brinell hardness. The method of producing spheroidal graphite, the chemical composition and heat treatment unless will be specified by the purchaser.

Ausferrite Spheroidal Graphite Cast Iron. This group of spheroidal graphite cast iron (ISO/WD 17804, ASTM 897-90) is well known as ADI (austempered cast iron), and recently as ausferrite spheroidal graphite cast iron. The development of ausferrite spheroidal graphite cast iron has given the design engineer with a new group of cast ferrous materials that offer the exceptional combination of mechanical properties equivalent to cast and forged steels and production costs similar to those of conventional spheroidal graphite cast iron.

Ausferrite spheroidal graphite cast iron provides a wide range of properties, all produced by varying the heat treatment (austempering) of the same castings. Austempering is a special heat treatment process, which consists of three steps:

- Austenitize in the temperature range of 840–950 °C for a time sufficient to produce a fully austenitic matrix that is saturated with carbon.
- Rapidly cool the entire part to an austempering temperature in the range of 230–400 °C without forming pearlite or allowing the formation of ausferrite to begin.
- Isothermally treat at the austempering temperature to produce ausferrite with an austenite carbon content in the range of 1.8–2.2%.

After heat treatment (austempering) the matrix consists of acicular ferrite and residual austenite without carbides.

Six grades of ausferrite spheroidal graphite cast iron are classified by their tensile properties in ISO/WD 17804 and two abrasion resistant grades are classified by Vickers hardness.

Compacted Graphite Cast Iron. Compacted graphite cast iron (vermicular graphite cast iron, VDG-sheet W50) is a recent addition to the family of commercially produced cast irons (Table 7.4). Its characteristics are between of the gray cast iron and spheroidal graphite cast iron. The graphite in compacted graphite cast iron is in the form of interconnected flakes. The short span and blunted edges of graphite in this material provide improved strength, some ductility and a better machined finish than gray cast iron. The interconnected compacted graphite cast iron provides slightly higher thermal conductivity, more damping capacity, and better machinability than those obtained with spheroidal graphite cast iron.

Compacted graphite cast iron provides similar tensile and yield strengths to ferritic spheroidal graphite cast iron and malleable cast iron, although the ductility is less.

Malleable Cast Iron. The starting point is a cast iron in which the carbon and silicon contents are arranged so that the casting is graphite-free after solidification, the entire carbon content being bonded to the iron carbide (cementite). If the casting is then heat-treated (tempered), the cementite decomposes without residue.

Two kinds of malleable cast iron are distinguished:

- White malleable cast iron, which is decarbonized during heat treatment; and
- black malleable cast iron, which is not decarbonized during heat treatment

White malleable cast iron (EN 1562) is produced by heating for 50–80 h at about 1050 °C in a decarburizing atmosphere (CO, CO_2, H_2, H_2O). In this process carbon

is removed from the casting, so that after cooling a purely ferritic microstructure is in the casting. White malleable cast iron with small cross sections is welds well.

Black malleable cast iron is produced by heating in a neutral atmosphere, first for about 30 h at 950 °C. In this process the cementite of the ledeburite decomposes into austenite and graphite (temper carbon), which is precipitated in fluky clusters. In a second step of the heat treatment the austenite is converted during slow cooling from 800 to 700 °C into ferrite and temper carbon or transformed during quick cooling into pearlite and temper carbon.

In EN 1562 five grades of white malleable cast iron and nine grades of black malleable cast iron are classified by tensile strength.

Austenitic Cast Iron. High-alloy cast iron is used to produce components that require resistance to corrosives in the operating environment such as seawater, sour well oils, commercial organic and inorganic acids, and alkalis. The ability to easily cast it into complex shapes and the ease of machining some types of this material, make high-alloy cast iron an attractive material for the production of components for chemical processing plants, petroleum refining, food handling, and marine service. Two types dominate high alloy corrosion resistant cast iron: nickel-alloyed cast iron (austenitic cast iron, EN 13835) and high-Si cast iron.

Nickel-alloyed cast iron owes its excellent corrosion resistance to the presence of nickel in concentrations of 12.0–36.0%, a chromium content of 1.0–5.5% and, in one type, s copper content of 5.5–7.5%. These cast irons have an austenitic matrix.

Ten grades of austenitic cast iron with spheroidal graphite and two grades of austenitic cast iron with flake graphite are classified in EN 13835 by chemical composition and mechanical properties, like austenitic steels.

The mechanical properties of austenitic cast iron with spheroidal graphite and with flake graphite are shown in Table 7.6.

Abrasion Resisting Alloyed Cast Iron. High-alloy white cast iron (EN 12513) is specially qualified for abrasion-resistant applications. The predominant carbides in its microstructure provide the high hardness necessary for crushing and grinding other materials without degradation. The supporting matrix structure may be adjusted by alloy content and/or heat treatment to develop the most cost-effective balance between resistance to abrasive wear and the toughness required to withstand repeated impact loading. High-alloy white cast iron is easily cast into shapes required for crushing and grinding or the handling of abrasive materials.

Abrasion resistance concerns the conditions under which a metal or alloy is used. The ability of a part to resist a weight loss due to abrasion depends upon its microstructure, the actual mechanical operations of the part, and the kind and size of material being moved, crushed or ground.

Most of the white cast iron designated for abrasion-resistant applications falls within the high-alloy cast iron category, but unalloyed white cast iron is common and provides satisfactory service where the abrading material is not fine or where replacement is not frequent or expensive. All alloyed cast iron contains chromium to prevent the formation of graphite and to ensure the stability of the carbides in the microstructure. Alloy white cast iron also may contain nickel, molybdenum, copper, or a combination of these alloying elements to prevent or minimize the formation of pearlite in the microstructure.

Unalloyed white cast iron castings develop hardnesses in the range 350–550 BHN. Their microstructures consist of primary iron carbides with a microhardness of 900–1200 VHN in a pearlitic matrix with a microhardness of 220–300 VHN. Alloyed martensitic white cast iron, however, develops Brinell hardnesses in the 500–700 range. The carbide hardness remains 900–1200 VHN, but martensitic, always associated

with some retained austenite, exhibits a microhardness of 600–700 VHN. For many abrasion-resistant applications; the more costly alloyed white cast iron with martensitic matrix structures provide the most economical service.

EN 12513 covers the composition and hardness of abrasion-resistant white cast iron. Martensitic white cast iron falls into two major groups:

- The low-chromium group with 1–4% chromium and 3–5% nickel
- The high-chromium white cast iron containing 14–28% chromium with 1–3% of molybdenum, often alloyed further with additions of nickel and copper

A third but minor category comprise the straight 25–28% chromium white cast iron.

Cast Steel

Cast steels can be classified into four groups:

- Cast carbon and cast low-alloy steel
- Cast high-alloy steel
- Cast stainless steel
- Cast heat-resisting steel

Cast Carbon and Cast Low-Alloy Steel. This group of cast steels consists of many subgroups: steel castings for general purposes (DIN 1681, EN 10293 steel casting for general engineering uses), steel casting for pressure purposes (partially EN 10213), steel castings with improved weldability and toughness for general purposes (DIN 17182, EN 10293 steel castings for general engineering uses, draft), quenched and tempered steel castings for general purposes (DIN 17205, EN 10293 steel castings for general engineering uses, draft), steel castings for use at room temperature and elevated temperatures (EN 10213-2), and steel castings for use at low temperatures (EN 10293-3).

Carbon steel is considered to be steel in which carbon is the principal alloying element. Other elements that are present and that, in general, must be reported are manganese, silicon, phosphorus, and sulfur. In a sense, all of these elements are *residuals* from the raw materials (coke, iron ore) used in the manufacture of the steel, although the addition of manganese is often made during the steelmaking process to counter the deleterious effect of sulfur.

Low-alloy cast steels are considered to be those steels to which elements (other than carbon) are added deliberately to improve mechanical properties.

For all cast carbon and cast low-alloy steels, the mechanical properties are controlled by the chemical composition, the heat treatment and the microstructure of these cast steels. Among the exceptions are the effect of carbon on increasing hardness, the effect of nickel on increasing toughness, and the effect of combinations of chromium, molybdenym, vanadium, and tungsten on increasing elevated temperature strength. The major reason for using alloying elements in low-alloy cast steels is to make the role of heat treatment on increasing strength effective over a wide range of material thickness by quenching and tempering. This effectiveness is termed *hardenability*.

30 grades of steel castings for general engineering uses (5 grades of carbon cast steels, 20 grades of low alloy cast steels, and 5 grades of high alloy cast steels) are classified by their chemical composition, heat treatment processes (austenitizing, air cooling/austenitizing, quenching, tempering), and mechanical properties in EN 10293 (Table 7.7).

EN 10213 consists of steel castings for pressure purposes, in specially cast steel grades for use at room temperature and elevated temperatures (carbon cast steels, low alloy cast steels, high alloy cast steels), cast steel grades for use at low temperatures (low alloy cast steels, high alloy cast steel), and cast austenitic and austenitic-ferritic steel grades (high alloy cast steel grades).

High-Alloy Cast Steel. There are two main groups of high-alloy cast steels: cast stainless steels and cast heat-resisting steels.

Cast Stainless Steel. Cast stainless steels (EN 10213, EN 10283, SEW 410) are distinguished by special resistance to chemically corrosive substances; in general, they have a chromium content of at least 12 wt %. The cast stainless steels in EN 10213, EN 10283, and SEW 410 are subdivided into martensitic, ferritic-carbidic, ferritic-austenitic, austenitic, and full austenitic steels. Cast stainless steels are suitable for welding. Their resistance to intercrystalline corrosion in mill finish is an important property of cast stainless steels.

A special kind of cast stainless steels are the duplex-steels (dual phase steels) with about 50% austenite and 50% soft martensite, in which the two phases fulfil different functions: the austenite guarantees corrosion

Table 7.7 Mechanical properties of steel castings for general engineering uses

protection, e.g. seawater resistance in this case, the soft martensite guarantees component strength.

In EN 10213, EN 10283, and SEW 410 44 grades of cast stainless steels are classified by chemical composition and mechanical properties. The main alloying elements are chromium, nickel, and molybdenum.

Heat-Resisting Cast Steel. The chief requirement for heat-resisting cast steels (EN 10295, SEW 471, SEW 595) is not especially good high-temperature strength but sufficient resistance to hot gas corrosion in the temperature range above 550 °C. The highest temperature at which a heat-resisting steel can be used depends on operational conditions. Recommended temperatures for air and hydrogen atmospheres are up to 1150 °C depending on the chemical composition.

The scaling limit temperatures for the heat-resisting steels is defined as the temperature at which the material loss in clean air is 0.5 mg cm^{-2} h^{-1}.

The scale resistance of heat-resisting cast steels is based on the formation of dense, adhesive surface layers of oxides of the alloying elements chromium, silicon, and aluminum. The protective effect starts when the chromium content is 3 to 5%, but chromium contents up to 30% can be alloyed. The protective effect of these layers is limited by the corrosive low-melting-point eutectics and by carburizing. To increase the heat resistance the alloying element nickel is added in addition to chromium (Cr + Ni = 25–35%).

In EN 10295, SEW 471, and SEW 595 25 grades of heat-resistant cast steels are classified by the chemical composition and the mechanical properties. The main alloying elements are chromium, silicon, and nickel.

The creep behavior with the creep rupture strength and the creep limit in the temperature range of 600 up to 1100 °C is the most important.

Cast Nonferrous Alloys

The cast nonferrous alloys are classified into four main groups:

- Cast aluminum alloys
- Cast magnesium alloys
- Cast copper alloys
- Cast zinc alloys

There are other groups: for example, cast titanium alloys, cast tin alloys, cast lead alloys, cast nickel alloys, cast cobalt alloys, etc.

Cast Aluminum Alloys. The specification of a cast aluminum alloy (EN 1706) for a cast component is based upon the mechanical properties it can achieve. These properties are obtained from one particular combination of cast alloy, melt treatment (grain refining, modification) foundry practice, and thermal treatment. In all cast aluminum alloys the percentage of alloying elements and impurities must be carefully controlled.

The main alloying elements of the cast aluminum alloys are copper, silicon, magnesium, and zinc. Grain refiners, which are usually materials that liberate titanium, boron, or carbon, are generally added in the form of master-alloy to the melt. In casting alloy this is a well-proven method to influence the nucleation conditions in a melt, so that it solidifies with as fine-grained and dense a structure as possible. Hypereutectic aluminum-silicon alloys can be grain-refined with additions that release phosphorus, which promotes the nucleation of primary silicon. Modifying aluminum-silicon alloys of eutectic and hypereutectic composition means treating the melt to binder primary silicon from precipitating to form coarse, irregularly shaped particles. The melt can be modified by adding capsules of metallic sodium or compounds that release sodium. Alternatively, the addition of strontium has proved successful in castings. In contrast to sodium, which burns off and is lost fairly quickly, strontium lasts longer.

Industrial casting processes consist of traditional sand casting, low-pressure sand casting, investment casting, lost-foam casting, permanent mold casting, high pressure die casting, low-pressure permanent mold casting, back-pressure die casting, vacuum die casting, squeeze casting, and thixocasting.

Sand and permanent mold castings may be heat treated to improve mechanical and physical properties. The following thermal treatments are industrially used:

- Stress relief or annealing
- Solution heat treatment and quenching, artificial aging

- Solution heat treatment, quenching, and artificial overaging (for the groups 1, 2 and 4 in Table 7.10)

In EN 1706 37 grades of cast aluminum alloys are classified by their chemical composition and mechanical properties (Table 7.10). The mechanical properties depend on the chemical composition of the cast aluminum alloys, the casting technology, and the heat treatment process.

Cast Magnesium Alloys. Magnesium combines a density two-thirds that of aluminum and only slightly higher than that of fiber-reinforced plastics with excellent mechanical and physical properties as well as processability and recyclability.

Cast magnesium alloys (EN 1753) can be divided into two groups: the sand-casting alloys that have a fine grain structure due to a melt treatment with small additions of zirconium, and the die casting alloys, in which aluminum is the principal alloying element. The alloys can also be classified as general purpose, high ductility, and high temperature alloys. Most of the alloys are produced as high-purity versions to reduce potential corrosion problems associated with higher levels of iron, nickel, and copper.

Aluminum improves the mechanical strength, corrosion properties, and castability of the castings. Ductility and fracture toughness are gradually reduced with increasing aluminum content.

Manganese is added to control the iron content of the alloys. The level of manganese additions varies from one alloy to the next, depending on the mutual solubilities of iron and manganese in the presence of other alloying elements. A basic requirement of high-purity alloys is that the iron content of diecast parts is limited to a maximum of 0.005 wt %. Other impurities like nickel and copper also must be strictly controlled. Other alloying elements are zinc, manganese, silicon, copper, zirconium, and rare earth elements.

Following are some of the advantages magnesium alloys offer casting designers:

- *Light weight* – The lightest of all structural alloys, magnesium alloys preserves the light weight of a design without sacrificing strength and rigidity.
- *High stiffness to weight ratio* – This characteristic is important where resistance to deflection is desired in a light-weight component.
- *Damping capacity* – Magnesium is unique among metals because of its ability to absorb energy inelastically. This property yields the vibration absorption capacity to ensure quieter operation of equipment.
- *Dimensional stability* – Annealing, artificial aging or stress-relieving treatments normally are not necessary to achieve stable final dimensions.
- *Impact and dent resistance* – The elastic energy absorption characteristics of magnesium alloys result in a good impact and dent resistance and energy management.
- *Anti-galling* – Magnesium alloys possess a low galling tendency and can be used as a bearing surface in conjunction with shaft hardness above 400 HB.
- *High conductivity* – Magnesium alloys have a high thermal conductivity and a good electrical conductivity.
- *Wall thickness* – Magnesium alloy die castings are commonly produced with a wall thickness from 0.15 to 0.4 cm.

Magnesium alloys can be cast by a variety of methods, including high-pressure die casting, low pressure permanent mold casting, sand casting, plaster/investment casting, and thixocasting and squeeze casting.

Different alloys may be specified for the different processes. In cases where the same alloy is used with different casting processes, it is important to note that the properties of the finished castings will depend on the casting method. The most prevalent casting method

for magnesium alloys is die casting. In this process, thin-walled parts are produced at high production rates with reduced tool wear compared to aluminum alloys, due to the lower heat content per volume of molten metal. Both hot chamber and cold camber machines are currently used for magnesium alloys. Thixocasting is another casting method that has shown progress with magnesium alloys.

There are seven cast magnesium alloys in EN 1753.

Cast Copper Alloys. Cast copper alloys (EN 1982) are known for their versatility. They are used in a wide range of applications because they are easily cast, have a long history of successful use, are readily available from a multitude of sources, can achieve a range of physical and mechanical properties, and are easily machined, brazed, soldered, polished, or plated.

The following lists the physical and mechanical properties common to cast copper alloys:

- Good corrosion resistance, which contributes to the durability and long-term cost-effectiveness.
- Favorable mechanical properties ranging from pure copper, which is soft and ductile, to manganese-bronze, which rivals the mechanical properties of quenched and tempered steel. In addition, all cast copper alloys retain their mechanical properties, including impact toughness at low temperatures.
- High thermal and electrical conductivity, which is greater than any metal except silver. Although the conductivity of copper drops when alloyed, cast copper alloys with low conductivity still conduct both heat and electricity better than other corrosion-resistant materials.
- Bio-fouling resistance, as copper inhibits marine organism growth. Although this property (unique to copper) decreases upon alloying, it is retained at a useful level in many alloys, such as copper-nickel.
- Low friction and wear rates, such as with the high-leaded tin-bronzes, which are cast into sleeve bearings and exhibit lower wear rates than steel; good castability, as all cast copper alloys can be sand cast and many can be centrifugally, continuously, and permanent mold cast, as well as diecast.
- Good machinability, as the leaded copper alloys are free-cutting at high machining speeds, and many unleaded alloys such as nickel-aluminum bronze are readily machinable at recommended feeds and speeds with proper tooling.
- Ease of post-casting processing, as good surface finish and high tolerance control is readily achieved. In addition, many cast copper alloys are polished to high luster, and platting, soldering, and welding also are routinely performed.
- Large alloy choice, since several alloys may be suitable candidates for any given application depending upon design loads and corrosivity of the environment.
- Comparable costs to other metals due to their high yield, low machining costs, and little requirement for surface coatings such as paint.

In EN 1982 the cast copper alloys are divided into cast copper, cast copper-chromium, cast copper-zinc, cast copper-tin, cast copper-tin-lead, cast copper-aluminum, cast copper-manganese-aluminum, and cast copper-nickel alloys.

35 grades of cast copper alloys are classified by their chemical composition and mechanical properties in EN 1982.

Cast Zinc Alloys. Cast zinc alloys (EN 1774 and EN 12844) are assigned to three alloy groups. The first group of alloys have 4% aluminum as the primary alloying element with 0.099% or less magnesium to control intergranular corrosion. Another alloying element is copper. The alloys with the highest copper content have the highest hardness. The mechanical properties can be improved with 0.005 to 0.2% nickel as alloying element. The second group has higher aluminum contents (8 to 27%) These alloys have superior hardness, wear and creep resistance that increase with the aluminum content. The third group is a cast zinc alloy that has copper as the primary alloying element. Castings of the cast zinc alloys are manufactured by the high pressure die casting.

In EN 12844 8 grades of cast zinc alloys are classified by their chemical composition and mechanical properties.

7.1.4 Primary Shaping

According to DIN 8580 [7.1], primary shaping is the manufacturing of a solid body from a shapeless material by creating cohesion. Thus primary shaping serves to give a component made from a material in shapeless condition an initial form. Shapeless materials are gases, liquids, powders, fibers, chips, granules, solutions, melts, and the like. Primary shaping may be divided into two groups with regard to the form of the products and their further processing:

- Products produced by primary shaping, which will be further processed by forming, severing, cutting, and joining. The final product no longer resembles the original product of primary shaping in form and dimensions, i. e. a further material change in shape and dimensions is accomplished by means of other main groups of manufacturing processes.
- Products produced by primary shaping, which essentially have the form and dimensions of finished components (e.g. machine parts) or end-products, i. e. their shape essentially corresponds to the purpose of the product. The attainment of the desired final form and dimensions usually requires only operations that fall into the main process group *cutting* (machining).

Most powders are produced by primary shaping, whereby the powders are atomized out of the melt, and rapid solidification is followed. From powder, sintering parts are produced as a result of powder metallurgical manufacturing.

The production of cast parts from metallic materials in the foundry industry (castings), from metallic materials in powder metallurgy (sintered parts), and from high-polymer materials in the plastics processing industry has major advantages for economic efficiency.

The production of cast parts is the shortest route from the raw material to the finished part. It bypasses the process of forming and all the associated expense. The final form of a finished component with a mass ranging from a few grams to several hundred tonnes is practically achieved in one direct operation.

The production of cast parts by primary shaping from the liquid state allows the greatest freedom of design. This cannot be achieved by any other manufacturing process.

Primary shaping also enables processing of materials that cannot be achieved by means of other manufacturing methods. The direct route from the raw material to the preform or the end-product results in a favorable material and energy balance.

The continual further development of primary shaping processes increasingly permits the production of components and end-products with enhanced practical characteristics, i. e. cast parts with lower wall thicknesses, lower machining allowances, narrower dimensional tolerances, and improved surface quality.

In the following, primary shaping of metallic materials from the liquid state in foundry technology, of metallic materials from the solid state in powder metallurgy, and of high-polymer materials (plastics) from the plasticized state or from solutions is discussed on a common basis with regard to the fundamental technological principles. The discussion is restricted to subjects relevant to mechanical engineering.

For a better appreciation of the relevant principle of action, many detailed technological operations are omitted, which although vital to the specific manufacturing technology, are of minor importance. Furthermore, when discussing the specific primary shaping processes, only products with a simple form are referred to, because the diversity of the possible geometric forms cannot be described here.

Only the most important primary shaping processes are selected, as the large number of technological processes and process variables means that it is impossible to provide anything like a complete description. The

processes are selected first according to their technical importance and second according to the principle of action.

Materials technology problems will only be mentioned briefly, although they are vital in order to understand the technological processes, their applicability and efficiency, and the changes in material properties brought about by the technological processes.

Process Principle in Primary Shaping

In the processes of primary shaping, the technological manufacturing process essentially comprises the following steps:

- Supply or production of the raw material as an amorphous substance
- Preparation of a material state ready for primary shaping
- Filling of a primary shaping tool with the material in a state ready for primary shaping
- Solidification of the material in the primary shaping tool
- Removal of the product of primary shaping from the primary shaping tool

These individual steps are discussed in the following section.

Material State Ready for Primary Shaping

In primary shaping of metallic materials from the liquid state, the raw materials (pig-iron, scrap, ferroalloys and the like) are melted in a metallurgical melting furnace by means of thermal energy. The melting furnaces are usually physically separated from the primary shaping tool. The molten metal is carried by means of transfer vessels (ladles) to the primary shaping tools, termed molds in the foundry industry, and cast there.

In primary shaping of high-polymer materials from the plasticized state, bulk raw materials (granules, powder) are fed after proportioning into a preparation device, which is usually integral with the primary shaping tool. There, thorough mixing, homogenizing and plasticizing of the material to be processed are accomplished under the action of heat and pressure. When solutions are used, these are produced in a mixing unit and then poured into the primary shaping tool. In primary shaping of metallic and also high-polymer materials from the solid state, the bulk raw materials (metal powder, plastic powder, or plastic granules) are poured straight into the primary shaping tool, where they sinter, or first become plastic and then solidify under the action of pressure and thermal energy.

Primary Shaping Tools

The primary shaping tool contains a hollow space which, with the allowance for contraction, usually corresponds to the form of the product (unmachined part) to be manufactured, but may be smaller or larger than the resulting unmachined part. Furthermore, primary shaping tools often contain systems of channels (runners) for feeding the material in the state ready for primary shaping. The allowance for contraction corresponds to the dimensional changes that occur in the material to be processed from the moment of solidification to its cooling to room temperature.

In the production of cast parts, a distinction is made between primary shaping tools for once-only use and those for repeated use. Primary shaping tools for once-only use are only used for primary shaping of metallic materials from the liquid state in foundry technology. They are termed expendable or *dead* molds. Only one product (casting) can be manufactured, as the mold is subsequently destroyed. However, primary shaping tools for repeated use (permanent molds) are also used in foundry technology. A larger quantity of cast parts can be produced. The primary shaping technologies for processing of high-polymer materials and powder metallurgy use only primary shaping tools for repeated use. Primary shaping tools for repeated use are usually made of metallic, and more rarely of nonmetallic, materials. Primary shaping tools for once-only use (dead molds) are made with the aid of patterns.

Filling the Primary Shaping Tools

Filling of the primary shaping tools with the material ready for primary shaping may be accomplished by means of the following principles of action: under the influence of gravity, elevated pressure or centrifugal force and by displacement. The material to be processed can be put into the primary shaping tools in solid, pourable form (e.g. powder), as molten metal in the case of metallic materials, or in plasticized condition, as a solution or as a paste in the case of high-polymer materials.

Change of State Ready for Primary Shaping

Shaping into the Solid State of Aggregation. Liquid metallic materials (molten metals) change by crystallization to the solid state of aggregation on cooling owing to the removal of heat.

Thermoplastics are cooled in the primary shaping tool after forming. As a result of temperature reduction, which is accomplished either by heat removal in cooled tools or in downstream equipment

(cooling baths), the plastic mass passes through the following states: plastic–rubberlike–elastic–solid. In setting by cooling, secondary valency bonds are restored. This process is repeatable; therefore thermoplastics cart be restored to the plastic state by reheating.

Thermosetting plastics or thermosets (cross-linkable plastics) are cured after forming by a hardening process. Primary valency bonds form, and the plasticized mass solidifies directly under the effect of heat and/or pressure. The curing is an irreversible chemical process: thermosets disintegrate on reheating without needing to pass through a plastic state. Fundamental chemical reactions during solidification are polymerization, polycondensation, and polyaddition.

In primary shaping of high-polymer materials, if solutions are used then the transformation to the solid state may be accomplished by the physical process of solvent evaporation.

In primary shaping by sintering, a process of shrinkage of the internal and external surface area of a body formed from powder by pressure takes place. Powder particles that are in contact are joined by the formation or reinforcement of bonds (material bridges) and/or by reducing the pore volume; at least one of the material constituents involved remains solid throughout the process. The bonding of the porous pressed body of powder takes place mainly through diffusion mechanisms.

In connection with the description of the technological aspects of primary shaping, further details of the processes, here not described, go to the special literature.

7.1.5 Shaping of Metals by Casting

Manufacturing of Semifinished Products

This group of primary shaping processes involves the production of initial and intermediate products, which are further processed by, for instance, metal forming (plastic deformation).

The Ingot Casting Process. Here, ingots, slabs, wirebars, etc. are produced in permanent molds made of metal (usually cast iron). These products are converted by metal forming (rolling, forging, pressing, wire drawing, etc.) into a semifinished product (sheet, plate, section, wire) that no longer resembles the original ingot in form and dimensions. In ingot casting a distinction is made between top pouring (downhill casting, Fig. 7.3a), where the mold is filled by directly pouring

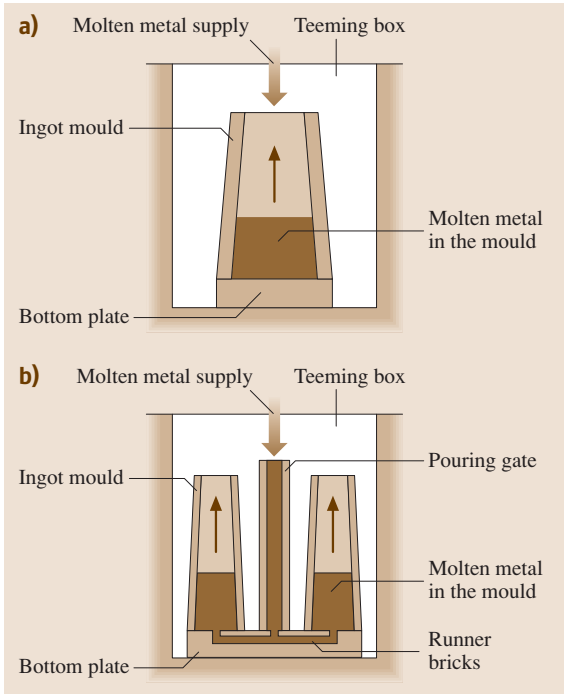

Fig. 7.3a,b Ingot casting methods: (a) top pouring, (b) bottom pouring (after [7.2])

the molten metal in from above, and bottom pouring (uphill casting, Fig. 7.3b), where one mold or several molds simultaneously (group casting) are filled from below by means of a distribution system (pouring gate and runner bricks).

Procedure: The prepared molds are set up into the teeming box as illustrated. They are filled with the liquid metal, which solidifies in them. The molds are stripped from the ingots, which are taken away.

Continuous Casting Processes. In these processes, which are used to produce either intermediate products for metal forming or semifinished products, the primary shaping tool (continuous mold, casting roller, casting belt, casting wheel) is always smaller than the product of primary shaping.

Casting with Stationary Molds. Continuous casting with a stationary mold. In this casting process, a bath of molten metal is fed into a stationary continuous mold, where the solidification begins.

Depending on the design, a distinction is made between batch or continuous vertical (Fig. 7.3a) and horizontal continuous casting systems (Fig. 7.3b). On

leaving the continuous mold the resulting continuous casting (solid or hollow section) is cooled until it solidifies completely. The continuous casting is usually cut into defined lengths at intervals. Like ingots from ingot casting, these are further processed by metal forming.

Traveling Primary Shaping Tools. In this continuous casting process, metal-forming equipment for rolling or drawing is installed directly following the casting plant, thus dispensing with the manufacturing stages of metal forming. In this case, there is usually no cutting of the continuous castings into sections.

Continuous Casting with Moving Molds. The continuous casting with moving molds is realized with strip and wire rod casting plants.

In vertical uphill casting between two casting rollers (Fig. 7.4a) the molten metal is fed from below between two casting rollers. Solidification takes place between these two rollers, and the finished continuous casting (a strip) emerges vertically upward from these rollers.

In horizontal casting (Fig. 7.4b), both the feeding of the molten metal and the discharge of the solidified continuous casting (strip) take place horizontally. In casting between a casting roller or a casting wheel having the profile of the desired strip or rod and an endless casting belt (Fig. 7.5a,b), the molten metal solidifies between the casting roller/wheel and the casting belt and emerges into the open air. In casting in belt molds

(two endless, rotating casting belts), solidification is accomplished with the aid of further rotating equipment to restrict the product laterally between these casting belts (Fig. 7.6a–c); the solidified continuous casting then emerges into the open air as a strip.

Manufacturing of Cast Parts

Manufacturing of cast parts is accomplished with primary shaping processes by means of which a practically finished component, e.g. a machine part or an end-product, is produced without metal forming. The product's shape and dimensions do not undergo any further significant change. However, primary shaping is followed by other manufacturing processes, e.g. cutting (turning, planing, milling, drilling), to obtain a component ready for fitting. The intention is to perfect and further develop the primary shaping techniques in order to, for instance, reduce the amount of machining work to a minimum. A good view of the manufacturing of cast parts – cast alloys, manufacturing processes and applications of cast parts – is given in [7.3, 4].

Use of Lost Primary Shaping Tools (Lost Molds). This technique, which is only used in primary shaping of metallic materials from the liquid state in foundry technology, uses a pattern to produce the expendable primary shaping tool. Depending on the type of pattern used, a distinction is made between processes using a permanent pattern and those using an expendable pattern. A permanent pattern can be used to make many expendable molds, but an expendable pattern can only be used for one expendable mold. Expendable patterns are also made in an appropriate primary shaping tool.

The patterns are similar in shape to the case part to be manufactured, but are larger by the allowance for contraction of the material to be cast. They also incorporate the machining allowances, which will subsequently be eliminated by machining of the casting with the aim of achieving accuracy in dimensions, shape and position, as well as tapers to enable the pattern to be removed from the mold. Most patterns have a pattern joint, i. e. they consist of at least two parts (pattern halves). In addition, for castings with hollow spaces the pattern has care marks for insertion of the cores in the mold.

In the case of permanent patterns for making an expendable mold for casting, these patterns or their sections made from metals, high polymers or wood are used to make the molds by the sand molding, template molding, or shell molding process.

Hand Molding. The mold is expendable (i. e. used only once). The medium used may be natural or synthetic sand with bentonite; other molds used sand with a resin binder. It is worked by hand.

Pattern. Patterns for repeated use, and patterns and core boxes, are made of wood or plastics.

Process Characteristics. Hand molding denotes the production of a sand mold without using a molding machine. The mold consists of the external parts for the external profile and the internal parts for the internal profile. Hollow spaces in the casting are formed by cores placed in the mold.

The principle of molding is illustrated in Fig. 7.7. First of all the bottom half of the two-part pattern is molded. After turning the molding box over, the top half of the pattern and the pouring gate and risers are placed in position and the top mold is made. The top box is lifted off, the pattern halves are removed from the mold, and the core is inserted. The halves of the mold are joined and the casting is made.

Casting Materials. All metals and alloys that are castable with the current technology.

Weight of Castings. The maximum transportable weight and the melting capacity determine the maximum weight.

Number of Castings. Single items, small production runs.

Tolerances. From about 2.5 to 5%.

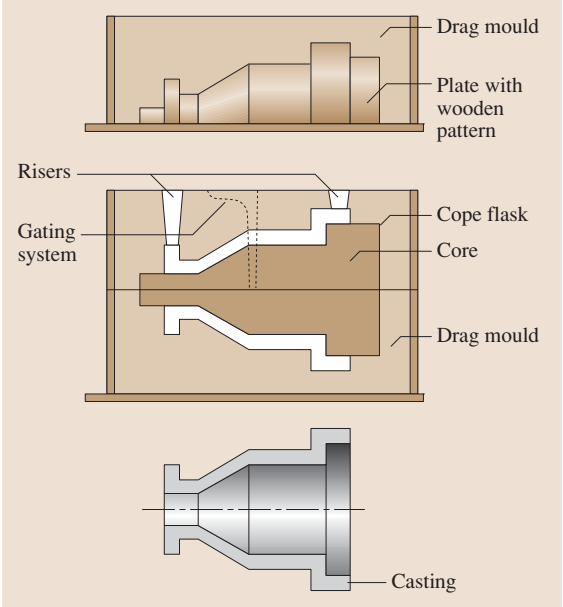

Fig. 7.7 Hand molding (after [7.2])

Machine Molding. The mold is expendable (used only once). Natural sand, artificial sand, sand with synthetic resin binders, CO, sand. Preparation on molding and core molding machines. Used in semiautomatic and fully automatic production lines.

Pattern. Patterns and core boxes are made of metal or plastic.

Process Characteristics. Mechanical molding is characterized by a semiautomatic or fully automatic manufacturing operation for efficient production of ready-to-cast sand molds (Fig. 7.8). The casting process is often incorporated into the production line. The main stages are: molding station, core insertion section, casting section and cooling section. The emptying station releases the cast molds. The molding station may consist of one automatic molding machine for complete molds or of two or more for making separate top and bottom boxes. There are also boxless molding units, where the molds are made using only a frame, which is withdrawn after compacting the sand.

Casting Materials. All metals and alloys that are castable with the current technology.

Weight of Castings. Limited by the size of the molding machines: up to ≈ 500 kg.

Number of Castings. Owing to the mechanical preparation, mechanical molding is suitable for series and mass production of quantities of 1000 and multiples thereof.

Tolerances. From about 1.5 to 3%.

Suction Molding. The mold is expendable (used once only), made from wet artificial casting sand (Fig. 7.9).

Pattern. Wood, plastic, metal.

Process Characteristics. The process is characterized by the formation of a vacuum by withdrawing air from the mold space and the incoming molding sand. This accelerates the sand, which spreads over the wall of the pattern. The sand can be subsequently pressed against the pattern. Advantages of the process are optimum mold, compaction around the pattern, no shadow effect with plane surfaces, decreasing hardness of compacted sand from the inside to the outside, high surface quality, dimensionally stable castings, reduced cleaning. This process should not be confused with vacuum molding.

Casting Materials. Iron, steel, aluminum.

Weights of Castings. From about 0.1 to 120 kg.

Number of Castings. Small, medium, and large production runs.

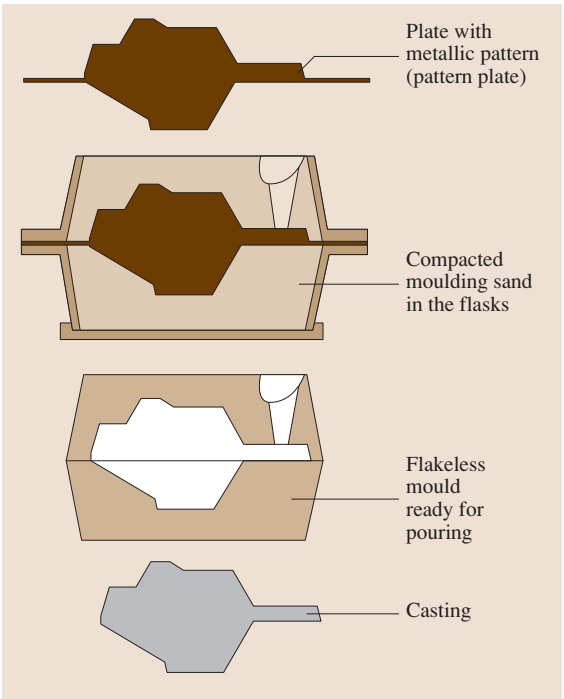

Fig. 7.8 Machine molding (after [7.5])

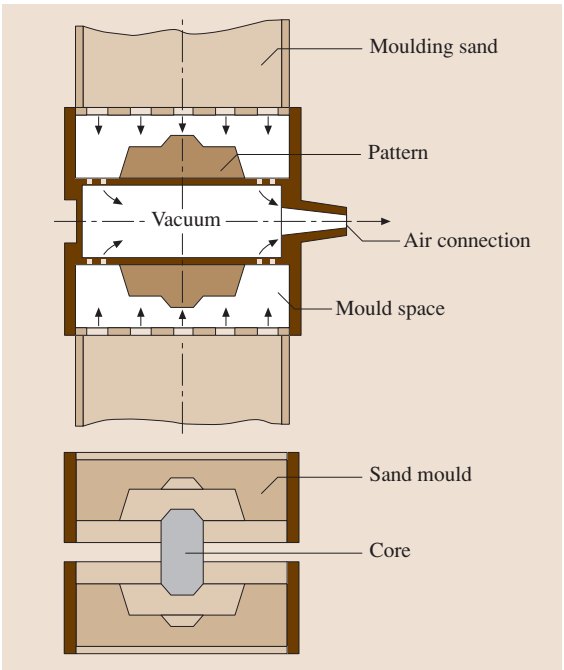

Fig. 7.9 Suction molding (after [7.5])

Tolerances. Conventional to DIN 1683; maximum offset of compacted sand 0.3 mm.

Shell Molding. The mold is expendable (used only once). Resin-coated sands or sand/resin mixtures (Fig. 7.10).

Pattern. Patterns for repeated use, heatable metal patterns, and metal core boxes.

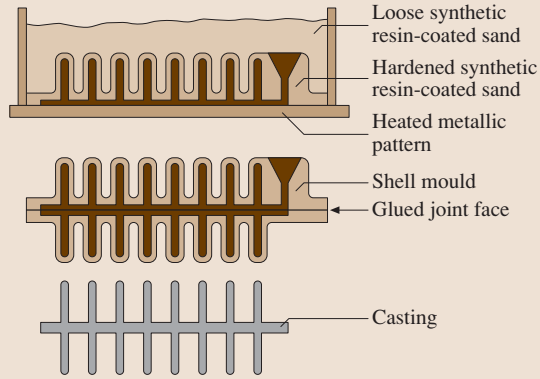

Fig. 7.10 Shell molding (after [7.5])

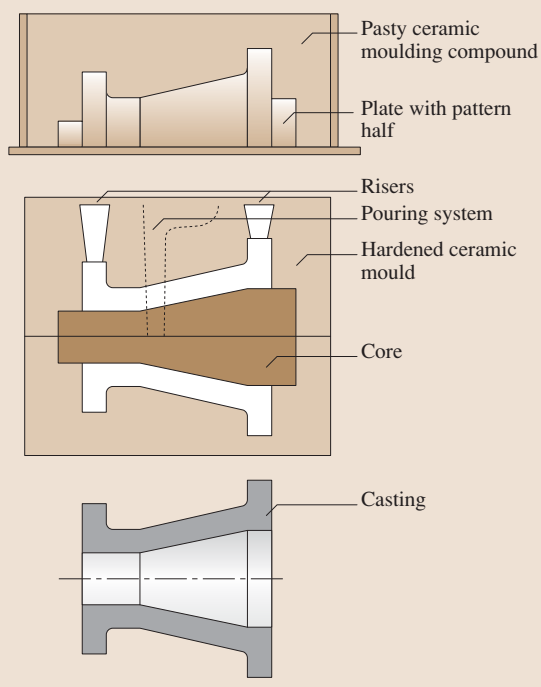

Fig. 7.11 Ceramic molding (after [7.5])

Process Characteristics. These molds are shell molds with walls only a few mm thick. The mold material is poured onto the heated metal pattern. This cures the synthetic resins in the mold material, solidifying the mold. The result is a self-supporting, stable shell mold. Shell molds are often molded in one piece and then divided. After putting in the cores, the two halves of the mold are glued together. The shell molding process is used in various stages of mechanization and automation. This process is used not only for making molds for shell casting, but also for producing hollow shell cores for sand and chill casting. These cores are produced on special core molding machines. Shell casting offers high dimensional accuracy with excellent surface quality.

Casting Materials. All metals and alloys that are castable with the current technology.

Weight of Castings. Up to 150 kg.

Number of Castings. Medium to large production runs.

Tolerances. From about 1 to 2%.

Ceramic Molding. The mold is expendable (used only once). This mold is made of highly refractory ceramic similar in kind to mold materials for investment casting (Fig. 7.11).

Pattern. Reusable, made of metal, plastic, or specially varnished wood.

Process Characteristics. A slip consisting of highly refractory substances is poured around the pattern; these substances then harden by chemical reaction. Often only one layer is poured, which is then back-filled with *normal* molding sand. After removing the pattern, the ceramic is fired or skin-dried (Shaw process). To keep ceramic molding, which is relatively expensive, to a minimum, it is usually only the parts of the mold that are made from special ceramic that will be cast in finished or near-finished shape. Castings from ceramic molds have no casting skin in the conventional sense and are among the precision casting processes that, as the technology develops, are becoming more and more widely used owing to their efficiency.

Casting Materials. All metals and alloys that are castable with the current technology, especially iron-based materials.

Weight of Castings. From about 0.1 to 25 kg, depending on the production equipment.

Number of Castings. Single items, small and medium runs, also larger runs in the case of fluid flow machines.

Tolerances. Up to about 100 mm ± 0.2%, over 100 mm ± 0.3 to 0.8% of nominal dimensions.

Vacuum Molding (V-Process). The mold is expendable (used only once). A plastic foil is vacuum-molded to the contours of the pattern, back-filled with fine-grained, binder-free quartz sand and sealed with a covering foil. Dimensional stability is preserved by means of a vacuum of 0.3 to 0.6 bar.

Pattern. Permanent patterns, not subject to significant wear. Patterns are made of wood or metal. Core boxes according to the core manufacturing method.

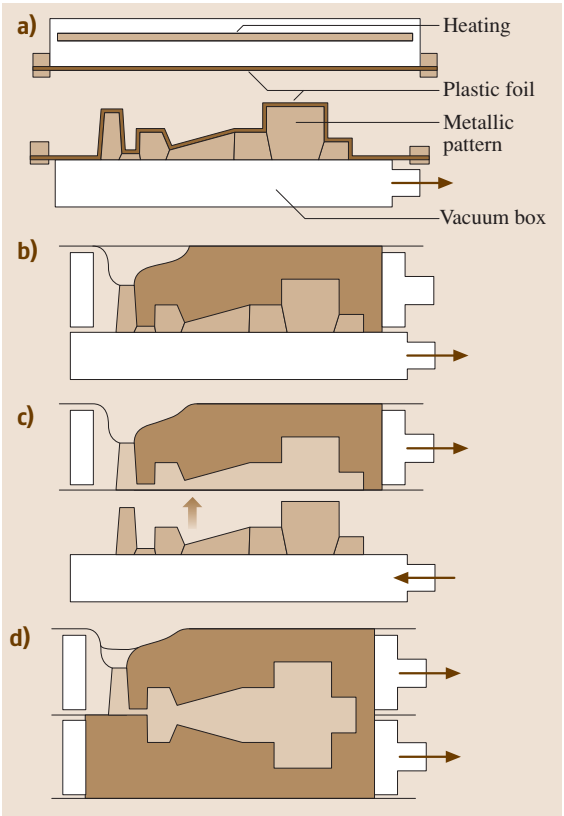

Fig. 7.12a–d Vacuum molding: **(a)** The plastic foil is softened by means of a foil-type heating element and drawn tightly against the pattern by vacuum through holes. **(b)** The mold box is placed on top, filled with binderless sand, precompacted, and the top of the box is covered with plastic foil. **(c)** Vacuum is applied to the mold box, compacting the sand. By switching off the vacuum, the mold box can easily be lifted off the pattern. **(d)** The top and bottom halves of the box are joined. The vacuum is maintained during pouring (after [7.5])

Process Characteristics (Fig. 7.12). The process is characterized by the use of a vacuum for both deep drawing the pattern sheet over a pattern with nozzle holes and maintaining the stability of the mold. A molding box equipped with suction systems is connected by a pipe to the vacuum grid. The fine, binder-free sand with which the mold box is filled is compacted by vibration. After applying a cover sheet, the air is evacuated from the sand and the mold thus becomes rigid. The mold is constantly connected to the vacuum grid before, during, and after casting. To empty the mold, the vacuum is switched off and the sand and cast parts drop out of the mold box without additional force. The advantages of the process are: high, reproducible dimensional accuracy with outstanding surface quality; the mold seam at the joins and core marks is very small; tapers can be entirely dispensed with in certain areas of the casting.

Casting Materials. All metals and alloys that are castable with the current technology.

Weight of Castings. Restricted by the equipment available, not by the process.

Tolerances. 0.3 to 0.6%.

Casting Under Vacuum. The mold is expendable (used once only), shell molds (for investment casting) and precision casting molds made of special mold materials.

Pattern. Wax for investment casting, also of metal, plastic or the like, depending on the type of mold.

Process Characteristics. Titanium and zirconium are among the reactive metals that have high affinities with oxygen, nitrogen, and hydrogen in the molten state. This is even the case when present as alloying constituents in appropriate percentages in, e.g., molten nickel. All these alloys must therefore be produced and cast under defined conditions, normally under high vacuum.

The new mold ceramics, e.g. those made of yttrium and zirconium oxides, resist attack by reactive metals and melts. However, these special ceramics are not (yet) required for nickel-base alloys that are only alloyed with titanium, aluminum, etc.

To optimize quality and structure, the castings are usually isostatically pressed at high temperature by means of the HIP process.

Casting Materials. Alloys based on (in order of importance) nickel, titanium, cobalt, iron, and zirconium.

Weight of Castings. Approximately 0.01 to 100 kg and more, depending on the manufacturing equipment.

Number of Castings. Small series to fairly large production runs.

Tolerances. From 0.3 to ±0.8% of nominal size, depending on the molding process.

Investment Casting (Lost Wax Process). The mold is expendable (used once only), made of highly refractory ceramic, single or group pattern with runners, combined to form casting units (*clusters* or *trees*) (Fig. 7.13)

Pattern. Made by injection molding from special waxes or the like, thermoplastics or mixtures thereof.

Process Characteristics. The distinguishing features are the expendable patterns, the one-piece molds and the casting in hot molds (900 °C for steel). A casting skin in the conventional sense does not form. The patterns are inject ion-molded in single or multiple tools made of aluminum, steel or soft metal, for which an original pattern is required. The most suitable injection molding tool in each particular case is chosen according to the planned total quantity, the form of the casting, and the nature of the pattern material. The formation of certain undercut contours may require the use of water-soluble or ceramic cores, for which a supplementary tool is used. The patterns are assembled into clusters by means of casting systems, usually again employing injection molding. The method of this assembly is crucial for the quality of the castings and for efficiency. Viscous ceramic coatings which cure by chemical reaction are then applied to these clusters. For aluminum, special plasters are also used. After melting out (lost wax process) or dissolving away the pattern material, the resulting one-piece molds are fired. Casting takes place in molds that are usually still hot from firing, so that narrow cross-sections and fine profiles *turn out* cleanly. Precision casting, with its tight tolerances and high surface quality, is the casting technology that offers the greatest freedom of design coupled with high quality.

Casting Materials (in Order of Importance). Steels and alloys based on iron, aluminum, nickel, cobalt, titanium, copper, magnesium, or zirconium, including aerospace, materials, produced at atmospheric pressure or under vacuum.

Weight of Castings. 0.001 to 50 kg, also up to 150 kg and over depending on manufacturing equipment.

Number of Castings. Small series to large production runs, depending on the complexity and/or machinability of the workpiece concerned.

Tolerances. From ±0.4 to ±0.7% of nominal dimensions.

Full Mold Casting (Evaporative Pattern Casting, Lost Foam Casting). The mold is lost (used only once), mold material is usually self-curing.

Pattern. Expendable, foam material.

Process Characteristics (Fig. 7.14). One-piece pattern made of foam material (polystyrene). Shape and dimensions match the part to be cast (taking into ac-

count allowance for contraction). The pattern need not be removed from the mold after mold-making. The heat of the molten metal flowing into the full mold vaporizes the pattern, which is continuously replaced by cast metal. Mold joints and cores are usually unnecessary. Bolts, sleeves, lubrication lines, etc. can be integrally cast in. The absence of mold tapers reduces the weight of the casting. The time and cost of manufacture are only a fraction of those encountered with a wooden pattern.

Casting Materials. All metals and alloys that are castable with the current technology, especially those with high casting temperatures.

Weight of Castings. From ≈ 50 kg up to maximum transportable weight; especially suitable for large components.

Number of Castings. Single pieces, small production turns.

Tolerances. From about 3 to 5%.

Magnet Molding. The mold is expendable (used once only), iron granules.

Pattern. Expendable, foam material.

Process Characteristics. Magnetic molding is a type of full mold casting. The casting units, prefabricated from foam material (patterns with pouring gates and runner), are coated with a refractory ceramic (similar to shell molds for precision casting). They are then backfilled with pourable iron granules in a mold box. By applying (or switching on) a DC magnetic field, the iron powder becomes rigid and thus supports the casting unit. After casting and solidification of the die metal, the magnetic field is switched off, causing the iron granules to become pourable again. Then the casting is removed. The iron granules can be reused.

Casting Materials. All metals and alloys that are castable with the current technology. As the thermal conductivity of the magnetizable mold material is higher than that of quartz sand, the cooling rate of the castings is higher and leads to a finer metallographic structure. The properties in use are especially improved in the case of steel castings.

Number of Castings. Single items, small production runs.

Tolerances. From about less than 3 to 5%.

Use of Permanent Molds.

Permanent Mold Casting (Gravity Die Casting). The mold is a permanent mold from cast iron or steel, cores made of steel.

Pattern. None required.

Process Characteristics (Fig. 7.15). Casting takes place by gravity in permanent metal molds. These molds are made in two or more parts for removal

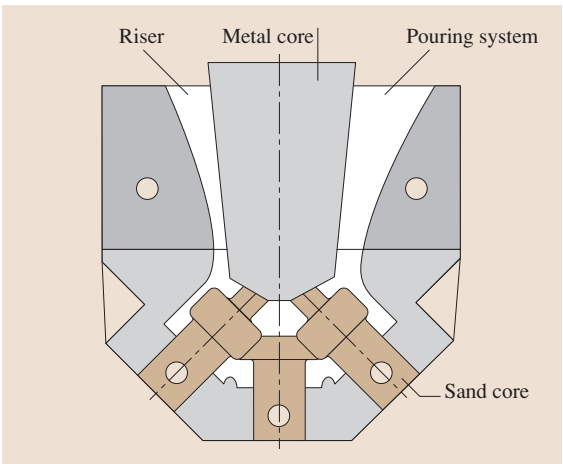

Fig. 7.15 Permanent mold casting (composite mold with metallic and sand cores, latter for undercuts) (after [7.5])

of the finished casting. The higher thermal conductivity of the metal mold compared with molding sand brings about faster cooling of the solidifying molten metal. The result is a relatively fine-grained, dense structure with better mechanical properties than parts made by sand casting. High dimensional accuracy, excellent surface quality, and good reproduction of contours characterize chill casting. This process fully meets the specifications for gas- and liquid-tight valves, owing to the production of a dense structure. A rapid, efficient casting sequence, with machining generally being unnecessary or requiring only small machining allowances, are further features of this process.

Casting Material. Copper-zinc alloys, copper-aluminum alloys, aluminum alloys, magnesium alloys, high-grade zinc alloys, also copper, copper-chromium alloys, super-eutectic aluminum-silicon alloys, lamellar and nodular graphite cast iron.

Weight of Castings. Nonferrous metals and cast iron up to ≈ 100 kg, more depending on equipment. Cast iron for certain purposes up to ≈ 20 t (= 20 000 kg).

Number of Castings. From about 1000 and multiples thereof, depending on the material being cast (e.g. Al ≈ 100 000 castings).

Tolerances. From about 0.3 to 0.6%.

Low-Pressure Permanent Mold Casting. The mold is a permanent mold from cast iron or steel.

Pattern. No pattern required.

Process Characteristics (Fig. 7.16). Casting is carried out under pressure (usually with compressed air) in permanent metal molds. These molds are made in two or more parts for removal of the finished casting. The higher thermal conductivity of the metal mold compared with molding sand brings about faster cooling of the solidifying molten metal. The result is a relatively fine-grained, dense structure with better mechanical properties than parts made by sand casting. The distinguishing feature is the application of pressure, which dispenses with the need for risers on the casting. High dimensional accuracy, excellent surface quality, and good contour reproduction together with a rapid, efficient casting sequence and considerable machining economies are further features of this process. Gas-tight and liquid-tight valves can be efficiently manufactured owing to the dense structure of the casting.

Casting Materials. Light metal, especially aluminum alloys.

Weight of Castings. Up to 70 kg.

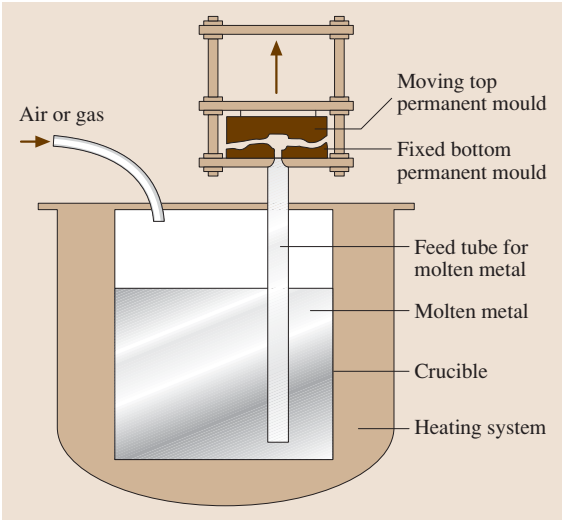

Fig. 7.16 Low-pressure permanent mold casting (after [7.5])

Number of Castings. From about 1000 and multiples thereof.

Tolerances. From about 0.3 to 0.6%.

High-Pressure Die Casting (Die Casting). The mold is a permanent mold, usually from high-tensile hot forming tool steel or special metals.

Pattern. No pattern required.

Process Characteristics (Fig. 7.17). The distinguishing feature of this process is that the molten metal is forced into the two-part permanent mold at high pressure and relatively high speed in pressure die casting machines. Two types of process are distinguished, namely:

- The hot-chamber process. Here the die casting machine and the holding furnace for the molten metal form a unit. The casting assembly is immersed in the molten metal. In each casting operation, a precisely predetermined volume of molten metal is forced into the mold. The hot-chamber die casting process is especially suitable for lead, magnesium, zinc, and tin. The output of components manufactured by this process is considerable, but varies according to the size of the component and the casting material.
- The cold-chamber process. In this process the die casting machine and the holding furnace for the molten metal are separate. After being taken from the furnace, the molten metal is poured into the cold pressure chamber and forced into the mold.

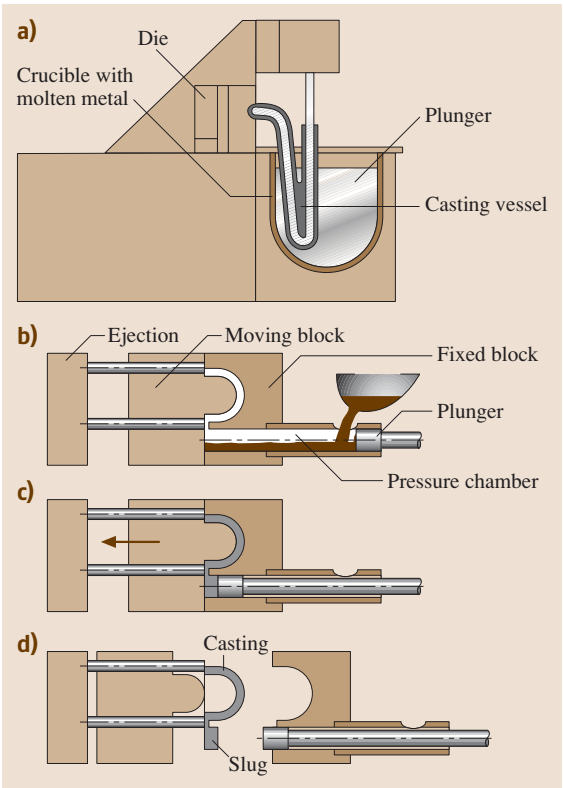

Fig. 7.17a–d High pressure die casting: **(a)** hot chamber process, **(b–d)** cold-chamber process, **(b)** filling of casting chamber, **(c)** plunger for molten metal into die, **(d)** ejection of casting (after [7.5])

The pressure chamber is mounted directly on the runner-side mold block. This process is chiefly suitable for aluminum-based and copper-based alloys, as these would attack the steel casting assembly when molten if the hot-chamber process were employed. Cold-chamber die casting machines do not achieve the rates of output of hot-chamber machines, owing to the nature of the process. Pressure die casting is today one of the most efficient casting processes around. The machines are mostly semiautomatic or fully automatic. Pressure die-cast parts have smooth, clean surfaces and edges. They are extremely dimensionally accurate. Therefore, only the fitting and bearing surfaces, at most, require machining. Very low machining allowances result in short machining times.

Special cases of high pressure die casting are squeeze-casting and thixocasting.

Squeeze-Casting and Thixocasting. In the direct squeeze casting, the die is filled with a defined amount of liquid metal via a trough. The die, which has two or more parts, is closed above by hydraulic pressure, forcing the metal to conform to the die surfaces. The pressure is maintained during solidification. Unlike direct squeeze-casting, the indirect version has proved itself in production and has obtained a foothold in foundries producing castings for special applications. The principle of operation differs from the direct process in that the melt is not poured directly into the die, but into a casting chamber situated below it. The bottom of the chamber is sealed by a piston whose actuating cylinder is fixed to a pivot. After filling, the chamber is swung into position under the die and the piston is raised to fill the die.

Thixocasting takes advantage of the thixotropic properties of metal alloys in the partly solidified state (semisolid state). Thixotropic behavior means that the material behaves as a solid when at rest but flows like a liquid when rapidly deformed, its viscosity falling as the stress increases. To bring this about, the alloy has to be heated to a point in its freezing range between solidus and liquidus temperatures. This point be chosen such that, for example, 40% of the volume is liquid, the rest remaining solid. Aluminum alloys having a long freezing range are suitable for thixocasting. To attain a good thixotropic state, the crystals in the solid solution must be equiaxed in order to ensure the liquid and solid phases flow uniformly and do not separate. Such a structure can be created by so-called *rheocasting*, whereby the melt is mechanically or electromagnetically stirred during solidification at continuous casting. This breaks off or melts off the dendrite arms, which condense to globular shapes when held just above the solidus temperature, resulting in indigenous growth of free-floating crystals with the desired equiaxed structure.

Current practice in thixocasting is as follows: The rheocasted bar is first cutted off in pieces having sufficient weight for the part to be casted. The pieces are then preheated to a predetermined temperature in their melting range. This is done automatically using temperature sensors to attain a definite proportion of liquid metal, often between 35 and 50%. It is placed in the casting chamber of the casting machine and is injected into the mold cavity by the casting piston.

Casting Materials. Materials suitable for pressure die casting are copper-zinc alloys, copper-aluminum alloys, aluminum alloys, magnesium alloys, lead alloys, tin alloys, high-grade zinc alloys. For the hot-chamber

process: lead, magnesium, zinc, and tin alloys. For the cold-chamber process: particularly aluminum- and copper-based materials.

Weight of Castings. Up to 45 kg for light alloys, up to 20 kg for other materials, depending on the material being cast and the working dimensions of the die casting machines.

Number of Castings. Varies widely depending on the material being cast (e.g. Zn alloys ≈ 500 000 castings).

Tolerances. From about 0.1 to 0.4%.

Centrifugal Casting. The mold is a permanent, water-cooled cast iron or steel mold.

Pattern. None required.

Process Characteristics (Fig. 7.18). The centrifugal casting process is used to manufacture hollow products having a rotationally symmetrical hollow space and an axis coinciding with the axis of rotation of the centrifugal casting machine. The external form of the casting is determined by the shape of the mold. The internal form is determined by the effect of the centrifugal force of the rotating mold. The wall thickness of the casting depends on the quantity of molten metal supplied. A variant of the process is centrifugal mold casting, which produces finished hollow or even massive castings using rotating molds. Composite centrifugal casting is also possible, as is centrifugal casting with a flange. The condition on delivery of centrifugal cast Fe, Ni and Co-based alloys is normally (at least) preturned.

Casting Materials. Especially cast iron, cast steel, heavy and light metals.

Weight of Castings. Up to about 5000 kg,

Number of Castings. From about 5000 to over 100 000, depending of the mold material and the casting material. In special cases, e.g. castings of stainless steel and the like, also single pieces and small production runs (from ≈ 104 mm internal diameter upwards).

Tolerances. About 1%.

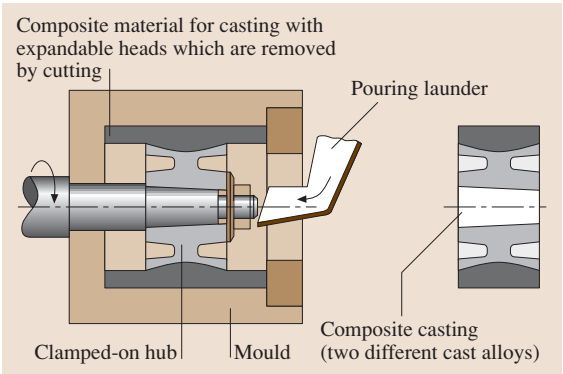

Fig. 7.19 Composite casting (after [7.5])

Composite Casting (Compound Casting). The mold is a lost or permanent mold. Metal mold. e.g. for centrifugal composite casting.

Pattern. None.

Process Characteristics (Fig. 7.19). These types of process are used to cast structural parts from two or more different metallic materials that are firmly joined together. At least one material is poured in the molten state into a mold, which may also be part of a product to be manufactured. For composite casting of various metals and/or alloys in molten or semisolid condition, e.g. in centrifugal casting and for casting in, casting round and lining solid components, which may be made not only of metal but also ceramic. The bonding may be formed by shrinkage, diffusion, or both.

Casting Materials.. All metals and alloys that are castable with the current technology.

Weight of Castings. Up to about 50 kg and over, depending on the manufacturing equipment.

Number of Castings. Medium and large production runs.

Tolerances. From about 0.1 to 0.6%, depending on the process.

7.1.6 Guidelines for Design

Forming by casting enables design ideas to be turned into reality to a particularly high degree, owing to the extensive freedom of design that it offers. A design appropriate for manufacturing, which contributes decisively to the efficient production of a casting, can generally be achieved only by close collaboration between the design engineer and the founder. Forming by casting differs from other forming processes in that the material only receives its shape, material structure, and quality after cooling; with shrinkage – which may

sometimes be considerable – in the liquid state and during solidification, and appreciable contraction in the solid state (Fig. 7.20, Table 7.14). The contraction in the solid state should be accounted for by means of a suitable allowance (allowance for contraction). The alloying specifications often suffer considerable deviations, owing to obstruction of contraction by ribs, projections, more or less flexible cores, and mold parts (Table 7.15). Provided that they fall within the acceptable dimensional variations or are compensated for by machining allowances, as is usually the case with small castings, they do not present a problem. With large castings, though, empirical values for the deviations due to contraction have to be taken into account when making the pattern. If there is a one-sided obstruction of contraction, e.g. due to the mold or even the shape, especially in the case of longer castings (different cross-sections along their length and consequently different cooling rates and thermal stresses), the castings would distort unless the pattern is curved in the opposite direction. Large wheel centers, for instance, are not infrequently split, e.g. to prevent unacceptable out-

of-roundness. Thermal stresses that are not reduced by plastic deformation may, besides distortion, also result in undesirable *relief by cracking*. Therefore, if insufficient attention is paid to contraction of the material being cast at the design stage, taking into account the possibilities afforded by gating of molds and risering, pipes (shrinkage cavities), shrinkage voids, sinks, hot (pipe) cracks, distortion, and stress cracks may form.

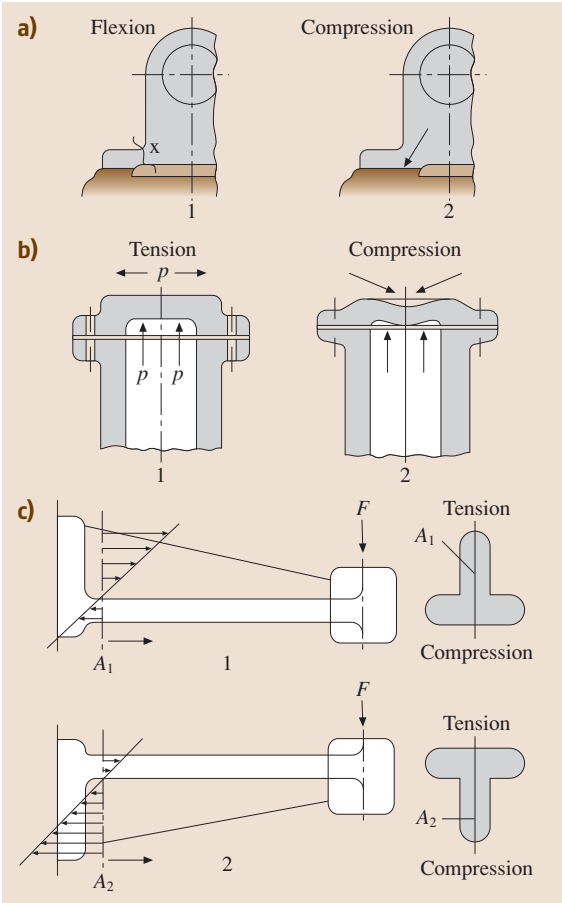

Fig. 7.21a–c Examples for stress-orientated casting design for a material having compression stress strength than tensile strength according to [7.8]: **(a)** pedestal (1 flexurally stressed – inadequate bearing surface, 2 compressively stressed – bearing surface widened); **(b)** cylinder cover (1 tensionally stressed – poor design, 2 compressively stressed – bearing surface – good design); **(c)** wall bracket arm (1 poor cross-sectional arrangement, 2 stress-absorbing cross-sectional arrangement) (after [7.8])

Manufacture-Orientated Design

The correct design of changes in wall thickness with a view to shrinkage during solidification and contraction in the solid state is outlined below.

- Wall thickness graduations should permit directional solidification.
- Junctions formed by the meeting of two or more walls. They should be separated as far as possible, or designed for efficient casting by narrowing the cross-section. Concentrations of material, especially at locations that are inaccessible to feeding, lead to piping.
- Sudden changes in wall thickness should be avoided, as they produce high thermal stresses due to different cooling rates. In addition, there is often increased obstruction of contraction by the mold. The risk of formation of hot cracks (*pipe cracks* between liquidus and solidus temperatures) and stress cracks (during further cooling in the solid state) is therefore high. Locations prone to cracking can be protected by ribs.
- Sharp corners additionally cause a heat build-up (hot sand effect) and, accordingly, not only hot cracks but also porosity due to contraction as well as drawholes.

For a summary of design recommendations see Fig. 7.22.

Stress-Orientated Design

When designing castings, the main stresses occurring during manufacture have to be taken as a basis. Here, the freedom of design offers excellent adaptation to the technical requirements. Forming by casting permits the efficient manufacture of parts of the most complicated kind with high strength in relation to shape. The stress condition of the design can often be made more favorable by suitable ribbing or slight modification (Figs. 7.21 and 7.22).

It is important to know the load-bearing capacity of the materials to be cast. For approximate values for lamellar graphite cast iron see Fig. 7.23.

Examples. A casting made from EN-GJL-150 gray cast iron (top horizontal gray bar) with a wall thickness of 10 mm or a test bar diameter of 20 mm (vertical line) has a tensile strength of $\approx 220\,\mathrm{N/mm^2}$, a hardness of $\approx 220\,\mathrm{HB}$, and a modulus of elasticity of $10\,000\,\mathrm{dN/mm^2}$. For a wall thickness of 45 mm, on the other hand, the tensile strength is $\approx 100\,\mathrm{N/mm^2}$, the hardness is $\approx 130\,\mathrm{HB}$, and the modulus of elasticity almost $8000\,\mathrm{dN/mm^2}$.

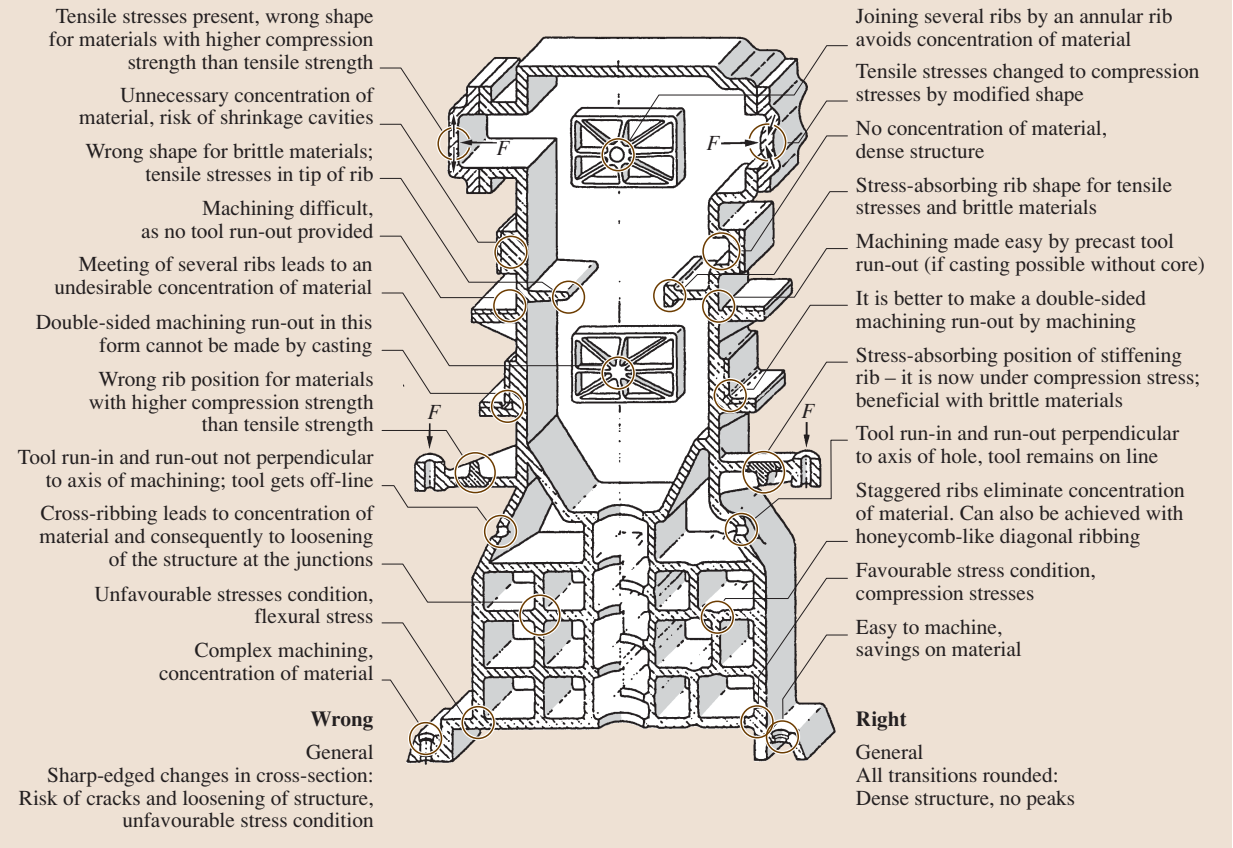

Fig. 7.22 Illustration of important design guidelines (after [7.9])

If however, the tensile strength of this 45 mm thick wall is 220 N/mm^2, a hardness ≈ 180 HB and an modulus of elasticity of ≈ 11 500 dN/mm^2 should be expected. The material grade EN-GJL-30 should be selected. For a wall thickness of 10 mm, this cast iron has a tensile strength of ≈ 350 N/mm^2, a hardness of ≈ 260 HB, and a modulus of elasticity of ≈ 13 000 dN/mm^2.

Near-Net-Shape Manufacturing and Integral Castings

The main advantage of shaping by casting is the realization of near-net-shape production of castings, thereby minimizing cutting processing and drastically shortening the process chains due to fewer process stages. The process chain is dominated up to the finished part by chip-arm shaping.

Development in shaping by casting is focused on two directions. First, the components become increasingly closer to the finished parts. Second, many single parts are aggregated to one casting (integral casting, one-piece-casting). Both directions of development are realized in all variants of casting technology.

For evaluation, the manufacturing examples in Figs. 7.24 and 7.25 were considered from melting up to a commensurable part.

Figure 7.24 shows a technical drawing of a flat part that had previously been produced by cutting stating from a bar, that is now made as a casting (malleable cast iron) using the sand-molding principle. In cutting from a semifinished material, material is utilized at only 25.5%. As a result of shaping by casting, utilization of material was increased to 40%. The effects of shaping by casting become evident in the energy balance (primary energy, cumulative energy demand). For cutting the flat part from a semifinished product, 49 362 GJ/t parts are required. For shaping by casting, 17 462 GJ/t parts are required. Consequently, 64.6% of the energy

can be saved. Compared to cutting of semifinished steel material, for part manufacturing about a third as much primary energy is required.

The doorway structure of an Airbus passenger door (PAX door: height about 2100 mm; width about 1200 mm) is illustrated in Fig. 7.25.

The conventional manufacturing of the doorway structure as practiced until now, apart from the standard parts such as rivets, rings, and pegs, 64 milling parts were cut from semifinished aluminum materials with very low material utilization. Afterwards, those parts were joined by about 500 rivets.

As an alternative technological variant, it is proposed that the doorway structure be made of three cast segments. Assuming almost the same mass, in production from semifinished materials, the ratio of chips amounted to about 63 kg, whereas in casting, this can be reduced to about 0.7 kg. Thus, in casting, the chip ratio amounts to only 1% in comparison to the present manufacturing strategy. In the method start-

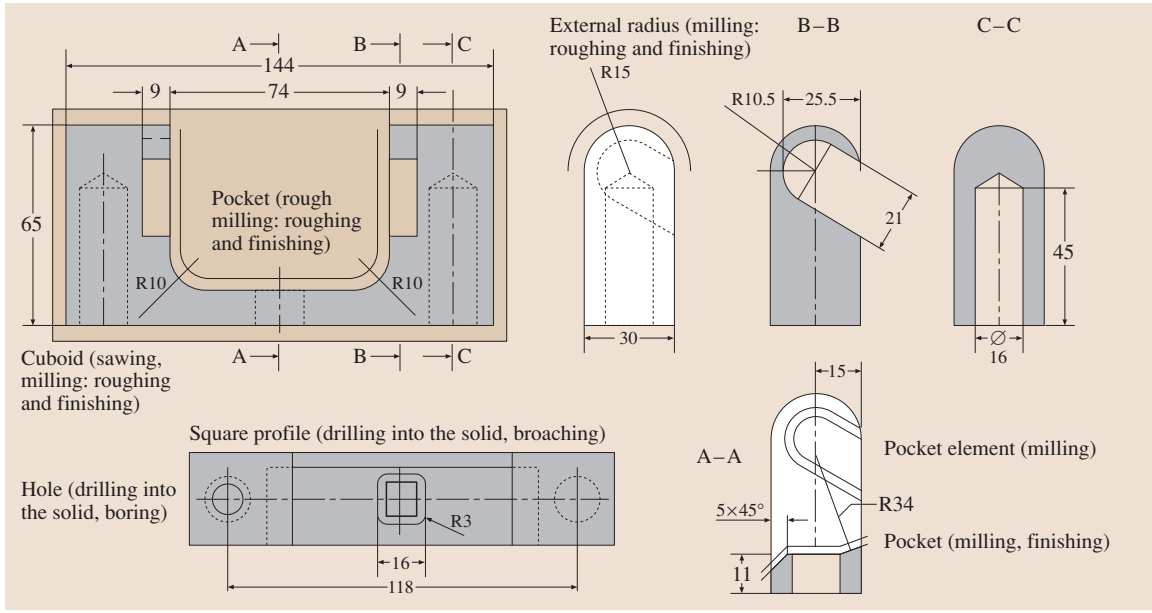

Fig. 7.24 Example: Flat part (after [7.12])

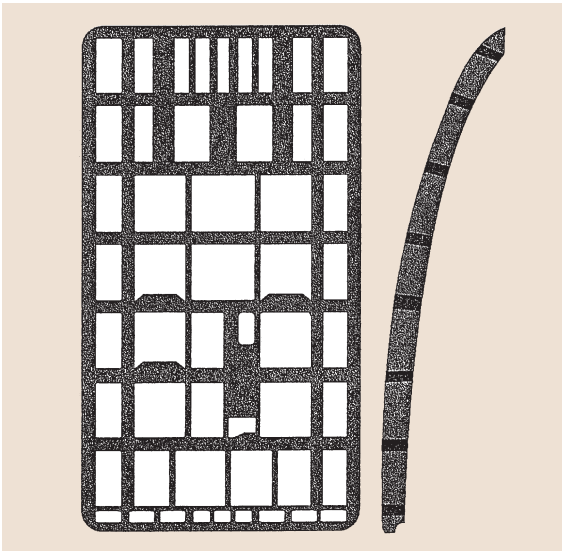

Fig. 7.25 Example: Airbus doorway (after [7.12])

ing from the semifinished material, about 175 kg of material have to be molten; however, in shaping by casting, this value is about 78 kg – that is 44.6%. As a result of the energy balance (primary energy, cumulative energy demand), about 34 483 MJ are required for manufacturing the doorway from the semifinished material. However, in shaping by casting, 15 002 MJ are needed – that is about 46%. The result of having drastically diminished the cutting volume due to near-net shaping can be clearly proven in the energy balance: in the variant starting from the semifinished material, 173 MJ were consumed for cutting, in casting, less than 2 MJ.

In contrast to the studies mentioned above, today, the Airbus door constructions that have been cast as one part only are used. 64 parts are aggregated to one casting (integral casting).

7.1.7 Preparatory and Finishing Operations

Melting of Materials for Casting

For transforming the metal to be cast and the additives into the molten state, a wide variety of melting equipment – e.g. shaft (cupola), crucible, and hearth-type furnaces – is available. These furnaces are heated with coke, gas, oil, or electricity. The most important types of melting equipment are: for cast iron, including malleable cast iron: cupola (shaft) furnaces, induction furnaces, rotary kilns (oil-fired); cast steel: electric arc furnaces, induction furnaces; nonferrous metal castings: induction furnaces, electrically, gas-heated or oil-heated crucible furnaces.

Cleaning of Castings

The molds are emptied by means of emptying jiggers. The sand adhering to the casting is generally removed by means of abrasive blasting equipment employing, without exception, steel shot or steel grit made from wire.

Heat Treatment

Many materials only obtain the physical and technological characteristics required in use from heat treatment. This treatment requires the use of electrically heated or gas- or oil-fired furnaces in continuous or batch operation. Their size is matched to the size and quantity of the castings and their mode of operation to the wide variety of heat treatment processes.

Inspection and Testing Methods

The diverse demands made on the casting, which become greater with advances in technology, and the trend towards lightweight construction and thus more efficient use of materials inevitably lead to stringent requirements with regard to casting quality, with particular emphasis on consistency. Inspections of the process and the castings begin with checking of the metallic and nonmetallic feedstocks and end with the final inspection of the castings. Materials and workpieces are mainly tested by means of nondestructive testing methods such as radiographic (EN 12681), ultrasonic (EN 12680, part 1, 2 and 3), magnetic powder (EN 1369), and liquid penetrant (EN 1371 part 1 and 2) testing [7.13–21]. Destructive tests, e.g. tensile, notched-bar impact and bending, are usually carried out with specimens cast either separately or as an appendage to the casting; in exceptional cases, specimens taken from the casting itself may be used.

In the last 20 years the certification of quality management systems on the basis of ISO 9000 etc. and QS 9000 has risen appreciably in the foundry industry.

7.2 Metal Forming

7.2.1 Introduction

Metal-forming is the manufacturing through plastic (permanent) change of the form of a solid body by preserving both the mass and the cohesion. The term forming should be used for controlled plastic straining with a predefined target shape, whereas the term deforming should be used for unwanted or uncontrolled plastic straining. Basic advantages of metal-forming processes as compared to alternative processes such as casting and machining are [7.22, 23]:

- High material utilization and hence high energy conservation
- High productivity with short production times
- High dimensional and shape accuracy within certain tolerances
- Superior mechanical material properties of the product (especially for dynamic loadings)

On the other hand, these processes are exposed to the following disadvantages:

- Due to the high loads required for plastic forming, the tools and machines are expensive requiring minimum batch sizes for economic production.
- The limited formability of metals restricts the range of product geometries.
- The process usually requires a high level of engineering including analytical modeling, numerical analysis (process simulation), and also extended experience.

Metal-forming processes can be classified according to various criteria. An academic classification is done according to the dominant stress state existing in the deformation zone. Accordingly forming processes can be classified into compressive, tensile, tensile–compressive, bending and shearing processes. A more practical classification is according to the type of product by which two classes of processes are identified: bulk forming and sheet forming processes. In bulk forming processes the workpieces have spatial geometries (i. e. their geometries are more or less balanced in all space-directions). During forming large changes in the cross-sections and in the thickness of the products are found. The material flows in all directions. Generally, multiaxial compressive stress states exist in the deformation zone. Larger relative forming forces are needed. Bulk forming can be done either with workpieces at room temperature (cold forming) or at an elevated temperature (warm or hot forming). Where hot forming is done with workpieces heated over their recrystallization temperature, warm forming is performed with workpieces between the room and the recrystallization temperature or slightly over the recrystallization temperature. Examples of typical bulk forming processes are given in the following.

Figure 7.26 shows the primary forming process of flat rolling: an initial blank is reduced in thickness by means of two rolls. The width of the workpiece remains usually approximately constant. The product is used as initial workpiece for other basically sheet forming processes. By rolling also the casting-microstructure is changed to a more homogenous defect-free microstructure.

Figure 7.27 shows the basic process of wire drawing. Here, an initial rod or wire is forced through a conical die in order to reduce its diameter. Due to the application of a drawing force the area reduction is limited to about 20%. Extrusion is demonstrated in Fig. 7.28.

Similar to wire drawing the cross-section of a rod is reduced by forcing it through a die opening. However this time the workpiece is pushed into the die instead of pulled through. The extrusion process shown in the figure produces continuous profiles with various cross-sections. These are usually semifinished products and are processed further in subsequent processes. Whereas

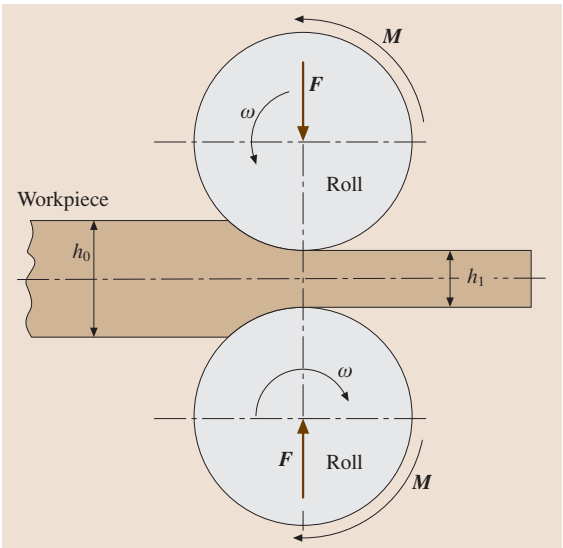

Fig. 7.26 Flat rolling

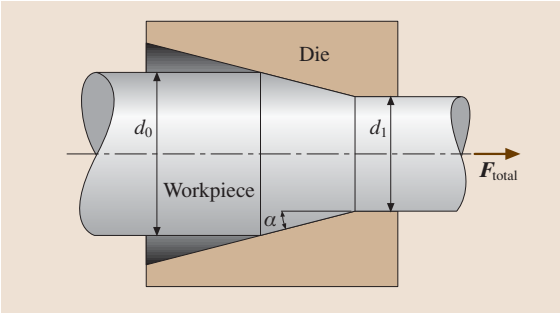

Fig. 7.27 Wire drawing

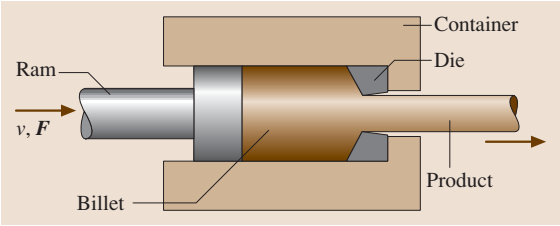

Fig. 7.28 Extrusion

the extrusion process in Fig. 7.29, also called impact extrusion or cold-forging, aims to produce discrete parts, here, net-shaped or near-net shaped parts, i. e. parts that need no or only minor machining or similar shaping operations are formed.

Figure 7.30 shows typical forging processes. In these processes the initial – usually heated – workpiece is formed between two dies. If the dies are flat this process is called upsetting or open-die forging (Fig. 7.30a). If the part is formed between shaped dies and during forging an excessive material flow occurs in form of a flash, this process is called impression die forging (Fig. 7.30b). Closed die forging is the forging process in which no flash is produced. This is also called trapped-die forging.

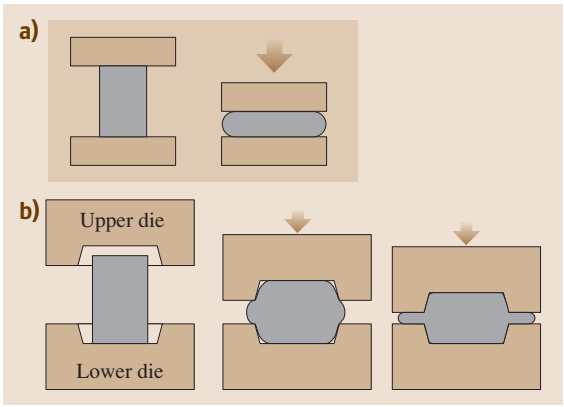

Fig. 7.30a,b Forging: (a) upsetting, (b) impression forging

Two further bulk forming processes that have sheet-like products are shown in Fig. 7.31. Ironing (Fig. 7.31a) is the process in which the wall-thickness of a cup is reduced. This is considered as a bulk forming process since the thickness is reduced and the stress states resembles a typical bulk forming process. Figure 7.31b shows a flow turning process. Also here the thickness of a hollow workpiece is reduced and the stress state is typical for bulk forming.

Sheet forming processes, on the other hand, deal with planar workpieces (sheets, plates) and aim to produce hollow pieces with almost constant wall thickness. Here a change of wall thickness is not intended. Generally two-axial stress states exist. These are either tensile–compressive or tensile–tensile, and the third stress component normal to the sheet plane is zero or nearly zero. Sheet forming processes are usually conducted with workpieces that are not heated. Figures 7.32–7.34 show some examples of typical sheet forming processes. Figure 7.32 describes the bending of sheets. The mechanics of deformation during bending depends

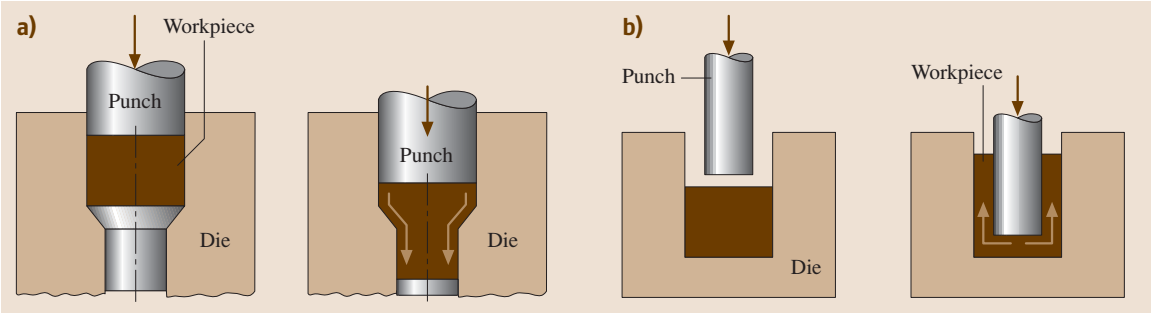

Fig. 7.29a,b Impact extrusion: (a) forward rod extrusion, (b) backward can extrusion

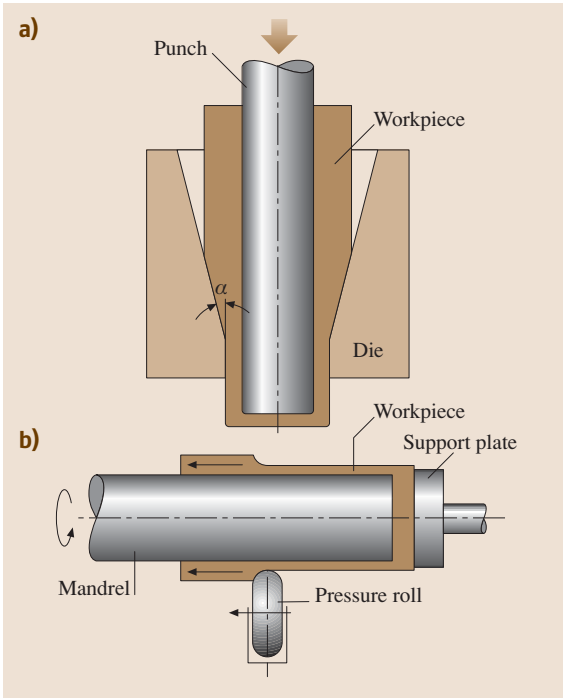

Fig. 7.31a,b Ironing and flow turning: (a) ironing, (b) flow turning

very much on the ratio of the sheet thickness to the bending radius. Mostly the thickness of the sheet varies only slightly during bending. In the figure the free bending process is shown. Bending can be also conducted in dies.

The process of stretching (Fig. 7.104) consists of applying tensile forces in the plane of the sheet. The thickness of the sheet is reduced considerably in stretching. Figure 7.105 shows the basic process of deep-drawing. During this process an originally mainly flat sheet is drawn by means of a punch into a die producing a hollow cup. The basic deformation occurs in the flange of the workpiece and the stress state here consists of a tensile and a compressive component. The sheet is thickening at the outer rim. In this process

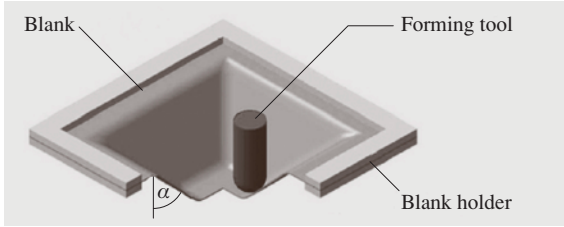

Fig. 7.34 Incremental sheet forming

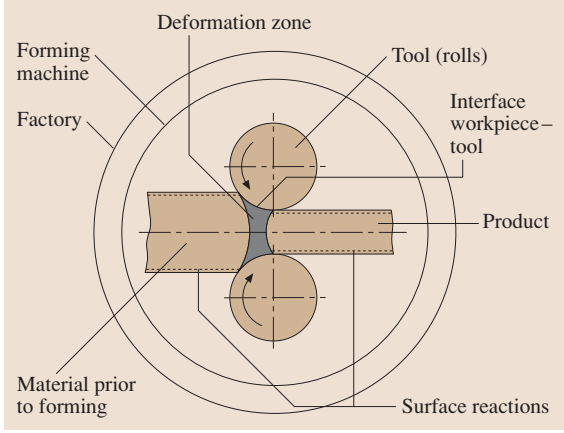

Fig. 7.35 Metal forming system (after [7.22, 23])

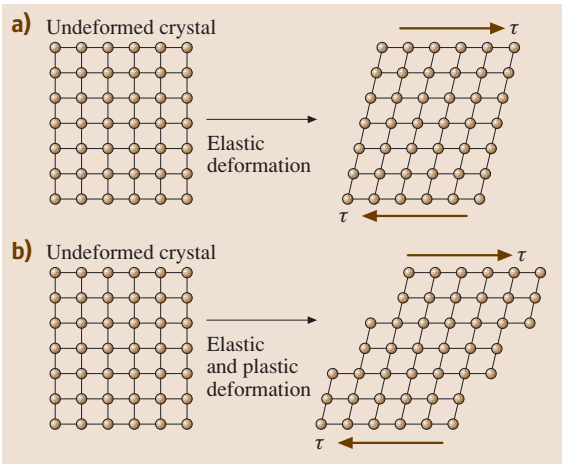

Fig. 7.36a,b Elastic and plastic deformations of the lattice structure

also bending at the die radius and stretching in the cup walls occur.

Figure 7.33 exhibits the process of spinning. Spinning is a typical incremental process in which an originally flat sheet is formed by means of a roll towards a mandrel where the sheet is rotating and the roll is performing a translatory motion.

Another recent incremental sheet forming process is sketched in Fig. 7.34. In this process a punch controllable in three to five axes is used to shape an originally flat sheet incrementally. The process is much slower than the classical deep-drawing or stretching process and has the advantage of being flexible. Besides solid tools also pressure media can be used in sheet forming operations (Figs. 7.114–7.116). Hydroforming, aqua-drawing, and tube-hydro-forming are various process variants of this process family.

Analysis of metal forming processes can be done most efficiently in a system approach. Basic items of the metal forming system are shown in Fig. 7.35 for the flat rolling process. The first item is the material prior to forming. The deformation zone is the second item. Material properties of the plastically formed workpiece, the product, constitute the third item. The tools, here the rolls, make up the another item. The interface between the workpiece and the tools is item five. The surface reactions of the workpiece before and after deformation constitute the sixth item of the system of metal forming. The two final items are the forming machine and the factory. All items influence each other and must, therefore, be mutually taken into considerations.

7.2.2 Metallurgical Fundamentals

Mechanisms of Plastic Deformation

If a metal crystal is exposed to shear stresses, first the lattice will deform elastically as shown in Fig. 7.36a. By removal of the shear stress the lattice will recover its original form. If the shear stress is increased the crystal will deform elastically and plastically, such that upon removal of stresses the crystal will not recover completely its original shape (Fig. 7.36b). Plastic deformations occur by the movement of atomic layers. This movement occurs on so-called slip planes along slip directions [7.24].

The theoretical shear stress necessary to move one part of the lattice along a slip plane with respect to the other part is estimated as

$$\tau_{\text{theoretical}} = \frac{G}{30} \text{ to } \frac{G}{2\pi}\,, \tag{7.1}$$

where G is the shear modulus of the metal. For typical metals the theoretical shear strength as calculated by (7.1) is tabulated in Table 7.16.

A second mechanism of plastic deformation is twinning (Fig. 7.37). During twinning atoms on one side of the twinning plane are almost instantaneously moved to a mirror position of the other side of the plane. Twinning is a preferred mechanism of plastic deformation in hexagonal closed packed (HCP) metals such as titanium, magnesium and zinc alloys. Also, for other metals twinning is preferred if

the strain rates are very high, since plastic deformation by twinning needs much less time than by sliding.

Actual shear strengths of metals are up to several orders of magnitudes less than the theoretical ones (Table 7.16). Real metals show crystal defects called dislocations that facilitate another mechanism of slip that requires much less shear stress than the slip in a defect-free crystalline structure. Figure 7.38 shows that the dislocation shear occurs only incrementally over the shear plane and hence requires much less shear stress. Dislocations are virtually present in any metal introduced during solidification. In annealed metals the length of dislocation lines are about 10^4 to 10^8 cm/cm^3 of metal. As plastic deformation proceeds new dislocations are generated through various mechanisms such as the Frank–Read mechanism. As the number of dislocations increase, they start to hinder each other's motion so that an increased shear stress is necessary to move them. This increase in yield strength is called strain hardening. In cold worked metals the density of dislocations rises up to 10^{10} to 10^{12} cm length per one cm^3 of metal. During plastic deformation about 85 to 90% of the deformation energy is dissipated as heat. Recent measurements indicate that this ratio varies with the amount of plastic strain. The remainder of the energy is stored in the lattice as strain energy and is directly related to the dislocations.

Other mechanisms increasing the yield strength are the solid solution hardening, particle (dispersion) hardening, and grain size hardening. These mechanisms can be superposed to supply an analytic relation for the yield strength as

$$Y = Y_0 + \Delta Y_\mathrm{s} + \Delta Y_\mathrm{d} + \Delta Y_\mathrm{p} \,, \tag{7.2}$$

where Y_0 is the yield stress in an pure single crystal metal with some dislocations, ΔY_s is the increase in yield strength due to solid solution hardening, ΔY_d is the increase due to dispersion hardening, and ΔY_p is the increase due to phase boundaries. For ferritic steel, for instance, Y_0 is about 30 MPa, and

$$\Delta Y_\mathrm{s} = \sum_i k_i x_i \,, \tag{7.3}$$

where x_i is the weight percentage of the alloying element and k_i is a weight factor given in Table 7.17.

Yield strength increase due to grain refinement is given by the Hall–Petch relationship

$$\Delta Y_\mathrm{p} = \frac{k_y}{\sqrt{d}} \,, \tag{7.4}$$

Element	Si	Mn	P	Ni	Mo	Cu	Sn	Al	N
k_i	81	18	590	8	15	40	130	24	2300

where d is the grain size and the constant k_y ranges between 15 to 24 MPa mm$^{1/2}$ for common steels. This relationship reflects the fact that grain boundaries impose geometrical constraints for the dislocation motion and hence increase the necessary shear stress to move them. The value of ΔY_d depends on the form and morphology of the carbides generated in ferrite.

Reverting Strain Hardening

If a polycrystalline metal is plastically deformed at temperatures below one third of its melting temperature T_m (in K) the grain shapes change (leading to texture) and the dislocation density increases, leading to strain hardening. Strain hardening is naturally accompanied by a reduction of ductility (Fig. 7.39). Although the strain hardened state of the material is mechanically stable it is thermodynamically unstable. Hence, at elevated temperatures this state of the plastically deformed material can be altered.

Recovery. Heating the deformed metal in a range of $0.3T_m < T < 0.5T_m$ will activate diffusion of atoms. This diffusion of atoms enables the motion of some dislocations, which will cancel each other or restructure themselves. Stored energy is relieved. Residual stresses will be removed, the yield stress will reduce slightly, and ductility will increase. Electrical and thermal properties will be recovered as well.

Recrystallization. If the deformed metal is heated at $T > 0.5T_m$ diffusion processes continue such that similar dislocations start to align in certain regions to form low-angle grain boundaries. If the number of aligned dislocations increases they build the large-angle grain boundaries. This process is called recrystallization. The movable collocated dislocations are the recrystallization nuclei. During recrystallization a refined grain structure is built and the yield stress of the metal drops to its original value, and the ductility also increases back to its preworked values (Fig. 7.40).

After recrystallization the new grains show a preferred orientation that is related to the deformation texture and also to the character of the grain boundaries. The temperature at which the whole structure is completely recrystallized within 1 h is called the recrystallization temperature of that metal (Table 7.18). The heat treatment involving recrystallization is called annealing. Recrystallization can only occur after a minimum amount of plastic deformation, since a minimum number of dislocations must be mobilized for forming the large-angle grain boundaries. The more the metal has experienced plastic deformation, the lower is its recrystallization temperature. Time and temperature and prior plastic deformation have interchangeable roles (Fig. 7.41). At high temperatures and following large prior cold plastic deformation, after recrystallization is completed grains may continue to grow such

that larger grains are built than before recrystallization. This process is called secondary recrystallization and results a material with less superior properties than after the primary recrystallization (such as lower ductility, orange peel effect in deep drawing and bending).

7.2.3 Theoretical Foundations

The theoretical framework of plastic deformation [7.26, 27] is based on four phenomenological columns: The basic concepts of strain and stress, the flow condition, the flow rule, and the flow curve. Utilizing these columns in conjunction with the equilibrium equations analytical and numerical methods are established. Also physical simulation makes use of these fundamentals.

Basic Concepts

The Concept of Strain. Intensity of plastic deformation in metal forming is measured by the true strain increment $d\varepsilon$. Considering the uniaxial tension test (Fig. 7.42) in which a uniform rod with current length ℓ and current cross-sectional area A is exposed to an axial force F, the instantaneous strain increment in axial direction is defined as

$$d\varepsilon = \frac{d\ell}{\ell} . \tag{7.5}$$

Assuming uniform straining the total strain at any point in the rod experienced from the original length ℓ_0 to the final length ℓ_1 is given by

$$\varepsilon = \int_{\ell_0}^{\ell_1} \frac{d\ell}{\ell} = \ln\left(\frac{\ell_1}{\ell_0}\right) . \tag{7.6}$$

Due to the logarithmic expression this strain is also called the logarithmic or natural strain. Compared to the engineering strain the true strain describes finite deformations correctly, is additive between different straining steps, and supplies the same strain values for the same amount of elongations and compressions.

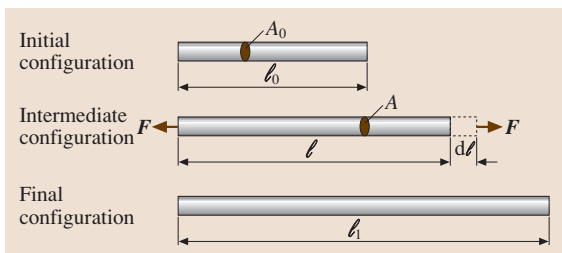

Fig. 7.42 Uniaxial tension of a rod

The total strain given in (7.6) is the sum of elastic (recoverable) and plastic (permanent) strains. However, in metal forming processes elastic strains are several orders of magnitude less than the plastic strains, so the elastic strains can be neglected

$$\varepsilon = \varepsilon^{\text{elastic}} + \varepsilon^{\text{plastic}} \approx \varepsilon^{\text{plastic}} \,. \tag{7.7}$$

Therefore, in the forthcoming sections the superscripts will be omitted.

Strain Rates. If the elongation $\mathrm{d}\ell$ takes place in time of $\mathrm{d}t$, the strain rate can be defined as

$$\dot{\varepsilon} = \frac{\mathrm{d}\varepsilon}{\mathrm{d}t} == \frac{\mathrm{d}\ell/\ell}{\mathrm{d}t} == \frac{\mathrm{d}\ell/\mathrm{d}t}{\mathrm{d}\ell} = \frac{v_{\text{tool}}}{\ell} \,, \tag{7.8}$$

where v_{tool} is the velocity of extension of the rod as imposed by the tool. The concept of strain rates is extended to three-dimensional general deformations by introducing the velocity field for each particle in three Cartesian directions (v_x, v_y, v_z). The components of the strain rate tensor are then defined by

$$\dot{\varepsilon}_{ij} \equiv \begin{pmatrix} \dot{\varepsilon}_{xx} & \dot{\varepsilon}_{xy} & \dot{\varepsilon}_{xz} \\ \dot{\varepsilon}_{yx} & \dot{\varepsilon}_{yy} & \dot{\varepsilon}_{yz} \\ \dot{\varepsilon}_{zx} & \dot{\varepsilon}_{zy} & \dot{\varepsilon}_{zz} \end{pmatrix}$$
$$= \begin{pmatrix} \partial v_x/\partial x & \frac{1}{2}(\partial v_x/\partial y + \partial v_y/\partial x) & \frac{1}{2}(\partial v_x/\partial z + \partial v_z/\partial x) \\ & \partial v_y/\partial y & \frac{1}{2}(\partial v_y/\partial z + \partial v_z/\partial y) \\ \text{symmetric} & & \partial v_z/\partial z \end{pmatrix} . \tag{7.9}$$

Total Strains. For the three-dimensional general deformation state the strain rates can be integrated over the time if and only if all shear strain rates are zero and the straining path, that is, the ratio of the normal strains, is constant over the respective time increment. In this case, the normal strains are also the principal strains. The total strains can then be determined for the deformation depicted in Fig. 7.43

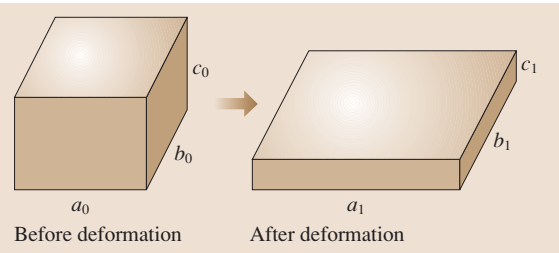

Fig. 7.43 Principal strains

$$\begin{aligned} \varepsilon_1 &= \ln(a_1/a_0) \,, \\ \varepsilon_2 &= \ln(b_1/b_0) \,, \\ \varepsilon_3 &= \ln(c_1/c_0) \,. \end{aligned} \tag{7.10}$$

Obviously, total strains can be used only in idealized cases. Here, the Arabic indices denote the principal directions.

Principle of Volume Constancy. Experimental observations have shown that the volume during plastic deformations remains approximately constant. Referring to Fig. 7.43 this means

$$V = \underbrace{a_0 \times b_0 \times c_0}_{\text{initial}} = \underbrace{a_1 \times b_1 \times c_1}_{\text{final}} = \text{const} \,. \tag{7.11}$$

Or in terms of strain-rates and strains:

$$\begin{aligned} & \dot{\varepsilon}_1 + \dot{\varepsilon}_2 + \dot{\varepsilon}_3 = 0 \\ \text{or} \quad & \varepsilon_1 + \varepsilon_2 + \varepsilon_3 = 0 \\ \text{or} \quad & \varepsilon_x + \varepsilon_y + \varepsilon_z = 0 \,. \end{aligned} \tag{7.12}$$

The Concept of Stress. Referring to Fig. 7.42 the true stress (also called Cauchy stress) in the axial direction is defined by

$$\sigma = \frac{F}{A} \,, \tag{7.13}$$

where A is the current area of the rod. This stress must be carefully distinguished from the engineering stress that refers to the original cross-sectional area.

The three-dimensional generalization of the internal forces according to (7.13) leads to the stress tensor at a point

$$\boldsymbol{\sigma}_{ij} = \begin{pmatrix} \sigma_{xx} & \tau_{xy} & \tau_{xz} \\ \tau_{yx} & \sigma_{yy} & \tau_{yz} \\ \tau_{zx} & \tau_{zy} & \sigma_{zz} \end{pmatrix} \,. \tag{7.14}$$

This tensor is also symmetric like the strain rate tensor. Two important special cases of the general stress tensor are the uniaxial stress state (with only the σ_{xx}-component being nonzero) and the plane stress state (all components with a z-index are zero).

The three independent stress invariants are defined as

$$\begin{aligned} I_1 &= \sigma_{xx} + \sigma_{yy} + \sigma_{zz} = \sigma_1 + \sigma_2 + \sigma_3 \,, \\ I_2 &= \tau_{xy}^2 + \tau_{yz}^2 + \tau_{zx}^2 - \sigma_{xx}\sigma_{yy} - \sigma_{yy}\sigma_{zz} - \sigma_{zz}\sigma_{xx} \\ &= -(\sigma_1\sigma_2 + \sigma_2\sigma_3 + \sigma_3\sigma_1) \,, \end{aligned}$$

$$I_3 = \sigma_{xx}\sigma_{yy}\sigma_{zz} + 2\tau_{xy}\tau_{yz}\tau_{zx} - \sigma_{xx}\tau_{yz}^2 - \sigma_{yy}\tau_{zx}^2 - \sigma_{zz}\tau_{xy}^2 = \sigma_1\sigma_2\sigma_3 \,, \tag{7.15}$$

where σ_1, σ_2, σ_3 are the principal stresses.

Hydrostatic and Deviatoric Stresses. The hydrostatic stress (a stress invariant) is defined as

$$\sigma_\mathrm{h} = \frac{\sigma_{xx} + \sigma_{yy} + \sigma_{zz}}{3} \,. \tag{7.16}$$

The respective hydrostatic stress tensor is hence

$$\boldsymbol{\sigma}_{ij}^\mathrm{h} = \begin{pmatrix} \sigma_\mathrm{h} & 0 & 0 \\ 0 & \sigma_\mathrm{h} & 0 \\ 0 & 0 & \sigma_\mathrm{h} \end{pmatrix} = \sigma_\mathrm{h} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \,. \tag{7.17}$$

It is an experimental observation that the hydrostatic stress does not initiate any plastic deformation. However, the ultimate amount of plastic deformation that a metal can withstand increases with increasing compressive hydrostatic stress. Plastic deformation is induced by the deviatoric stress tensor obtained by

$$\boldsymbol{\sigma}_{ij}' = \boldsymbol{\sigma}_{ij} - \boldsymbol{\sigma}_{ij}^\mathrm{h} = \begin{pmatrix} (\sigma_{xx} - \sigma_\mathrm{h}) & \tau_{xy} & \tau_{xz} \\ \tau_{yx} & (\sigma_{yy} - \sigma_\mathrm{h}) & \tau_{yz} \\ \tau_{zx} & \tau_{zy} & (\sigma_{zz} - \sigma_\mathrm{h}) \end{pmatrix} \,. \tag{7.18}$$

Flow Condition

The flow condition (also called yield condition) is a hypothesis describing the condition that must be fulfilled for plastic flow to start or to pursue. Most of the flow conditions are in terms of the components of the stress tensor. Any flow condition must fulfil the trivial case of the uniaxial stress state for which plastic flow starts if the axial stress is equal to the yield stress. In metal forming, instead of the yield stress the term flow stress is preferred. Referring to Fig. 7.44 the elastic region is terminated by the initial yield stress or the initial flow stress $\sigma_{\mathrm{f}0}$. Increasing the tension force further will also increase the axial stress, however with a much lower gradient than in the elastic region. If loading is terminated at a flow stress of $\sigma_{\mathrm{f}1}$ and the specimen is unloaded and then reloaded, plastification will this time start at a higher flow stress of $\sigma_{\mathrm{f}1}$. This phenomenon is called strain or work hardening. Under certain circumstances the flow stress $\sigma_{\mathrm{f}1}$ may be equal to the initial flow stress $\sigma_{\mathrm{f}0}$. Such kinds of materials are called non-hardening or perfect-plastic materials. If the flow stress after plastification decreases the material is strain softening material.

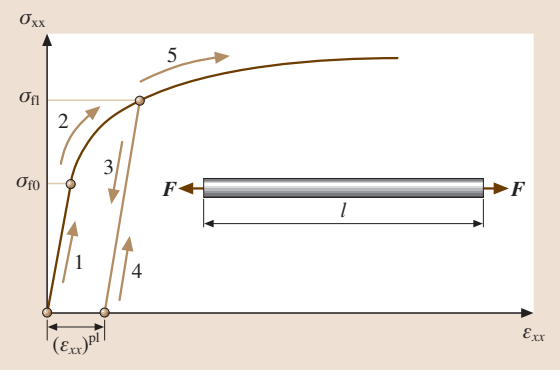

Fig. 7.44 Flow stress in simple tension test (numbers give the sequence)

The two flow conditions used extensively in metal forming for general three-dimensional stress cases are the Tresca flow condition and the von Mises flow condition.

The Tresca Flow Condition. The Tresca flow condition states that plastic flow will start or pursue if the maximum shear stress $\tau_{\max}$ is equal to a material constant that can be found as $\sigma_\mathrm{f}/2$ after tuning this criterion by the simple tension test

$$\tau_{\max} = \frac{\sigma_\mathrm{f}}{2} \,. \tag{7.19}$$

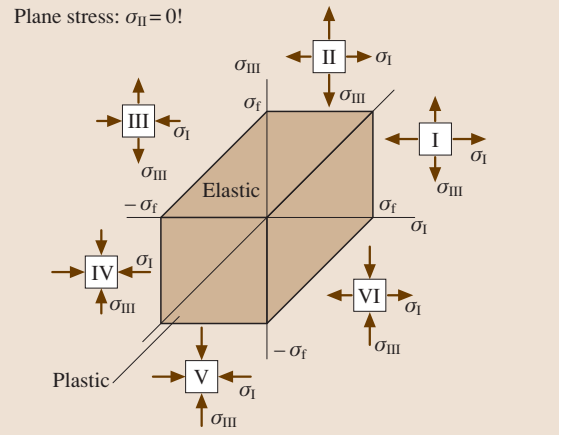
Or, in terms of principal normal stresses

$$\sigma_{\max} - \sigma_{\min} = \sigma_\mathrm{f} \,, \tag{7.20}$$

where $\sigma_{\max}$ and $\sigma_{\min}$ are the largest and smallest principal normal stresses. Figure 7.45 shows the flow locus for plane stress states according to Tresca. The table in the figure depicts the various forms that the Tresca flow criterion takes in terms of the spatial plane stress components σ_I and σ_III.

The von Mises Flow Condition. Different to the Tresca flow condition the von Mises flow condition considers all the principal shear stresses. Accordingly, plastic flow starts or pursues if

$$c' = \sqrt{\frac{1}{3}\left[\left(\tau_{\max}^1\right)^2 + \left(\tau_{\max}^2\right)^2 + \left(\tau_{\max}^3\right)^2\right]} \,, \tag{7.21}$$



Region		
I	$\sigma_I > \sigma_{III} > 0$	$\sigma_f = \sigma_I$
II	$\sigma_{III} > \sigma_I > 0$	$\sigma_f = \sigma_{III}$
III	$\sigma_{III} > 0 > \sigma_I$	$\sigma_f = \sigma_{III} - \sigma_I$
IV	$0 > \sigma_{III} > \sigma_I$	$\sigma_f = -\sigma_I$
V	$0 > \sigma_I > \sigma_{III}$	$\sigma_f = -\sigma_{III}$
VI	$\sigma_I > 0 > \sigma_{III}$	$\sigma_f = \sigma_I - \sigma_{III}$

Fig. 7.45 Tresca flow hexagon

where c' is a material constant. Again tuning this equation by the simple tension test supplies

$$\sigma_f = \sqrt{\frac{1}{2}\left[\begin{array}{l}(\sigma_{xx}-\sigma_{yy})^2+(\sigma_{yy}-\sigma_{zz})^2\\ \quad +(\sigma_{zz}-\sigma_{xx})^2+6\left(\tau_{xy}^2+\tau_{yz}^2+\tau_{zx}^2\right)\end{array}\right]}\,. \tag{7.22}$$

Figure 7.46 shows the flow locus for plane stress states. In this case, (7.22) reduces to

$$\sigma_f = \sqrt{\sigma_I^2 + \sigma_I\sigma_{III} + \sigma_{III}^2}\,. \tag{7.23}$$

A comparison of the von Mises flow criterion with the Tresca criterion reveals that for plane stress states the maximum deviation between the two criteria is 15.5%. Each criteria finds a different shear stress in pure shear for initiating plastic flow k

$$k = \begin{cases} \frac{1}{2}\sigma_f & \text{by Tresca} \\ \frac{1}{\sqrt{3}}\sigma_f & \text{by von Mises}\,. \end{cases} \tag{7.24}$$

Both criteria assume that plastic flow is independent of the hydrostatic stress and that plastic flow is independent of the sense of the stresses. Violation of the latter is also called the Bauschinger effect or kinematic hardening.

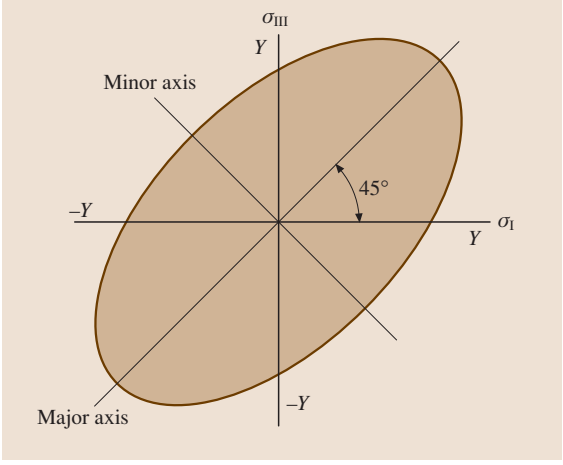


Fig. 7.46 Von Mises flow ellipse

Flow Rule

The relationship between plastic strains and stresses is expressed by the Levy–Mises flow rule. Unlike in Hooke's law for elastic deformations, in plasticity true strain rates are related to deviatoric stresses

$$\dot{\boldsymbol{\varepsilon}}_{ij} = \lambda\boldsymbol{\sigma}'_{ij}\,, \tag{7.25}$$

where λ is a nonnegative real number. By inserting (7.25) into (7.22) the nonnegative parameter can be eliminated, yielding

$$\dot{\boldsymbol{\varepsilon}}_{ij} = \frac{\sqrt{3I_2^{\dot{\varepsilon}_{ij}}}}{\sigma_f}\boldsymbol{\sigma}'_{ij}\,, \tag{7.26}$$

where $I_2^{\dot{\varepsilon}_{ij}}$ is the second invariant of the strain rate tensor.

Equivalent Plastic Strain and the Flow Curve

The plastic power per unit volume due to the stresses during plastic deformation can be expressed by

$$p = \sum_i^3\sum_j^3 \sigma_{ij}\dot{\varepsilon}_{ij} = \sum_i^3\sum_j^3 \sigma'_{ij}\dot{\varepsilon}_{ij}\,. \tag{7.27}$$

Equating this power to the power done by the respective flow stress and a fictitious strain rate leads to the definition of the equivalent plastic strain rate $\dot{\bar{\varepsilon}}$

$$p = \sum_i^3\sum_j^3 \sigma'_{ij}\dot{\varepsilon}_{ij} = \sigma_f\dot{\bar{\varepsilon}}\,. \tag{7.28}$$

Together with (7.26) this yields

$$\dot{\bar{\varepsilon}} = \sqrt{\frac{4}{3} I_2^{\dot{\varepsilon}_{ij}}} = \sqrt{\frac{2}{3}\left(\sum_i^3 \sum_j^3 \dot{\varepsilon}_{ij}\dot{\varepsilon}_{ij}\right)}$$
$$= \sqrt{\frac{2}{3}\left[\left(\dot{\varepsilon}_{xx}^2 + \dot{\varepsilon}_{yy}^2 + \dot{\varepsilon}_{zz}^2\right) + 2\left(\dot{\varepsilon}_{xy}^2 + \dot{\varepsilon}_{yz}^2 + \dot{\varepsilon}_{xz}^2\right)\right]} . \quad (7.29)$$

The total equivalent plastic strain is the time integral of (7.29)

$$\bar{\varepsilon} = \int_t \dot{\bar{\varepsilon}}\, \mathrm{d}t , \quad (7.30)$$

or in terms of total strain components

$$\bar{\varepsilon} = \sqrt{\frac{2}{3}\left(\dot{\varepsilon}_1^2 + \dot{\varepsilon}_2^2 + \dot{\varepsilon}_3^2\right)} . \quad (7.31)$$

The equivalent plastic strain is a measure of the increase of dislocation density and the mutual hindering of dislocations, i. e. it measures the increase of flow stress. The change of flow stress with the equivalent plastic strain is a material property called the flow curve

$$\sigma_\mathrm{f} = \sigma_\mathrm{f}(\bar{\varepsilon}) . \quad (7.32)$$

Typical flow curves for various temperatures and strain rates are shown in Fig. 7.47 for the typical cold forming steel C15. Usually, the flow stress at a given equivalent strain decreases with temperature and increases with the strain rate. The flow curve can be determined basically in simple tension, compression, and torsion tests. All theses tests have their limits regarding attainable strain values and stress states [7.29].

Temperature Increase During Forming

During plastic deformation about 85 to 90% of the plastic work is dissipated as heat. For a homogenous adiabatic deformation the average temperature increase can be computed by

$$\Delta T = \frac{(0.85\text{–}0.95)\bar{\sigma}_{\mathrm{f,mean}}\bar{\varepsilon}}{\rho c} , \quad (7.33)$$

where $\bar{\sigma}_{\mathrm{f,mean}}$ is the mean flow stress during deformation, $\bar{\varepsilon}$ is the mean equivalent plastic strain, c is the specific heat capacity, and ρ is the density of the material. Table 7.19 shows the average temperature increase for a moderate equivalent plastic strain of unity for various materials.

Analytical Methods

All methods discussed in this section assume rigid-plastic behavior and quasi static loading [7.30–32].

Elementary Methods of Plasticity and Friction Models.

Here only the equilibrium methods are discussed. The equilibrium methods are based on the static equilibrium of simple, elementary, standard free-bodies (semiinfinitesimal slabs) for which the strain-rate state can be easily determined. Basically three types of elementary free-bodies are used: rectangular slab (Fig. 7.48a), circular slab (Fig. 7.48b), and tubular slab (Fig. 7.48c). The basic assumptions are:

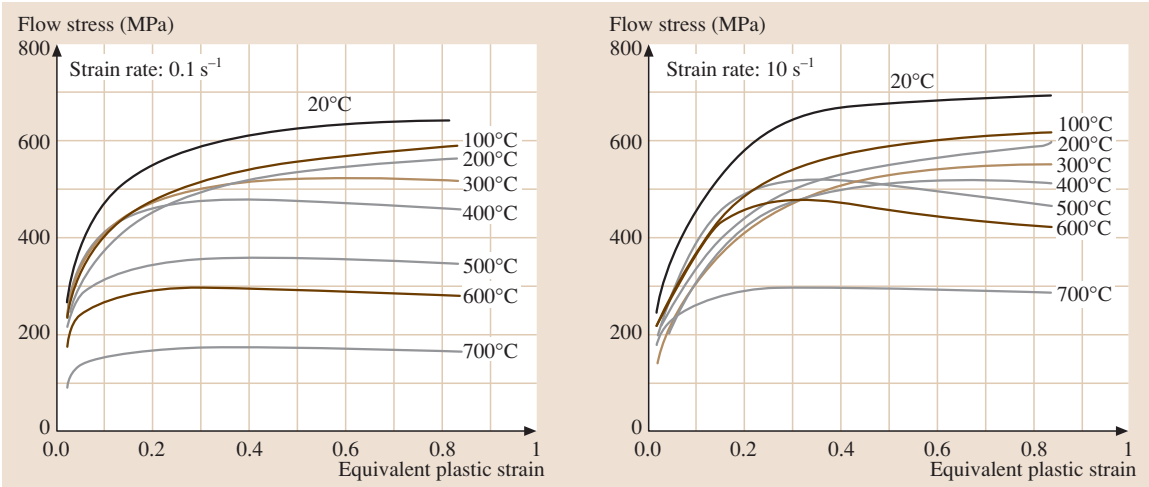

Fig. 7.47 Flow curve of a low carbon steel for various temperatures and strain rates for a C15 steel (after [7.28])

Table 7.19 Average temperature increases during a homogeneous metal forming process with average plastic strain of unity (after [7.33])

Ti-alloy	≈ 4.5	≈ 600	750–1500	250–500

1. The strain-rate state in each semiinfinitesimal slab is homogenous.
2. Plane sections remain plane.
3. The stresses along the characteristic directions of the slabs are principal stresses.
4. Friction at the contact interfaces is described either by the Coulomb friction model or by the constant shear model.

The Coulomb friction model states that the frictional shear stress at a surface element at the interface is proportional to the normal stress

$$\tau_{\text{friction}} = \mu \sigma_{\text{normal}} \,. \tag{7.34}$$

The proportionality factor μ is called the coefficient of friction. In metal forming the range for μ is given as

$$0 \le \mu \le 0.577 \,. \tag{7.35}$$

The constant shear friction model states that the frictional stress is proportional to the flow stress in shear k

$$\tau_{\text{friction}} = mk \,. \tag{7.36}$$

The proportionality factor m is called the friction factor. The range of m is given by

$$0 \le m \le 1 \,. \tag{7.37}$$

Both models only approximately describe reality. Recent friction models are a combination of both elementary models. Typical values for the coefficient of friction and the friction factor are given in Table 7.20.

The unknown stresses can be solved by the equilibrium equations and the flow condition. The flow rule is not used. The accuracy of this approach is less, the larger the friction or the inclination of the free surfaces are.

Upper and Lower Bound Methods. The upper bound method is based on the first law of thermodynamics. For a kinematically admissible velocity field that satisfies volume constancy and all velocity boundary conditions of a plastically deforming body, an upper bound for the forming force is given by [7.34]

$$F_{\text{tool}}\big|_{\text{upper bound}} = \frac{1}{v_{\text{tool}}} \left(\int_V \sigma_f \dot{\bar{\varepsilon}} \, \mathrm{d}V + \int_{A_s} mk v_{\text{shear}} \, \mathrm{d}A - \int_{A_f} \boldsymbol{p}\boldsymbol{v} \, \mathrm{d}A \right), \tag{7.38}$$

where v_{tool} is the tool velocity, $\boldsymbol{p}$ is the known pressure vector acting on the workpiece, v_{shear} is the shearing velocity at shear surfaces, $\boldsymbol{v}$ is the velocity vector of points on the workpiece surface, A_s is the workpiece area on

which friction is specified, and A_f is the workpiece area on which forces are specified. To apply the upper bound method the plastic region has to be estimated, the constant flow stress has to be estimated in the plastic region, friction stresses must be constant and hence described by the constant shear model, and finally, a kinematically admissible velocity field or appropriate shear planes have to be assumed.

Lower bound methods lead to forces that are always lower than the actual forces. Here, a statically admissible stress field has to be guessed that fulfils the equilibrium equations and the stress boundary conditions. Ideally, for an analysis the force can be limited between an upper and lower bound. Yet, the application of the lower bound method is much more difficult since the guess of an admissible stress field is not straightforward. Furthermore, in practical applications an upper bound for the forming forces are sufficient. The *upper bound* property for the forming force is given if and only if the material's flow stress is correct and the friction stresses are correct. Otherwise, the computed *upper bound* may also be *lower* than the actual physical forces.

The Slip Line Field Solution. The slip line field solution also assumes rigid perfectly plastic material behavior. Furthermore, the plane strain state is assumed. Moreover, the processes have to be frictionless. If these assumptions are fulfilled, then the theory supplies the exact solution. The slip line field solution is based on the governing equations including the flow condition, the volume constancy equation, the flow rule, and the equilibrium equations for the plane strain state. These equations build up a hyperbolic system of partial differential equations that can be solved by the method of characteristics. If the stresses are expressed in terms of the hydrostatic stress and the orientation of the stress element in the maximum shear stress direction, the two characteristics lines are orthogonal to each other (α and β-slip lines) and correspond to the directions of maximum shear stress; therefore they are called slip lines. The governing equations can be written as ordinary differential equations along each slip line. These equations can be summarized as the Hencky equations for the stresses

$$\begin{aligned} \sigma_h - 2k\phi &= \text{constant along the } \alpha\text{-slip line,} \\ \sigma_h + 2k\phi &= \text{constant along the } \beta\text{-slip line,} \end{aligned} \qquad (7.39)$$

and the Geiringer equations in terms of the particle velocities

$$\begin{aligned} \frac{dv_\alpha}{ds} &= v_\beta \frac{d\phi}{ds} \quad \text{along } \alpha\text{-slip line,} \\ \frac{dv_\beta}{ds} &= v_\alpha \frac{d\phi}{ds} \quad \text{along } \beta\text{-slip line,} \end{aligned} \qquad (7.40)$$

where ϕ is the inclination of the slip line and s is distance along the slip line. Constructing the slip line field from known boundary conditions, using (7.39) and

(7.40) supplies the stress and velocity (and hence strain rates) at any point in the deformation zone.

Empirical Methods

The Visio-Plasticity Method. The visio-plasticity consists of splitting the workpiece before deformation into two parts and marking a grid on one side, then closing these two parts and forming the workpiece. After forming the grids are deformed and are measured out in order to determine the particle velocities and their displacements. From this data the strain rates and then the stresses can be computed. Figure 7.66 shows a typical visio-plasticity specimen used in forward rod extrusion. The basic assumption is that the initial plane on which the grid produced remains plane during plastic deformation. The grids can be marked on the specimens by mechanical methods, photomechanical methods, electrochemical methods, and photolithographical methods.

The velocities can be determined in the case of steady state processes (Fig. 7.49) by first computing a time increment

$$\Delta t = \frac{u_{z0}}{\dot{u}_{z0}} = \frac{u_z}{\dot{u}_z(\bar{r}_B, \bar{z}_B)} = \frac{u_r}{\dot{u}_r(\bar{r}_B, \bar{z}_B)} , \qquad (7.41)$$

where $\bar{r}_B$ and $\bar{z}_B$ are the mean coordinates of point B. Hence the velocity components of the point B can be found as

$$\dot{u}_z(\bar{r}_B, \bar{z}_B) = \frac{u_z}{\Delta t} = \frac{u_z}{u_{z0}}\dot{u}_{z0} ,$$
$$\dot{u}_r(\bar{r}_B, \bar{z}_B) = \frac{u_r}{\Delta t} = \frac{u_r}{u_{z0}}\dot{u}_{z0} . \qquad (7.42)$$

Using these components the strain rate components can be found. The deviatoric stress components are given by the flow rule (7.26). The hydrostatic stress found from stress boundary conditions and the previously found deviatoric stresses are used to determine the total stress components at the end.

Physical Simulation. Using modeling materials like wax or plastiline the flow pattern can be visualized and observed through transparent dies for instance [7.35]. The key idea here is the fact that two materials behave similarly from the viewpoint of plasticity if they have the same strain hardening exponent n. It is possible to add to wax and plastiline additives such as Kaolin, Indramic, and Filia to change the n value and even the strain-rate sensitivity value m. Also, the ductility and the strength level can be manipulated by additives. Hence, the basic difference to the forming process of metals is the much lower stress level.

Numerical Methods

The governing equations of plasticity cannot be solved in closed form except for very few simple applications. The approximate solution of the differential equations can be performed numerically by various methods. Among these methods the finite element solution has found the most extended application because of its generality and efficiency.

Rigid-Plastic Finite Element Formulations. The elastic part of the strain is neglected and the whole body is assumed to deform rigid-plastically. The solutions obtained by these formulation are not able to supply residual stresses, springback, and similar elastic strain dependent variables. Furthermore, since the formulation assumes a pseudo-elastic behavior in the rigid parts of the workpiece, friction in these parts may be modeled wrongly [7.36].

The rigid-plastic formulation is based on the Markov's variational principle that holds only for the rigid-plastically deforming bodies

$$\Pi(v) = \int_V \sigma_f \dot{\bar{\varepsilon}}\, dV + \int_V \frac{S}{2}\dot{\varepsilon}_V^2\, dV - \int_{A_t} \boldsymbol{t}\boldsymbol{v}\, dA$$
$$\Rightarrow \text{stationary}, \qquad (7.43)$$
